What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

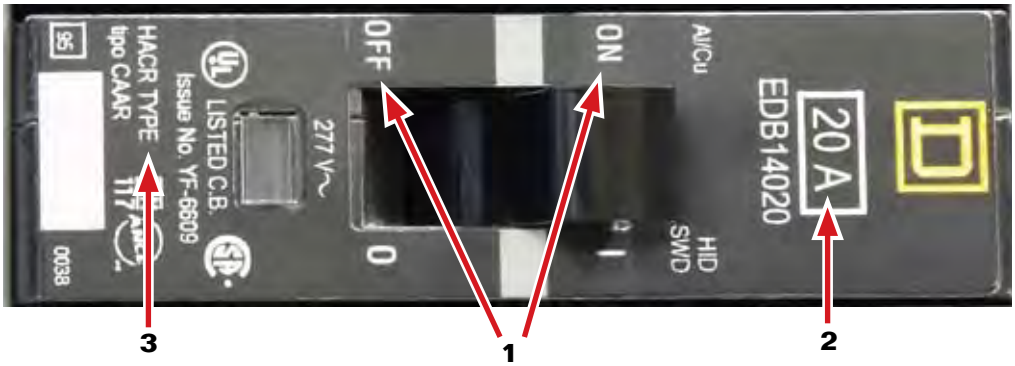

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

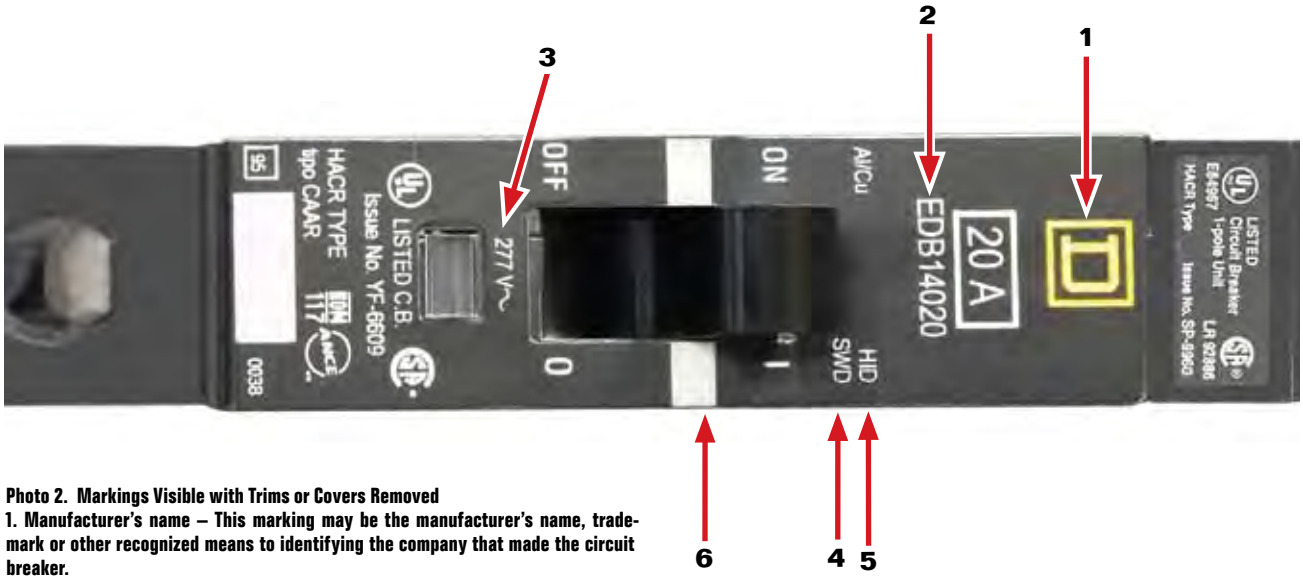

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. He is a member of several UL, IEEE and NEMA technical committees. His other memberships include NFPA, IAEI and CANENA.

About Mobile Dual-Band 2m/440 -- Roger K6XQ advises - Can I build a 2m/440mhz 5/8 mobile antenna? A 1/4 wave on 144 MHz is 3/4 wave on 440. The SWR is usually acceptable on the 3rd harmonic, although that is partly due to the increased feeder losses on 440. But SWR is not the whole story. A 3/4 wave radiator on 440 has radiation lobes that send some of your signal at high angles, not toward the horizon where you probably want it. This is usually not so severe to make the antenna unusable, and may be considered a reasonable compromise for the dual band coverage. A 5/8 wave antenna on 144 MHz is 15/8 waves on 440. If you do the simple math you will see that on 440 you will have almost a 2 wavelength antenna, which is becoming what we call a "long wire" on the HF bands. As you probably know, a long wire radiates with multiple lobes, the largest of which are toward the ends of the wire. In other words, most of your signal will be radiated up toward the sky. The reason for the coil in commercial dual band antennas is to phase the antenna currents so you actually end up with two colinear elements which both radiate at low angles, reinforcing each other and providing gain. Without the phasing coil you get multiple undesirable lobes. Also keep in mind that 5/8 wave is NOT a resonant length. There are several ways to compensate for the reactance at the base of a 5/8 wave radiator, the easiest being to add a small inductance in series which makes the antenna electrically equivalent to a 3/4 wave. (3/4 wave is resonant, as you have already discovered). Given that the gain advantage of a 5/8 wave antenna over a 1/4 wave antenna is probably not noticeable except under the most difficult conditions, and even then may or may not make a difference, my suggestion is to stick with the 1/4 wave antenna. It is simple and works OK.

This book is a year in the writing and features the DXing advice of several noted DXers and technical gurus. This is not a brag book on my personal DX exploits, but tried and true practical DX advice from those who have been there, done that, and worked them all.

It is intended for those entering into HFing and the wacky world of DXing. Old timers not yet on the Internet will want this book as well.

226 Pages

Deluxe Covers
Book Weighs In At ~1 lb - 11.1 Ounces
Laser Printed On 24 lb Paper, 8-1/2" x 11"
All Chapter Text In 12 Point Times Roman For EZ Reading

From Universal Radio Reynoldsburg, OH ***We are most impressed with the scope and currentness of this excellent book. Best title on the subject.*** **Universal Book Order Page**

GW0ANA wrote: Greetings Rod, I would like to thank you & yours first for your amazing book & secondly your taste in "Post Cards". I enjoyed looking at both.

Again I must applaud you for the immense effort you have put in on your book. The subject matter is of great help to Novice & Expert alike. It is like having an "DX Elmer" always at your shoulder.

I just love the relaxed way you impart real DX knowledge to the deserving. Your description on how you caught Malpelo was inspirational to this DX-ER. I got the guy on 10 by abiding by the first law of DX,"Listen & listen again" He popped up on 10 metres on a so called dead band, heard him & got him simplex 100 watts into a mini beam at 30 feet. I have big planning problems. But using wires in trees & lots of listening skill I have 310 countries confirmed & 5BDXCC. Again my thanks for your wonderful book I will dip in & out of it at will.

Best 73 Glyn, GW0ANA, Nirvana Castle Precinct, Wales UK
P/S I am sure your book is my "Passport to honour roll"

Hi Rod. I'm new to ham radio since late Jan of this year (KD7ZHS). I'm sure you've heard this 10,000 times, but your DX book has been an incredible help to me. Ditto for your web site. Hope to meet you on the air some day. Sincerely, Don Keller KD7ZHS

It's like, DXing for Dummies

Best book for DXing for newbies or perhaps anyone. I'm sure even the seasoned pro could glean stuff from here. It's a must have for people like me who know nothing. Well I know something now. This book is laid out logically and is an easy read. I even chuckled a few times. His sense of humor is perfectly timed. But mostly it's so handy and I keep referring too it daily while DXing. It's got useful tricks to DXing and tips on equipment and procedures. Really enjoyed his DXing secrets. IMHO, probably the most important thing is the frequency listings and their uses. I'm hoping that will help standardize things as far as where the DX is. But I'm amazed how knowledgeable AC6V is on this subject. I've got tabs pasted all over it for quick reference and it is right next to me in the ham shack. . . usually opened to something like frequency list or the "Q" codes. Tons of stuff in there like that. I'm VERY glad I bought this one and I don't buy many "how to" books. N5WVN

Fantastic dx book

What a great dx book! When I was called to jury duty I selected THIS BOOK to read while waiting in the jury assembly room! It's a great way to learn and review dxing techniques. Those dxing secrets are great (but don't tell anyone!). I know a lot of work went into this book and I thank and respect all those who worked on it. Another thing that makes it great is the humor mixed in - in fact, I'm asking my local radio club if they want to go on a dxpedition to Charcoal Island in the Barbecues IOTA group! Thank you Rod and everyone for a great book. 73 Martin G. (Marty) Blaise (AG5T)

Rod, 5 star rating. I just bought your DX 101 book, and although I already have snagged 225 countries and have DXCC, I have found quite a few really neat hints and tips that will prove useful. I must admit to reading a bunch of tips and thinking - "Hey that's right, that's what I do . . . ". So I'm learning new stuff and getting a kick out of the "secrets" that I already stumbled upon. Your book will be invaluable to beginners. I hope you can find a publisher who will bind using perfect bound or some regular book binding. . . Best DX and 73, Rich KY6R

Ed Note -- comb binding allows the book to be updated as additions and suggestions come in. These are incorporated into all new books -- books are printed on demand. Updates at URL:
MANUAL UPDATES

Although licensed for several years, been away from Amateur Radio for about 10 years, so getting restarted with all the new technology and information available was a chore, but DX101X made things a whole lot more enjoyable.

The bottom line is this, I have read the book three times and extracted only a small percentage of the available information; and, if you are either new to our hobby or think you have a strong enough ego not to be humbled but to absorb the information contained in this book, you are in for a very pleasant surprise! From KB1GZ at eHam.reviews

---

Hello Rod, Tks so much fer the book I rcvd hr last week – vy vy psed wid it es still a lot to learn/to pick up; in particular the contesting part. Cuagn 73 de Harry PA3ARM pa3arm@arrl.net

---

Rod ... Outstanding book! Just got the book in the mail today. I've only had it a short time - but I can't put it down. This book is very well done - outstanding job! I can tell a ton of care and time went into this book. What I like the most about it is it is full of Practical information. I'm learning about stuff I've never really understood until I read this book. I hope you will keep adding to it an updating it. My two cents worth in just the first part of the book I've read - add the Icom - 746 to your list of good contesting HF rigs. I have the Yaesu 1000mp and I'd put the 746's receiver up against it any day. Keep up the great work and thanks for an outstanding book. Feel free to use my comments for your testimonials.73 Dave Sass KC0IWV, Savage MN kc0iwv@mindspring.com

---

Hi Rod, Thanks very much for sending me an advanced copy of DXing 101x per Paul DeCicco's NN6X request. You've really done an outstanding job in writing a comprehensive text at a beginning and intermediate level for dx'ing. There's a great introductory section on contesting, one of my passions, that should serve the budding contester very well indeed. Included is a very complete treatment of all the important equipment features and performance parameters that the budding dx'er should give attention to when selecting his gear. You've put together in one place information that previously could only be gleaned from countless sources. It really is a unique and rich source of information! 73 Barry N1EU Delmar NY n1eu@yahoo.com

---

Rod, All I can say about DX'ing 101X is it is Fantastic. An unbelievable reference for any dx'er. Thanks for your efforts. 73 de N1LQ, David Hammond, Middleton, MA dhhdeh@concentric.net

---

DX101 contains essential information for the beginner DXer. It is also valuable for the DXer who is seeking to tap the wealth of resources available on the Internet. I am neither and still enjoy reading thru this work. It is well written and deals with all relevant topics - it is a valuable DX tool ! Josh, Grand Junction CO, N7XM
n7xm@qsl.net

Rod, the book arrived and I haven't taken my nose out of it..... I know that a lot of hard work went into getting this book out ..... You would be surprised at all the helpful information that I've already acquired from reading your book.....and I have only gotten through chapter five..... Thanks to you and to all the people that assisted you in making it available to the Ham World.....Best regards..Bill NU5C, North Little Rock, Arkansas
Bdretpd@aol.com

Hello Rod, Just would like to congratulate you on the book. I'm just almost halfway reading it and I've already learned a lot. Considering that I just need a few countries to qualify for DXCC Honor Roll, I still find your book to be an invaluable tool for dx'ers. Congratulations! 73, de Ernie, DU1COO, also KH0DK

TESTIMONIALS (UNSOLICITED)

Universal Radio comments: Many new hams find repeater operation intimidating. This book lets you skip that awkward early stage. It provides the knowledge and confidence you need to enjoy repeater operation immediately.

I would like to send a thanx to you for your book on repeaters. Just starting out in the hobby. I could not have asked for a better guide to the world of fm repeaters. I have now started working 2 m ssb and have logged over 17 grid squares in 4 months. Thanx again for a great start in the hobby. 73 George KG6TVC, San Leandro, CA

KF6HBJ writes -- I purchased the FM101x Guide last week and have gone through the material relating to my HT. Basically I purchased it to bring me up to date as I had dropped off from using my radio quite awhile ago. Being a computer guy, I found the material easy to follow and found the essentials pointing me to further readings on web links for increased knowledge and detail. From the first page to the last page, I never felt slighted because I wasn't a seasoned Ham Radio

Operator. Rod's vernacular clearly expresses what I needed to get accustomed to without the academia sort of information that I have read in other technical types of volumes. Thanks Dave KF6HBJ, Temecula CA

Excellent Book. I recently taught a one day ham class for new technician hams. I purchased a copy of the FM101X book for each student. All the students had many compliments for the contents of the books. One comment "including the book in the course was a very good idea" Another comment"FM101X answered all my questions about repeater operation as a new ham - great book"
The new hams loved it! For new hams this is the book! Dick Decker K6SUU, Turlock CA

N5ACM comments on eHam reviews: Get up to Speed Quickly with this Guide. This book is well worth the price. You get current, practical information on topics of interest to both new and old HAMs. Information is presented in a straightforward, succinct and readable manner, the illustrations are basic, but adequate. You don't need or pay for glossy fluff here- the book provides a well thought out treatise on FM ops in one place, from simplex, repeaters, digital and the vagaries of Echolink. Lots of links for further information too. A great place to get up to speed quickly. New HAMS will feel completely comfortable on VHF/UHF after perusing this book. Well Done. N5ACM, Arlington TX

AB7NI Wrote: Rod, Received the book today. I read it, and was impressed. Great minds must think alike. Your comments were EXACTLY what I have been telling new hams for years. Very much interested in buying in volume for the next class I teach. Meanwhile this copy is getting some yellow highlighted sections. Great job! Thanks -- Gary AB7NI Colbert, WA

KG6JPX Wrote -- Bravo on AC6V'S FM101x. Also, the internet website references are great. However I think it would help a lot if you repeated them in the back of the book, grouped according to their purpose. That would help locate them later on when the reader has forgotten the context, chapter and page number where it was first seen.

Author note -- this will be added --see MANUAL UPDATES

TABLE OF CONTENTS

Chapter 1 Introduction - Click Here For Sample

Covers an introduction to the book as well as an example of the bewildering jargon that one will encounter on Amateur Radio Repeaters and where in the book to decipher the alphabet soup and jargon. CTCSS, PL, Offset, Desense, Alligator, Machine, Picket-Fencing, Quieting, Q-Signals, beeps, hang-time, protocol, OM, capturing, etc.

Chapter 2. Your First FM Radio - Click Here For Sample

Information on what to select as your first FM radio. Discusses advantages of Handi-Talkies vs Mobiles, antennas, batteries, features to consider. All mode radios and multi-banders are discussed. Mobile installation, Mobile Antennas, DC power supplies, Noise Abatement, Mobile Power considerations, Coax Considerations, and VSWR checks.

Chapter 3. Operating Simplex - Click Here For Sample

Discusses how to operate simplex (without a repeater). Range to be expected, antennas, cross polarization, and protocol. Includes a complete list of simplex frequencies from 2 meters thru 1.2 GHz including the recommended National Calling frequencies. VHF/UHF DXing techniques.

Chapter 4. How Repeaters Works - Click Here For Sample

Simplified pictorial of a repeater. Covers simplex, half duplex, full duplex operation. Explains offsets, splits, input and output frequencies. Lists the standard offsets for USA repeaters - 10 meters thru 2.4 GHz. Thoroughly covered are CTCSS, PL, SUBAUDIBLE TONES | TONE SQUELCH | DCS, DTCS |TONE BURST | DTMF | BEEPS & BE-BOPS.

Chapter 5. Programming a Rig - Click Here For Sample

Covers the nightmare of programming a radio. How to make a cheat sheet. Using programming cables. A source for a handy wallet size programming accessory. Generic outline for programming any radio.

Chapter 6. Antennas, Power Sources, VSWR, and DeciBels - Click Here For Sample

Covers rubber duck antennas, better antennas such as ¼ wave, ½ wave, ¾ wave and 5/8 wave, Yagis, and J-Poles. Gives numerous URL's and tips for building your own antennas. The battery paragraphs cover Sealed Lead Acid (SLA),

Lithium, NICAD and NIMH Batteries. Power Supplies, VSWR, and dB are covered in a non-technical approach.

Chapter 7. Using Repeaters - Click Here For Sample

This chapter covers how to find repeaters, repeater guides on the internet, complete rundown on repeater protocol, soliciting a conversation, asking for information, jargon heard, radio checks and signal reports, what to say, breaking in, multiple conversations - rotations, nets, roll calls and demos, autopatching. Also listed is a complete listing of 2 Meter repeater pairs, packet simplex, and voice simplex frequencies.

Chapter 8. Phonetics, Q-Signals, and Callsigns - Click Here For Sample

All about Q-Signals used on repeaters. Recommended Phonetics are covered (Alpha, Bravo, etc). A list of all USA callsign districts and classes of license callsigns are explained.

Chapter 9. Funny Repeater Sounds and Myths - Click Here For Sample

Covers the many sounds heard on a repeater, path noise, distortions, alternator whine, ignition noise, capturing, picket fencing, Morse characters, hum, over and under deviation, kerchunk, desense, motor boating, Station is Calling - But No Beep, Q-Signals, CB talk & ten codes (a no no) etc.

Chapter 10. Cops and Jammers - Click Here For Sample

When and when not to play repeater policeperson. How to deal with jammers and interlopers.

Chapter 11. Inside A Repeater - Click Here For Sample

Detailed block diagrams of the elements of a repeater, receivers, transmitters. Plain language non-technical discussions of duplexers, limiters, discriminators, deviation, bandwidth, channel spacing, modulation index, FM modulation.

Chapter 12. IRLP, ILINK,ECHOLINK, WIRES II™, CrossBand Repeating, Long Range Intertie Systems, - Click Here For Sample

Glossary and Jargon -- 16 pages of terms, slang, repeater speak - Click Here For Sample

An extensive compendium			**Time owned: 0 to 3 months**
I had picked up a copy of FM101x and was quite impressed (I had planned to use it for a followup class for new hams). So I took a look at DX101x too. Wow, it is great! So much info. And lots of stuff I didn't know even tho I have over 200 countries. This book is definitely worth it, right up there with The COmplete DXer.			

GW0ANA	Rating: 5/5	Apr 22, 2004 06:18	Send this review to a friend

I found it very educational on the subject of HFDX-ing. In fact is was like having your own Elmer in the shack. I have built up a good libary of books over 25 years of "hamming" & I can recomend AC6V`s book DXing 101X as the Definitive guide. Each chapter is very well laid out in a easy to read format. His writing style is great as it is not bogged down with waffle & padding. Its the facts the real facts & nothing but the facts. As I told Rod, I am sure with the advice found in his book I an sure it will be my "Passport to DXCC Honour Roll" 73 de Glyn GW0ANA

VE9VIC	Rating: 5/5	Feb 16, 2004 20:31	Send this review to a friend
a must			**Time owned: more than 12 months**

I HAVE BEEN DXING FOR THE PAst 1o years and
this book is really good for the newcomers
and for the more experimented dxer's.
nice job,it will sure help a lots of news
amateurs specialy if they don't have or
find a elmer to help them,I also have the
complete dxer by w9kni AND LOW BAND dxing
by ON4UN ,all are a must if you want to
improve your skill and have fun,73 best dx.rino

N5VWN	Rating: 5/5	Dec 31, 2003 06:14	Send this review to a friend
It's like, DXing for Dummies			**Time owned: 6 to 12 months**

Best book for DXing for newbies or perhaps anyone. I'm sure even the seasoned pro could glean stuff from here. It's a must have for people like me who know nothing. Well I know something now. This book is layed out logically and is an easy read. I even chuckled a few times. His sense of humor it perfectly timed. But mostly it's so handy and I keep refering too it daily while DXing. It's got usefull tricks to DXing and tips on equipment and procedures. Really enjoyed his DXing secrets. IMHO, probably the most important thing is the frequency listings and their uses. I'm hoping that will help standardize things as far as where the DX is. But I'm amazed how knowledgable AC6V is on this subject. I've got tabs pasted all over it for quick refrence and it is right next to me in the ham shack. . . usually opened to something like frequency list or the "Q" codes. Tons of stuff in there like that. I'm VERY glad I bought this one and I don't buy many "how to" books.

KU4BP	Rating: 5/5	Jul 31, 2003 00:49	Send this review to a friend
Great Book			**Time owned: 6 to 12 months**
This book is a must for new DXers and DX veterans alike. The chapter on DX secrets is an invaluable resource because nobody knows every "trick of trade". Ed KU4BP			

KE6NHS	Rating: 5/5	Jul 26, 2003 15:56	Send this review to a friend
Excellent			**Time owned: 0 to 3 months**
If you are new to HF this book is your new best friend. All of the basics are well covered. Once you get past the basics, you will find a lot of advanced information that can only be acquired through years of experience. After spending 2 weeks with the book I am still finding valuable information and I am constantly referring to the many operating aids provided. Thank you Rod!			

AD6WL	Rating: 5/5	Jun 25, 2003 17:00	Send this review to a friend
Great book			**Time owned: more than 12 months**
This book dosn't have anything it in that I havn't read before, but it has it all in one place. I have read many books, and websites on HF and DXing. This book will save you lots of time by having it all in one easy reference. It is a great book for newcomers to DX and the oldtimers alike.			

N6SDK	Rating: 5/5	Dec 27, 2002 16:21	Send this review to a friend
Great HF'ing Book			**Time owned: more than 12 months**
[redacted]			

This book has helped me time and time again. It is packed with years of useful information, which the author, Rod AC6V, has learned in through his experiences. It is organized in a straight forward easy to understand manner. I use this book whenever I have unanswered questions or simply want to read about High Frequency Ham Radio operation. I highly recommend it!

AG5T	Rating: 5/5	Dec 26, 2002 12:11	Send this review to a friend
Fantastic dx book			**Time owned: more than 12 months**

What a great dx book! When I was called to jury duty I selected THIS BOOK to read while waiting in the jury assembly room! It's a great way to learn and review dxing techniques. Those dxing secrets are great (but don't tell anyone!). I know a lot of work went into this book and I thank and respect all those who worked on it. Another thing that makes it great is the humor mixed in - in fact, I'm asking my local radio club if they want to go on a dxpedition to Charcoal Island in the Barbecues IOTA group! Thank you Rod and everyone for a great book.

KB1GZ	Rating: 5/5	Sep 5, 2002 13:01	Send this review to a friend
Terrific			**Time owned: 6 to 12 months**

Although licensed for several years, been away from Amateur Radio for about 10 years, so getting restarted with all the new technology and information available was a chore, but DX101X made things a whole lot more enjoyable.

The bottom line is this, I have read the book three times and extracted only a small percentage of the available information; and, if you are either new to our hobby or think you have a strong enough ego not to be humbled but to absorb the information contained in this book, you are in for a very pleasant surprise!

Get up to Speed Quickly with this Guide	**Time owned: 0 to 3 months**
This book is well worth the price. You get current, practical information on topics of interest to both new and old HAMs. Information is presented in a straightforward, succint and readable manner, the illustrations are basic, but adequate. You don't need or pay for glossy fluff here- the book provides a well thought out treatise on FM ops in one place, from simplex, repeaters, digital and the vagaries of Echolink. Lots of links for further information too. A great place to get up to speed quickly. New HAMS will feel completely comfortable on VHF/UHF after perusing this book. Well Done.	

NA4M	**Rating: 3/5**	**Apr 10, 2003 16:37**	**Send this review to a friend**
New Book on FM			**Time owned: 0 to 3 months**
New book on FM repeaters. This will be removed when first review posted.

Book is comb-bound so the latest updates will be inserted prior to all orders as we print on demand. This way all updated URL's, reader feedback, and corrections will be in your manual. As further addendums are received, they will be posted here under
MANUAL UPDATES

CHAPTER 1. INTRODUCTION

PARAGRAPH & TOPIC	PARAGRAPH & TOPIC
1-2. Using This Guide	1-6. The Joy Of DXing
1-3. A Little Background	1-7. The DXer and The Civilian
1-4. The Six Meter Band	1-8. Awards
1-5. Why DX	

CHAPTER 2. THE SIX METER BAND PLAN

PARAGRAPH & TOPIC	PARAGRAPH & TOPIC
2-2. Six Meter Frequency Allotments	2-5. Tuning In A Nutshell
2-3. USA Recommended Six Meter Band Plan	2-6. Typical Six Meter Fm Band Plan
2-4. Calling Frequencies	Notes

CHAPTER 3. DXING EQUIPMENT

PARAGRAPH & TOPIC	**PARAGRAPH & TOPIC**
3-2. Transceivers	3-26. Antenna Height
3-3. Transceiver Specifications	3-27. Yagi Beams
3-4. Sensitivity	3-28. Vertical Antennas
3-5. Dynamic range	3-29. Cubical Quads
3-6. Selectivity	3-30. Homebrew Antennas
3-7. Superheterodyne Receivers	3-31. Towers & Rotors

3-8. Frequency Stability and Accuracy	3-32. Bearing And Distance
3-9. Cross -Modulation	3-33. RFI Safety And RFI To The Neighbors
3-10. Gain Compression	3-34. Lightning Protection And Grounding
3-11. Intermodulation Distortion	3-35. Computer Equipment
3-12. Phase Noise	3-36. Coax Cable & Cable Management
3-13. S-Units	3-37. Voltage Standing Wave Ratio
3-14. Decibels	3-38. Antenna Tuners
3-15. Transmitter Specifications	3-39. Microphones
3-16. Duty Cycle	3-40. Headphones And Speakers
3-17. Whizbang DSP Radios	3-41. ESP Hearing
3-18. Transceiver Programmability	3-42. KeysAnd Keyers
3-19. Transceiver Operating Controls	3-43. DSP Units
3-20. Your Sideband Audio	3-44. Antenna Analyzers
3-21. Modifications	3-45. SWR Meters
3-22. Linear Amplifiers	3-46. Scratch Pads
3-23. Selecting Power Amplifiers	3-47. Monitor Scopes
3-24. Tubes VS. FETS	3-48. Foot Switches
3-25. Antennas	3-49. Other Goodies

CHAPTER 4. OPERATING AIDS

PARAGRAPH & TOPIC	PARAGRAPH & TOPIC
4-2. Logging Programs	4-9. Prefix Finder Programs
4-3. Grid Squares	4-10. Macintosh Programs
4-4. Beacons	4-11. Propagation Websites
4-5. Distance & Bearing Programs	4-12. Propagation Software
4-6. Antenna Programs	4-13. Radio Control Programs
4-7. DXer Programs	4-14. RTTY, PSK31 & SSTV Programs
4-8. Great Circle Programs	4-15. Q-Signals & RST

CHAPTER 5. PROPAGATION

PARAGRAPH & TOPIC	PARAGRAPH & TOPIC
5-2. The Regions Of The Ionosphere	5-13. Sporadic E Mapping
5-3. Ionosphere Variations	5-14. F2 Skip
5-4. Solar Flux, A Index, K Index	5-15. Beacons
5-5. Six Meter Propagation	5-16. F2 Backscatter
5-6. Line Of Sight	5-17. Aurora
5-7. Sporadic E Propagation	5-18. Trans-Equatorial Propagation. (Tep)
5-8. Sporadic E Seasons	5-19. Troposcatter
5-9. Hourly Sporadic E Occurrences	5-20. Ionoscatter
5-10. Sporadic E Geographical Areas	5-21. Tropo (Tropospheric Bending)
5-11. Sporadic E Solar Cycle Variations	5-22. Meteor Scatter
5-12. Sporadic E Indicators	5-23.Propagation Modes Comparison Chart

CHAPTER 6. WORKING DX

PARAGRAPH & TOPIC	**PARAGRAPH & TOPIC**
6-2. The Big Gun myth	6-8. CW Operation
6-3. Finding DX	6-9. DX Packet Clusters and Telnet
6-4. Non-Contest DXing	6-10. Worked All States
6-5. Working Split	6-11. Worked 100 Grids Squares (VUCC)
6-6. Working Contests	6-12. DXCC Awards
6-7. QRP Operation	6-13. Other Awards

CHAPTER 7. QSLING

PARAGRAPH & TOPIC	**PARAGRAPH & TOPIC**
7-2. The QSL Card	7-15. Envelopes

7-3. Logging	7-16. Envelope Sizes
7-4. QSL Card Design	7-17. Return Postage
7-5. Finding QSL Addresses	7-18. Postage Stamps
7-6. QSLing Domestically	7-19. Cash
7-7. Sending QSL Cards	7-20. Bank Checks
7-8. Sending QSLs Direct	7-21. IRCs
7-9. QSLing Via A DX Manager	7-22. Monetary Tips For QSL Managers
7-10. Outgoing QSL Bureaus	7-23. Current US Postal International Rates
7-11. Incoming QSL Bureaus	7-24. What Is A Good IRC?
7-12. QSLing To A DX Bureau Direct	7-25. How Much Postage To Send
7-13. QSL Forwarding Services	7-26. QSL Checklist
7-14. QSLing Electronically	

Appendices

ANTENNAS, COAX, TOWERS, TUNERS & ROTOR MFG

- AEA -- Analyzers & Coax Tracer
- ALF Enterprises -- Larson, Comet, Maxrad, Pryme, Smiley, Wilson, and Antron

- Alpha Delta Antennas
- Aluma Tower Company - Crank up towers for Fixed, Mobile and Portable use
- Amac Automatic Antenna and Rig Control -- For the IC-706 / FT-100 and Screw Driver Antennas
- Antennas & More - Wayne KC7NMZ -- HF, Mobile, VHF/UHF Antennas
- Antenna Analyzers - See Autek, MFJ & AEA
- Antenna Specialists -- Mobile Antennas -- Via Universal Radio
- .htm
- Anti-oxidation products -- NOALOX, PENETROX, more -- Also See AES Ham Store See On-Line Catalog #14 Page 131-137 or Local Hardware Store -- Also see Coax-Seal
- Anntron Antennas -- 80 thru 10M Vertical, Hamwhip Single Banders, 10 - 11 Meter Base, VHF/UHF
- AN Wireless -- Self Supporting Towers
- Arrow Antennas -- VHF/UHF Antennas includes Satellite Antennas, Yagis, J-Poles, Corner Reflectors
- ARS antenna rotator control with a computer From EA4TX
- Atoc Iron Horse HF Mobile -- Via Universal Radio
- Autek - Antenna Analyzers

- BandHopper -- Mobile/portable/fixed antennas
- Barker & Williamson - Antennas, Coils, Accessories for HF Radio
- Belden Cable -- go to Products and Services, then Belden Catalog -- in the search box -- type in cable number or 50 (75) ohm coax
- Beverage Antenna Transformers - From K1FZ
- BlueSky Masts -- Portable Antenna Masts
  -- Up to 20 meters
- Bozak Antennas - VHf & UHF Antennas
- BuddiPole -- W3FF Products
- Butternut Antennas - Via Bencher Pages
- BUX CommCo ™® Antennas, Connectors, Parts and Accessories.

- C3I® Antennas - VHF/UHF antennas
- Cable Experts
- Cable To Go
- CAL-AV, INC - Antennas, Baluns, Mobile Antenna Springs, and Morse Keys.
- Carolina Cyclone Mobile Antennas - From K4KWH
- CB Antennas
- Centaur Baluns.com
- Champion Radio Products - Professional tower supplies and specialty products
- CliffDweller II antenna - Antenna restrictions? - Short on Space? SEE THIS ONE!!
- Coax Seal™ -- Hand-moldable, plastic mastic, a waterproof, long-lasting seal for coaxial cable.

- CobWeb Antenna -- From G3TPW
- Cojot Antennas - Mobile Antennas
- Comet Antennas - NCG Companies
- Comtek - Phased Array Systems, Remote Antenna Switches, Hybrid Phasing Coupler
- Cubex Quad - SkyMaster Kits
- CushCraft Antennas
- CushCraft R5/R7 Vertical Maintenance Tips Schematic Of Black Box.
- ---
- Davis RF Co - Wire, Cable, Dacron Rope Supplier
- Decibel Products -- Wide Range Of Antennas
- Degen Designs -- MiniQuad three band, portable, high performance mini-quad antenna
- Delta X-Ray Antennas - - HF Delta Loops and VHF/UHF ground plane antennas
- Diamond Antennas - via RF Parts Company
- N5FC's Notes on the DK9SQ Telescoping Mast
- DWM Communications -- Yo Yo Wind up Dipole Antenna, Tiny Tenna, Travel Tenna
- DX Engineering - Boom-to-Mast Plates, Element-to-Boom Plates, Element Clamps, and Harbach Saddle Clamps.
- DX System Radio - HF thru UHF Antennas

- EA4TX Antenna Rotator Control Systems
- Elk Antennas -- log periodic antennas for VHF/UHF
- EUR-AM -- VHF/UHF Base and Mobile Antennas
- EZ HANG -- SlingShot & Reel Device for installing wire antennas

---

- Ferrite Loop Antenna -- for BC band -- From Oceanstate Electronics
- Fluid Motion Antennas -- Steppir Antennas
- Forbes Group -- VENTENNA -- A vent pipe antenna Click Here For eHam Reviews
- Ventanna HFP-2 10 Foot HF Antenna -- 6.5 to 30 MHz
- Force 12 Antennas

- GB Antennas - From The Netherlands
- Gem Quad - Cubical Quads
- GeoTool - Truck Antenna Mount
- Giovannini Antennas - Italian Site -- D2T Antenna 1.5/200 MHz, 1 KW, Low band DXing Antennas, Broad Band Antennas 1.8/30 MHz 1 KW, Quads, Fiberglass Masts, Rotators
- Glen Martin Engineering - Towers, Hazer, Telescoping Tower Trailer, Roof-Top Towers, Kevlar Guy Cable & Rope
- GLA Antennas - Texas BugCatcher
- Guided Wave Technology -- analyze and design rectangular waveguide filters.

- HamAntenna -- Canadian Mfg
- HamStick Antennas
- Harger Lightning Protection
- Heights Tower Systems
- Helitrix ™ Slinky becomes an antenna
- Hex-Beam From Traffie Technology
- Hi-Q Antennas - Mobile
- Hustler - New-Tronics Antenna Corporation
- Hybrid Quad Antenna -- From TGM Communications
- Hy-Gain - By Telex -- New page - Diect Marketing
- HyperLink Technologies - Antennas, Cable, Accessories
- Hy Power Antenna Company - Several wire antenna designs
- ---
- IIX Equipment Ltd ---- Via W9IIX -- GinPoles, Rotor Mounts, Lots of Tower Accessories

---

- K0XG -- Guy Ring Bearings, Ground Mounted Base Rotor, Elevated Base Rotor, Elevated Base Bearing
- K1CRA Radio Web Store -- RF Connectors, Liquid Tape, Plasti-Dip Products
- K3IWK -- VHF & UHF Antennas
- KB6KQ Loop Antennas -- 10 M through 70 cM Stackable Loops
- K0XG Rotating Tower Equipment -- Guy Ring Bearings, Ground Mounted Base Rotor, Elevated Base Rotor, Elevated Base Bearing
- KMA Antennas - HF - VHF - UHF Log Periodics & unique 6 meter antennas
- KVK Antennas -- Vipole, NU-Beam and the multi-band Quad-Folded-Dipole

---

- Lakeview Co. -- HamStick Mobile antennas and accessories by WD4BUM
- Larsen Antennas -- Now a division of Radiall
- LDG Electronics - Automatic Antenna Tuners
- Lightning Bolt Antennas
- ---
- M2 Antennas
- Magnetic Loops for HF -- From W2BRI
- Maldol - VHF/UHF and new Vertical 80/40/30/20/17/15/10/6/2/70cm Via Universal Radio
- Max Gain Systems - RF coaxial switches, Gin Poles, Antenna Accessories, HF quads
- MaxRad Antennas -- VHF and UHF Antennas
- MFJ catalog -- Antennas and Antenna Analyzers
- MoonRaker Antennas -- UK Manufacturer
- Mosley HF Beam & Vertical Antennas Mosely Home page

- N1LO's Tower Page -- HomeBrew Tower, Guying, Safety, Etc
- Nemal Electronics International -- Connectors and Cables
- Nil-Jon VHF/UHF Base -- Via Universal Radio
- NI8F HF Dipole Antennas -- Via Universal radio
- NOALOX -- Anti-Oxidation Product Also See AES Ham Store See On-Line Catalog #14 Page 131-137 or Local Hardware Store
- Norm's Rotor Service -- Sales, Service & Exclusive Exchange Program
- NorthWest Antenna -- 2 meters to 160 meters. Compact as well as high power antennas.

- OPAR - the One Person Antenna Raiser -- drive a vehicle on the base for portable operations or mount permanently at your QTH by bolting base to concrete inserts.
- OptiBeam -- Now in North America From Array Solutions
- Outbacker Antennas -- Terlin

- PalStar - Tuners and accessories, SW radio, Dummy loads, SWR Meters, Filters
- Par End-Fedz -- full length half wave dipoles, but with an important difference. The coax connector is at one end of the dipole, where it is most needed. From Universal Radio
- Par Omniangle Antennas -- 10M/6M/VHF/UHF - Also available From Universal Radio
- PCE International -- Towers and Antennas
- PENETROX -- Anti-oxidation product Also See AES Ham Store See On-Line Catalog #14 Page 131-137 or Local Hardware Store
- PolyPhaser Corp. - Lightning Protection Devices
-

- Quicksilver Radio Products MinuteMan™ HF Portable Antennas
-

- Radio Shack
- RadioWare -- HF Mobile, VHF/UHF Mobile, Yagis, Omnidirectional
- Radio Warehouse - distributor of Coax and Wire products to the Amateur Radio Market.
- Radio Waves -- Microwave Antennas
- Radio Works -- CAROLINA Windom/Beam, SuperLoop, Isolators, Baluns
- Raibeam Antennas International -- A Wide Variety of Beam Antennas
- R.F. Connection -- Specialist in RF Connectors and Coax
- Rohn and Unr-Rohn - Towers and Other Products
- Rotor Service - Norm's

- The ScrewDriver.Com -- High quality full legal limit with mount and digital controller at an affordable price.
- SETI Antennas -- From The SETI League
- SGC World -- Smarttuner & Antennas

- Shakespeare Antennas -- Composite Marine Antennas
- Sinclair Technologies -- Base/mobile antennas, duplexers, cavity filters
- Smiley Antennas
- Solarcon A99 - Via Universal Radio
- Solarcon IMAX 2000 Base Antenna -- a 5/8 version of the A99
- Solder-It -- All Kinds Of Solder Products
- Sommer Antennas
- Spider Antennas -- From Multi-Band Antennas
- SpiRo's MultiBand Antennas
- SSB Electronics -- Big Wheel Antennas 2M & 70cm
- Stealth Antennas -- HF Mobile Antennas By VE7BOC
- Steppir Antennas -- Fluid Motion
- Stuf -- Dielectric Water-Proof Connector Filler - See AES Ham Store See #14 Page 131-137 or Local Hardware Store
- Super Antennas - Vern Wright's HF Mobile Antennas, MP1 etc.

- T-Hunting Equipment
- TarHeel Mobile Antennas
- Telewave -- Combiners, MultiCouplers, cavities
- Telex -- Hy-Gain Products
- Tennadyne Corp -- Log Periodics
- Texas BugCatcher And Texas Twister- GLA Antennas
- Texas Towers
- T.G.M. Communications -- Mini-Quads
- Thrust Bearing FAQ -- From The YCCC
- Times Microwave Systems -- Coax and Connectors
- Titanex Antennas
- Top Ten Devices, Inc - Data decoders and antenna switching
- Traffie Technologies -- Hex Beams
- Transel Technologies. -- Antenna Mounts, Thread Mounts, HF and VHF/UHF Antennas
- Trilogy Communications -- High Grade Cable
- Trival Antennas -- From Slovenia

- Unadilla Antenna Mfg Co. -- Baluns, Traps, Coaxial Relays, Insulators, Wire
- Universal Radio -- Large Selection of Antennas, Towers, Rotors, Tuners, Switches, Coax
- US Tower

- Valcom -- Fibreglass Whip Antennas
- Valor VHF/UHF Antennas -- Via Universal Radio

- Vectronics -- Tuners, Filters, Dummy Loads, Keyers, Wattmeters
- VENTENNA -- A VHF/UHF vent pipe antenna -- Click Here For eHam Reviews
- Ventanna HFP-2 10 Foot HF Antenna -- 6.5 to 30 MHz

- W3FF Antennas -- Buddipole™, the new Buddistick™ for HF Portable operations.
- W7FG - Ladder Line and Antennas. 600 Ohms. Doublets and G5RV antennas
- WB0W, Inc - Antennas, Towers, Hazers, more
- Wellbrook Communications -- Antenna Loops for MEDIUM WAVE, LONG WAVE & SHORT WAVE

- WideBand Loop Antenna -- From Maarten Haag
- Wilderness Radio - For the outdoor QRP enthusiast
- Wilson Antennas
- WireMan Inc -- Wires, Coax, Baluns A Bunch
- WorldRadio -- SD-20 Antenna Support extends from 47 inches to 20 feet. It weighs less than 2 pounds. Go to Products.
- W5AJ Tower Raising
- WX0B -- StackMatch - for stacking, phasing, and switching antennas

---

- XXTowers -- Experts in amateur radio installations of all types and sizes.

31 m ____9250 -- 9990 kHz	

The "Radio Regulations" of the International Telecommunications Union define the shortwave broadcast bands. At the 1992 World Administrative Radio Conference, new bands were created and existing bands were expanded. The band limits in the following table reflect the WARC-92 agreements and broadcast band expansions used on a non-interfering basis (e.g., the 41 m band starting at 6890 kHz on a non-interference basis): Although the allocations do not become official until 2007, in practice many stations have already started using the expanded portions under the motto "use it or lose it." Additionally, there are a few stations that broadcast outside the band edges above, e.g., Iran on 9022 and a number of African stations around 9200 kHz. Clearly, receivers with continuous coverage between 1.6 and 30 MHz are preferred.

NONRESIDENT TRAINING COURSE

SEPTEMBER 1998

Navy Electricity and Electronics Training Series

Module 10—Introduction to Wave Propagation, Transmission Lines, and Antennas

NAVEDTRA 14182

DISTRIBUTION STATEMENT A: Approved for public release; distribution is unlimited.

Although the words "he," "him," and "his" are used sparingly in this course to enhance communication, they are not intended to be gender driven or to affront or discriminate against anyone.

DISTRIBUTION STATEMENT A: Approved for public release; distribution is unlimited.

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: To introduce the student to the subject of Wave Propagation, Transmission Lines, and Antennas who needs such a background in accomplishing daily work and/or in preparing for further study.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards*, NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

2. Radio Wave Propagation 2-1
3. Principles of Transmission Lines 3-1
4. Antennas 4-1

APPENDIX

I. Glossary AI-1

INDEX INDEX-1

NAVY ELECTRICITY AND ELECTRONICS TRAINING SERIES

The Navy Electricity and Electronics Training Series (NEETS) was developed for use by personnel in many electrical- and electronic-related Navy ratings. Written by, and with the advice of, senior technicians in these ratings, this series provides beginners with fundamental electrical and electronic concepts through self-study. The presentation of this series is not oriented to any specific rating structure, but is divided into modules containing related information organized into traditional paths of instruction.

The series is designed to give small amounts of information that can be easily digested before advancing further into the more complex material. For a student just becoming acquainted with electricity or electronics, it is highly recommended that the modules be studied in their suggested sequence. While there is a listing of NEETS by module title, the following brief descriptions give a quick overview of how the individual modules flow together.

Module 1, *Introduction to Matter, Energy, and Direct Current,* introduces the course with a short history of electricity and electronics and proceeds into the characteristics of matter, energy, and direct current (dc). It also describes some of the general safety precautions and first-aid procedures that should be common knowledge for a person working in the field of electricity. Related safety hints are located throughout the rest of the series, as well.

Module 2, *Introduction to Alternating Current and Transformers,* is an introduction to alternating current (ac) and transformers, including basic ac theory and fundamentals of electromagnetism, inductance, capacitance, impedance, and transformers.

Module 3, *Introduction to Circuit Protection, Control, and Measurement,* encompasses circuit breakers, fuses, and current limiters used in circuit protection, as well as the theory and use of meters as electrical measuring devices.

Module 4, *Introduction to Electrical Conductors, Wiring Techniques, and Schematic Reading,* presents conductor usage, insulation used as wire covering, splicing, termination of wiring, soldering, and reading electrical wiring diagrams.

Module 5, *Introduction to Generators and Motors,* is an introduction to generators and motors, and covers the uses of ac and dc generators and motors in the conversion of electrical and mechanical energies.

Module 6, *Introduction to Electronic Emission, Tubes, and Power Supplies,* ties the first five modules together in an introduction to vacuum tubes and vacuum-tube power supplies.

Module 7, *Introduction to Solid-State Devices and Power Supplies,* is similar to module 6, but it is in reference to solid-state devices.

Module 8, *Introduction to Amplifiers,* covers amplifiers.

Module 9, *Introduction to Wave-Generation and Wave-Shaping Circuits,* discusses wave generation and wave-shaping circuits.

Module 10, *Introduction to Wave Propagation, Transmission Lines, and Antennas,* presents the characteristics of wave propagation, transmission lines, and antennas.

Module 11, *Microwave Principles,* explains microwave oscillators, amplifiers, and waveguides.

Module 12, *Modulation Principles,* discusses the principles of modulation.

Module 13, *Introduction to Number Systems and Logic Circuits,* presents the fundamental concepts of number systems, Boolean algebra, and logic circuits, all of which pertain to digital computers.

Module 14, *Introduction to Microelectronics,* covers microelectronics technology and miniature and microminiature circuit repair.

Module 15, *Principles of Synchros, Servos, and Gyros,* provides the basic principles, operations, functions, and applications of synchro, servo, and gyro mechanisms.

Module 16, *Introduction to Test Equipment,* is an introduction to some of the more commonly used test equipments and their applications.

Module 17, *Radio-Frequency Communications Principles,* presents the fundamentals of a radio-frequency communications system.

Module 18, *Radar Principles,* covers the fundamentals of a radar system.

Module 19, *The Technician's Handbook,* is a handy reference of commonly used general information, such as electrical and electronic formulas, color coding, and naval supply system data.

Module 20, *Master Glossary,* is the glossary of terms for the series.

Module 21, *Test Methods and Practices,* describes basic test methods and practices.

Module 22, *Introduction to Digital Computers,* is an introduction to digital computers.

Module 23, *Magnetic Recording,* is an introduction to the use and maintenance of magnetic recorders and the concepts of recording on magnetic tape and disks.

Module 24, *Introduction to Fiber Optics,* is an introduction to fiber optics.

Embedded questions are inserted throughout each module, except for modules 19 and 20, which are reference books. If you have any difficulty in answering any of the questions, restudy the applicable section.

Although an attempt has been made to use simple language, various technical words and phrases have necessarily been included. Specific terms are defined in Module 20, *Master Glossary*.

Considerable emphasis has been placed on illustrations to provide a maximum amount of information. In some instances, a knowledge of basic algebra may be required.

Assignments are provided for each module, with the exceptions of Module 19, *The Technician's Handbook*; and Module 20, *Master Glossary*. Course descriptions and ordering information are in NAVEDTRA 12061, *Catalog of Nonresident Training Courses*.

Throughout the text of this course and while using technical manuals associated with the equipment you will be working on, you will find the below notations at the end of some paragraphs. The notations are used to emphasize that safety hazards exist and care must be taken or observed.

WARNING

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN INJURY OR DEATH IF NOT CAREFULLY OBSERVED OR FOLLOWED.

CAUTION

AN OPERATING PROCEDURE, PRACTICE, OR CONDITION, ETC., WHICH MAY RESULT IN DAMAGE TO EQUIPMENT IF NOT CAREFULLY OBSERVED OR FOLLOWED.

NOTE

An operating procedure, practice, or condition, etc., which is essential to emphasize.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

http://courses.cnet.navy.mil

Grading by Mail: When you submit answer sheets by mail, send all of your assignments at one time. Do NOT submit individual answer sheets for grading. Mail all of your assignments in an envelope, which you either provide yourself or obtain from your nearest Educational Services Officer (ESO). Submit answer sheets to:

COMMANDING OFFICER
NETPDTC N331
6490 SAUFLEY FIELD ROAD
PENSACOLA FL 32559-5000

Answer Sheets: All courses include one "scannable" answer sheet for each assignment. These answer sheets are preprinted with your SSN, name, assignment number, and course number. Explanations for completing the answer sheets are on the answer sheet.

Do not use answer sheet reproductions: Use only the original answer sheets that we provide—reproductions will not work with our scanning equipment and cannot be processed.

Follow the instructions for marking your answers on the answer sheet. Be sure that blocks 1, 2, and 3 are filled in correctly. This information is necessary for your course to be properly processed and for you to receive credit for your work.

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment--they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

ERRATA

Errata are used to correct minor errors or delete obsolete information in a course. Errata may also be used to provide instructions to the student. If a course has an errata, it will be included as the first page(s) after the front cover. Errata for all courses can be accessed and viewed/downloaded at:

http://www.advancement.cnet.navy.mil

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail. If you write or fax, please use a copy of the Student Comment form that follows this page.

For subject matter questions:

E-mail: n315.products@cnet.navy.mil
Phone: Comm: (850) 452-1001, ext. 1728
DSN: 922-1001, ext. 1728
FAX: (850) 452-1370
(Do not fax answer sheets.)
Address: COMMANDING OFFICER
NETPDTC N315
6490 SAUFLEY FIELD ROAD
PENSACOLA FL 32509-5237

For enrollment, shipping, grading, or completion letter questions

E-mail: fleetservices@cnet.navy.mil
Phone: Toll Free: 877-264-8583
Comm: (850) 452-1511/1181/1859
DSN: 922-1511/1181/1859
FAX: (850) 452-1370
(Do not fax answer sheets.)
Address: COMMANDING OFFICER
NETPDTC N331
6490 SAUFLEY FIELD ROAD
PENSACOLA FL 32559-5000

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you will receive retirement points if you are authorized to receive them under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 6 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty*, BUPERSINST 1001.39, for more information about retirement points.)

CHAPTER 1

WAVE PROPAGATION

LEARNING OBJECTIVES

Learning objectives are stated at the beginning of each chapter. These learning objectives serve as a preview of the information you are expected to learn in the chapter. The comprehensive check questions are based on the objectives. By successfully completing the NRTC, you indicate that you have met the objectives and have learned the information. The learning objectives are listed below.

Upon completion of this chapter, you should be able to:

1. State what wave motion is, define the terms reflection, refraction, and diffraction, and describe the Doppler effect.
2. State what sound waves are and define a propagating medium.
3. List and define terms as applied to sound waves, such as cycle, frequency, wavelength, and velocity.
4. List the three requirements for sound.
5. Define pitch, intensity, loudness, and quality and their application to sound waves.
6. State the acoustical effects that echoes, reverberation, resonance, and noise have on sound waves.
7. Define light waves and list their characteristics.
8. List the various colors of light and define the terms reflection, refraction, diffusion, and absorption as applied to light waves.
9. State the difference between sound waves and light waves.
10. State the electromagnetic wave theory and list the components of the electromagnetic wave.

INTRODUCTION TO WAVE PROPAGATION

Of the many technical subjects that naval personnel are expected to know, probably the one least susceptible to change is the theory of wave propagation. The basic principles that enable waves to be propagated (transmitted) through space are the same today as they were 70 years ago. One would think, then, that a thorough understanding of these principles is a relatively simple task. For the electrical engineer or the individual with a natural curiosity for the unknown, it is indeed a simple task. Most technicians, however, tend to view wave propagation as something complex and confusing, and would just as soon see this chapter completely disappear from training manuals. This attitude undoubtedly stems from the fact that wave propagation is an invisible force that cannot be detected by the sense of sight or touch. Understanding wave propagation requires the use of the imagination to visualize the associated concepts and how they are used in practical application. This manual was developed to help you visualize

and understand those concepts. Through ample use of illustrations and a step-by-step transition from the simple to the complex, we will help you develop a better understanding of wave propagation. In this chapter, we will discuss propagation theory on an introductory level, without going into the technical details that concern the engineer. However, you must still use thought and imagination to understand the new ideas and concepts as they are presented.

To understand radio wave propagation, you must first learn what wave propagation is and some of the basic physics or properties that affect propagation. Many of these properties are common everyday occurrences, with which you are already familiar.

WHAT IS PROPAGATION?

Early man was quick to recognize the need to communicate beyond the range of the human voice. To satisfy this need, he developed alternate methods of communication, such as hand gestures, beating on a hollow log, and smoke signals. Although these methods were effective, they were still greatly limited in range. Eventually, the range limitations were overcome by the development of courier and postal systems; but there was then a problem of speed. For centuries the time required for the delivery of a message depended on the speed of a horse.

During the latter part of the 19th century, both distance and time limitations were largely overcome. The invention of the telegraph made possible instantaneous communication over long wires. Then a short time later, man discovered how to transmit messages in the form of RADIO WAVES.

As you will learn in this chapter, radio waves are propagated. PROPAGATION means "movement through a medium." This is most easily illustrated by light rays. When a light is turned on in a darkened room, light rays travel from the light bulb throughout the room. When a flashlight is turned on, light rays also radiate from its bulb, but are focused into a narrow beam. You can use these examples to picture how radio waves propagate. Like the light in the room, radio waves may spread out in all directions. They can also be focused (concentrated) like the flashlight, depending upon the need. Radio waves are a form of radiant energy, similar to light and heat. Although they can neither be seen nor felt, their presence can be detected through the use of sensitive measuring devices. The speed at which both forms of waves travel is the same; they both travel at the speed of light.

You may wonder why you can see light but not radio waves, which consist of the same form of energy as light. The reason is that you can only "see" what your eyes can detect. Your eyes can detect radiant energy only within a fixed range of frequencies. Since the frequencies of radio waves are below the frequencies your eyes can detect, you cannot see radio waves.

The theory of wave propagation that we discuss in this module applies to Navy electronic equipment, such as radar, navigation, detection, and communication equipment. We will not discuss these individual systems in this module, but we will explain them in future modules.

Q1. What is propagation?

PRINCIPLES OF WAVE MOTION

All things on the earth—on the land, or in the water—are showered continually with waves of energy. Some of these waves stimulate our senses and can be seen, felt, or heard. For instance, we can see light, hear sound, and feel heat. However, there are some waves that do not stimulate our senses. For

example, radio waves, such as those received by our portable radio or television sets, cannot be seen, heard, or felt. A device must be used to convert radio waves into light (TV pictures) and sound (audio) for us to sense them.

A WAVE can be defined as a DISTURBANCE (sound, light, radio waves) that moves through a MEDIUM (air, water, vacuum). To help you understand what is meant by "a disturbance which moves through a medium," picture the following illustration. You are standing in the middle of a wheat field. As the wind blows across the field toward you, you can see the wheat stalks bending and rising as the force of the wind moves into and across them. The wheat appears to be moving toward you, but it isn't. Instead, the stalks are actually moving back and forth. We can then say that the "medium" in this illustration is the wheat and the "disturbance" is the wind moving the stalks of wheat.

WAVE MOTION can be defined as a recurring disturbance advancing through space with or without the use of a physical medium. Wave motion, therefore, is a means of moving or transferring energy from one point to another point. For example, when sound waves strike a microphone, sound energy is converted into electrical energy. When light waves strike a phototransistor or radio waves strike an antenna, they are likewise converted into electrical energy. Therefore, sound, light, and radio waves are all forms of energy that are moved by wave motion. We will discuss sound waves, light waves, and radio waves later.

Q2. How is a wave defined as it applies to wave propagation?

Q3. What is wave motion?

Q4. What are some examples of wave motion?

WAVE MOTION IN WATER

A type of wave motion familiar to almost everyone is the movement of waves in water. We will explain these waves first to help you understand wave motion and the terms used to describe it.

Basic wave motion can be shown by dropping a stone into a pool of water (see figure 1-1). As the stone enters the water, a surface disturbance is created, resulting in an expanding series of circular waves. Figure 1-2 is a diagram of this action. View A shows the falling stone just an instant before it strikes the water. View B shows the action taking place at the instant the stone strikes the surface, pushing the water that is around it upward and outward. In view C, the stone has sunk deeper into the water, which has closed violently over it causing some spray, while the leading wave has moved outward. An instant later, the stone has sunk out of sight, leaving the water disturbed as shown in view D. Here the leading wave has continued to move outward and is followed by a series of waves gradually diminishing in amplitude. Meanwhile, the disturbance at the original point of contact has gradually subsided.

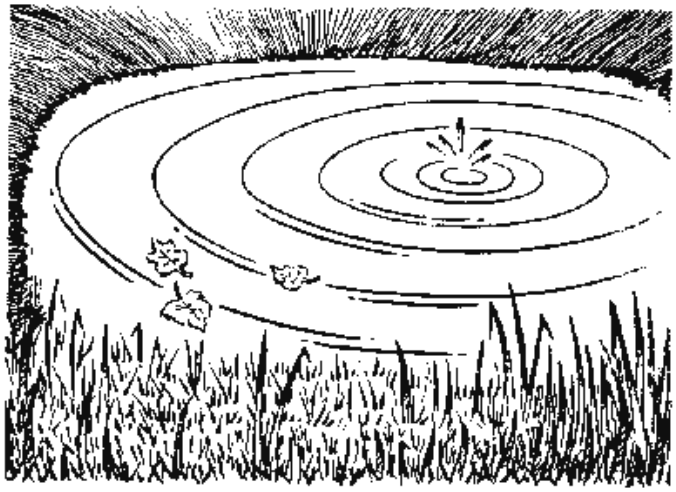

Figure 1-1.—Formation of waves in water.

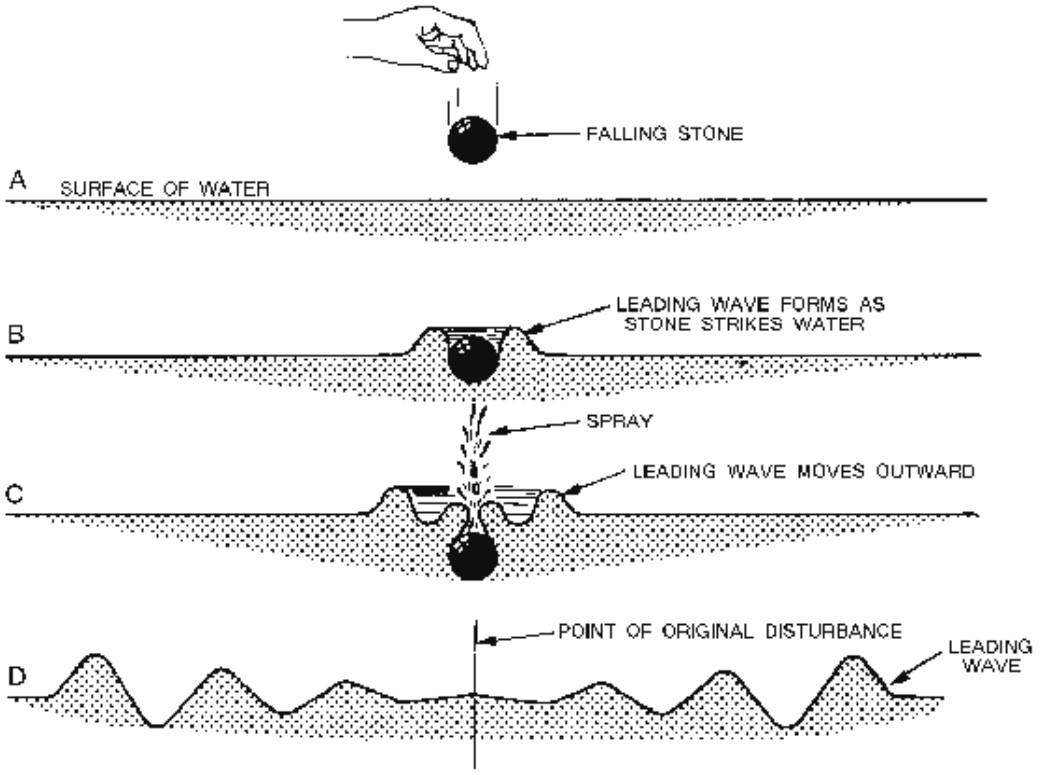

Figure 1-2.—How a falling stone creates wave motion to the surface of water.

In this example, the water is not actually being moved outward by the motion of the waves, but up and down as the waves move outward. The up and down motion is transverse, or at right angles, to the outward motion of the waves. This type of wave motion is called TRANSVERSE WAVE MOTION.

Q5. What type of wave motion is represented by the motion of water?

TRANSVERSE WAVES

To explain transverse waves, we will again use our example of water waves. Figure 1-3 is a cross section diagram of waves viewed from the side. Notice that the waves are a succession of crests and troughs. The wavelength (one 360 degree cycle) is the distance from the crest of one wave to the crest of the next, or between any two similar points on adjacent waves. The amplitude of a transverse wave is half the distance measured vertically from the crest to the trough. Water waves are known as transverse waves because the motion of the water is up and down, or at right angles to the direction in which the waves are traveling. You can see this by observing a cork bobbing up and down on water as the waves pass by; the cork moves very little in a sideways direction. In figure 1-4, the small arrows show the up-and-down direction the cork moves as the transverse wave is set in motion. The direction the wave travels is shown by the large arrow. Radio waves, light waves, and heat waves are examples of transverse waves.

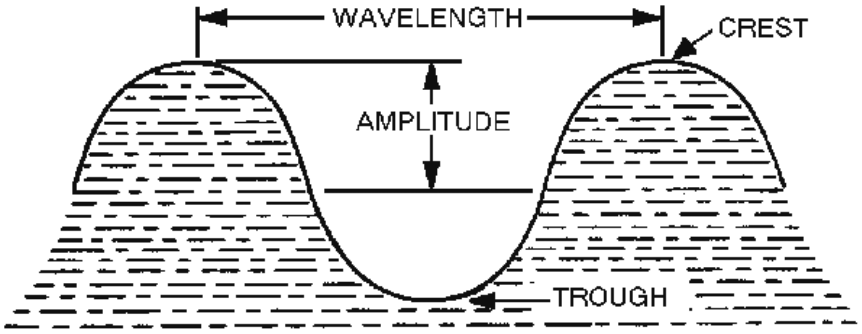

Figure 1-3.—Elements of a wave.

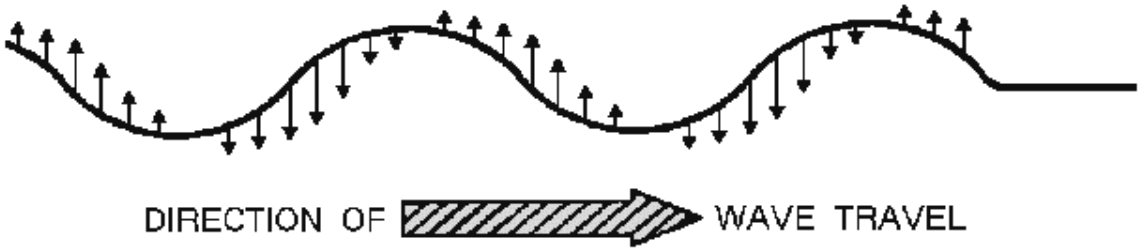

Figure 1-4.—Transverse wave.

LONGITUDINAL WAVES

In the previous discussion, we listed radio waves, light waves, and heat waves as examples of transverse waves, but we did not mention sound waves. Why? Simply because sound waves are LONGITUDINAL WAVES. Unlike transverse waves, which travel at right angles to the direction of propagation, sound waves travel back and forth in the same direction as the wave motion. Therefore, longitudinal waves are waves in which the disturbance takes place in the direction of propagation. Longitudinal waves are sometimes called COMPRESSION WAVES.

Waves that make up sound, such as those set up in the air by a vibrating tuning fork, are longitudinal waves. In figure 1-5, the tuning fork, when struck, sets up vibrations. As the tine moves in an outward direction, the air immediately in front of it is compressed (made more dense) so that its momentary

pressure is raised above that at other points in the surrounding medium (air). Because air is elastic, the disturbance is transmitted in an outward direction as a COMPRESSION WAVE. When the tine returns and moves in the inward direction, the air in front of the tine is rarefied (made less dense or expanded) so that its pressure is lowered below that of the other points in the surrounding air. The rarefied wave is propagated from the tuning fork and follows the compressed wave through the medium (air).

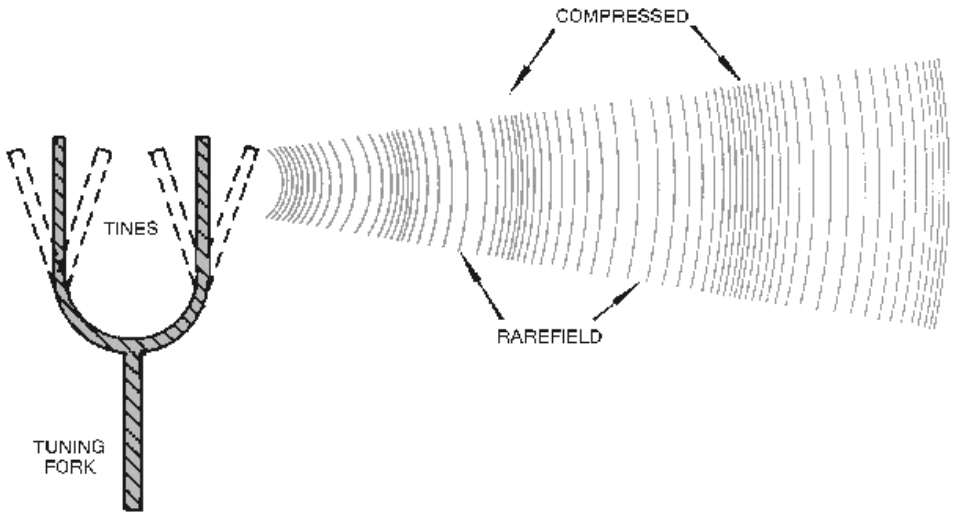

Figure 1-5.—Sound propagation by a tuning fork.

Q6. What are some examples of transverse waves?

Q7. What example of a longitudinal wave was given in the text?

MEDIUM

We have used the term *medium* in describing the motion of waves. Since *medium* is a term that is used frequently in discussing propagation, it needs to be defined so you will understand what a medium is and its application to propagation.

A MEDIUM is the vehicle through which the wave travels from one point to the next. The vehicle that carries a wave can be just about anything. An example of a medium, already mentioned, is air. Air, as defined by the dictionary, is the mixture of invisible, odorless, tasteless gases that surrounds the earth (the atmosphere). Air is made up of molecules of various gases (and impurities). We will call these molecules of air *particles of air* or simply *particles*.

Figure 1-6 will help you to understand how waves travel through air. The object producing the waves is called the SOURCE—a bell in this illustration. The object responding to the waves is called a DETECTOR or RECEIVER—in this case, the human ear. The medium is air, which is the means of conveying the waves from the source to the detector. The source, detector, and medium are all necessary for wave motion and wave propagation (except for electromagnetic waves which require no medium). The waves shown in figure 1-6 are sound waves. As the bell is rung, the particles of air around the bell are compressed and then expanded. This compression and expansion of particles of air set up a wave motion in the air. As the waves are produced, they carry energy from particle to particle through the medium (air) to the detector (ear).

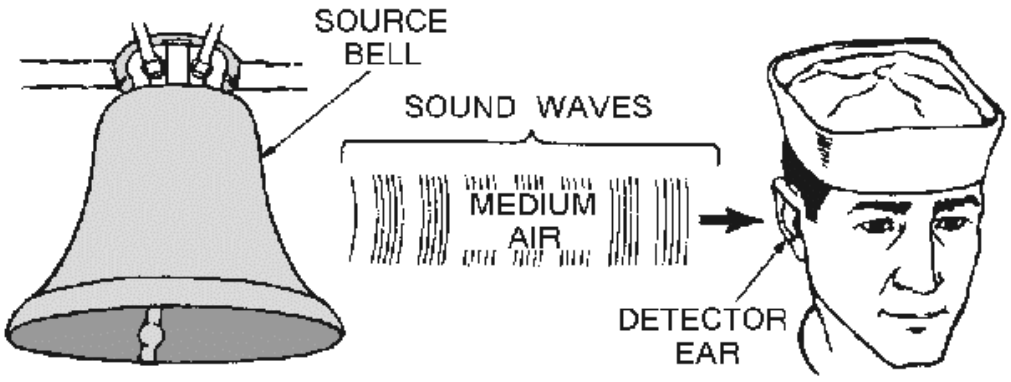

Figure 1-6.—The three elements of sound.

Q8. What are the three requirements for a wave to be propagated?

TERMS USED IN WAVE MOTION

There are a number of special terms concerning waves that you should know. Many of the terms, such as CYCLE, WAVELENGTH, AMPLITUDE, and FREQUENCY were introduced in previous *NEETS* modules. We will now discuss these terms in detail as they pertain to wave propagation. Before we begin our discussion, however, note that in the figure, wave 1 and wave 2 have equal frequency and wavelength but different amplitudes. The REFERENCE LINE (also known as REST POSITION or POINT OF ZERO DISPLACEMENT) is the position that a particle of matter would have if it were not disturbed by wave motion. For example, in the case of the water wave, the reference line is the level of the water when no wave motion is present. With this in mind, let's go on to our discussion of the four terms, as shown in figure 1-7.

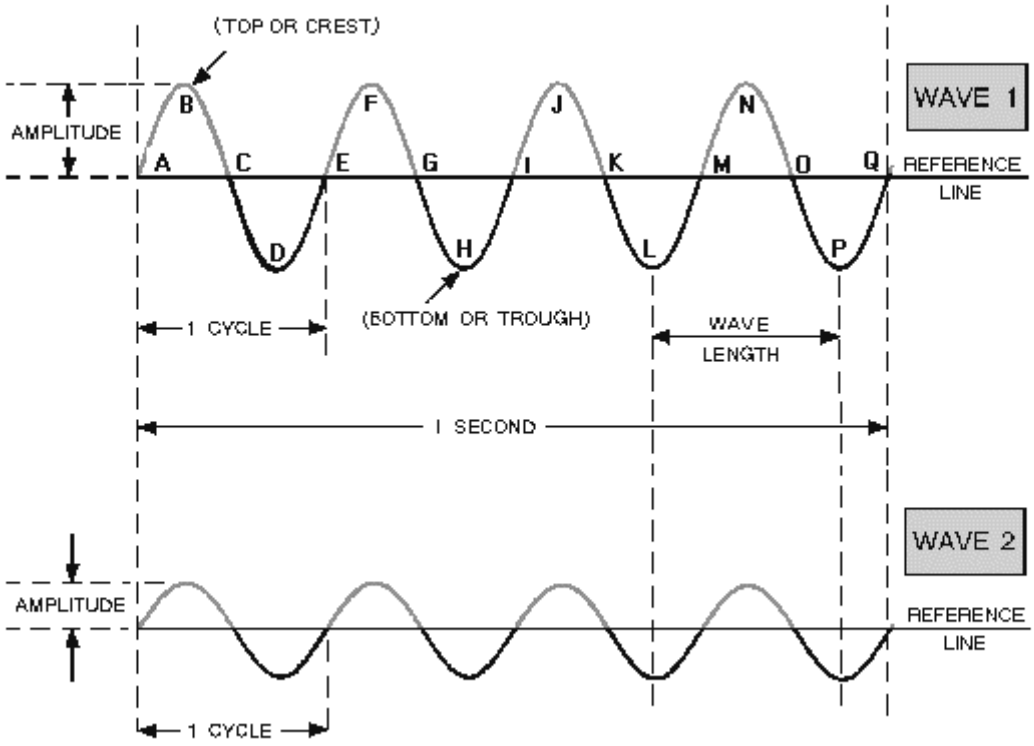

Figure 1-7.—Comparison of waves with different amplitudes.

Cycle

Refer to wave 1 in figure 1-7. Notice how similar it is to the sine wave you have already studied. All transverse waves appear as sine waves when viewed from the side. In figure 1-7, wave 1 has four complete cycles. Points ABCDE comprise one complete cycle having a maximum value above and a maximum value below the reference line. The portion above the reference line (between points A and C) is called a POSITIVE ALTERNATION and the portion below the reference line (between points C and E) is known as a NEGATIVE ALTERNATION. The combination of one complete positive and one complete negative alternation represents one cycle of the wave. At point E, the wave begins to repeat itself with a second cycle completed at point I, a third at point M, etc. The peak of the positive alternation (maximum value above the line) is sometimes referred to as the TOP or CREST, and the peak of the negative alternation (maximum value below the line) is sometimes called the BOTTOM or TROUGH, as depicted in the figure. Therefore, one cycle has one crest and one trough.

Wavelength

A WAVELENGTH is the distance in space occupied by one cycle of a radio wave at any given instant. If the wave could be frozen in place and measured, the wavelength would be the distance from the leading edge of one cycle to the corresponding point on the next cycle. Wavelengths vary from a few hundredths of an inch at extremely high frequencies to many miles at extremely low frequencies; however, common practice is to express wavelengths in meters. Therefore, in figure 1-7 (wave 1), the distance between A and E, or B and F, etc., is one wavelength. The Greek letter lambda (λ) is used to signify wavelength. Why lambda and not "l" or "L"? This is because "L" is used conventionally as the

symbol for inductance, and "l" is used for dimensional length; therefore, λ; is used to indicate the length of waves.

Amplitude

Two waves may have the same wavelength, but the crest of one may rise higher above the reference line than the crest of the other. Compare wave 1 and wave 2 of figure 1-7 again. The height of a wave crest above the reference line is called the AMPLITUDE of the wave. The amplitude of a wave gives a relative indication of the amount of energy the wave transmits. A continuous series of waves, such as A through Q, having the same amplitude and wavelength, is called a train of waves or WAVE TRAIN.

Frequency and Time

Time is an important factor in wave studies. When a wave train passes through a medium, a certain number of individual waves pass a given point in a specific unit of time. For example, if a cork on a water wave rises and falls once every second, the wave makes one complete up-and-down vibration every second. The number of vibrations, or cycles, of a wave train in a unit of time is called the FREQUENCY of the wave train and is measured in HERTZ. If 5 waves pass a point in one second, the frequency of the wave train is 5 cycles per second. In figure 1-7, the frequency of both wave 1 and wave 2 is four cycles per second (cycles per second is abbreviated as cps).

In 1967, in honor of the German physicist Heinrich Hertz, the term HERTZ was designated for use in lieu of the term "cycle per second" when referring to the frequency of radio waves. It may seem confusing that in one place the term "cycle" is used to designate the positive and negative alternations of a wave, but in another instance the term "hertz" is used to designate what appears to be the same thing. The key is the time factor. The term cycle refers to any sequence of events, such as the positive and negative alternations, comprising one cycle of electrical current. The term hertz refers to the number of occurrences that take place in one second.

Q9. What is a cycle?

Q10. What is wavelength (λ)?

CHARACTERISTICS OF WAVE MOTION

The two types of wave motion, transverse and longitudinal, have many of the same characteristics, such as frequency, amplitude, and wavelength. Another important characteristic that these two types of wave motion share is VELOCITY. Velocity of propagation is the rate at which the disturbance travels through the medium, or the velocity with which the crest of the wave moves along. The velocity of the wave depends both on the type of wave (light, sound, or radio) and type of medium (air, water, or metal). If longitudinal waves are plotted as a graph, they appear as transverse waves. This fact is illustrated in figure 1-8.

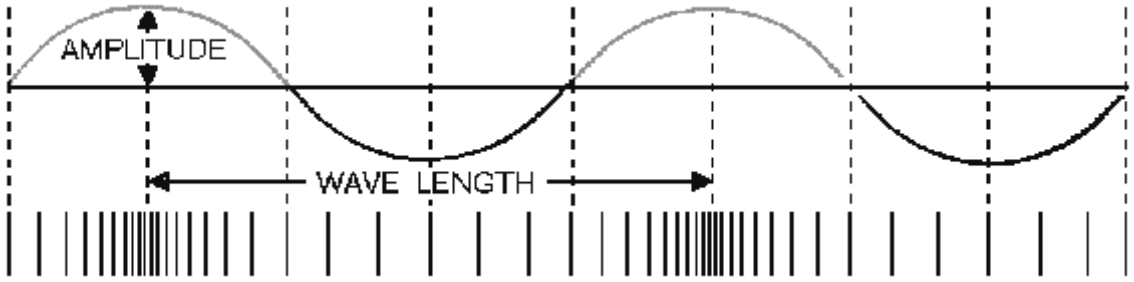

Figure 1-8.—Longitudinal wave represented graphically by a transverse wave.

The frequency of a longitudinal wave, like that of a transverse wave, is the number of complete cycles the wave makes during a specific unit of time. The higher the frequency, the greater is the number of compressions and expansions per unit of time.

In the two types of wave motion described in the preceding discussion, the following quantities are of interest:

a. The PERIOD, which is the time (T) in which one complete vibratory cycle of events occurs,

b. The FREQUENCY OF VIBRATION (f), which is the number of cycles taking place in one second, and

c. The WAVELENGTH, which is the distance the disturbance travels during one period of vibration.

Now, consider the following concept. If a vibrating object makes a certain number of vibrations per second, then 1 second divided by the number of vibrations is equal to the period of time of 1 vibration. In other words, the period, or time, of 1 vibration is the reciprocal of the frequency; thus,

$$\text{time (T) of one vibration} = \frac{1}{\text{frequency (f)}}$$

or

$$T = \frac{1}{f}$$

If you know the velocity of a wave, you can determine the wavelength by dividing the velocity by the frequency. As an equation:

Where:

$$\lambda = \frac{v}{f}$$

λ = wavelength
v = velocity of propagation
f = frequency of vibration

When you use the above equation, be careful to express velocity and wavelength in the proper units of length. For example, in the English system, if the velocity (expressed in feet per second) is divided by the frequency (expressed in cycles per second, or Hz), the wavelength is given in feet per cycle. If the metric system is used and the velocity (expressed in meters per second) is divided by the frequency (expressed in cycles per second), the wavelength is given in meters per cycle. Be sure to express both the wavelength and the frequency in the same units. (Feet per cycle and meters per cycle are normally abbreviated as feet or meters because one wavelength indicates one cycle.) Because this equation holds true for both transverse and longitudinal waves, it is used in the study of both electromagnetic waves and sound waves.

Consider the following example. Two cycles of a wave pass a fixed point every second, and the velocity of the wave train is 4 feet per second. What is the wavelength? The formula for determining wavelength is as follows:

$$\lambda = \frac{v}{f}$$

Where:

λ = wavelength in feet
v = velocity in feet per second
f = frequency in Hz

Given:

v = 4 feet per second
f = 2 Hz

Solution:

$$\lambda = \frac{v}{f}$$

$$\lambda = \frac{4 \text{ feet per second}}{2 \text{ Hz}}$$

$$\lambda = 2 \text{ feet}$$

NOTE: In problems of this kind, be sure NOT to confuse wave velocity with frequency. FREQUENCY is the number of cycles per unit of time (Hz). WAVE VELOCITY is the speed with which a wave train passes a fixed point.

Here is another problem. If a wave has a velocity of 1,100 feet per second and a wavelength of 30 feet, what is the frequency of the wave?

By transposing the general equation:

By transposing the general equation:

$$f = \frac{v}{\lambda}$$

We have the equation:

$$\lambda = \frac{v}{f}$$

Given:

$v = 1{,}100$ feet per second
$\lambda = 30$ feet

Solution:

$$f = \frac{1{,}100 \text{ feet per second}}{30 \text{ feet}}$$

$$f = 36.67\text{Hz}$$

To find the velocity, rewrite the equation as:

$$v = \lambda f$$

Let's work one more problem, this time using the metric system.

Suppose the wavelength is 0.4 meters and the frequency is 12 kHz. What is the velocity?

Use the formula:

velocity = wavelength × frequency ($v = \lambda f$)

Given:

wavelength (λ) = 0.4 meters
frequency (f) = 12kHz

Solution:

$v = \lambda \times f$
$v = 0.4 \text{ meters} \times 12{,}000\text{Hz}$
$v = 4{,}800$ meters per second

Other important characteristics of wave motion are reflection, refraction, diffraction, and the Doppler effect. Big words, but the concept of each is easy to see. For ease of understanding, we will explain the first two characteristics using light waves, and the last two characteristics using sound waves. You should keep in mind that all waves react in a similar manner.

Within mediums, such as air, solids, or gases, a wave travels in a straight line. When the wave leaves the boundary of one medium and enters the boundary of a different medium, the wave changes direction. For our purposes in this module, a boundary is an imaginary line that separates one medium from another.

When a wave passes through one medium and encounters a medium having different characteristics, three things can occur to the wave: (1) Some of the energy can be reflected back into the initial medium; (2) some of the energy can be transmitted into the second medium where it may continue at a different velocity; or (3) some of the energy can be absorbed by the medium. In some cases, all three processes (reflection, transmission, and absorption) may occur to some degree.

Reflection

REFLECTION WAVES are simply waves that are neither transmitted nor absorbed, but are reflected from the surface of the medium they encounter. If a wave is directed against a reflecting surface, such as a mirror, it will reflect or "bounce" from the mirror. Refer to figure 1-9. A wave directed *toward* the surface of the mirror is called the INCIDENT wave. When the wave bounces off of the mirror, it becomes known as the REFLECTED wave. An imaginary line perpendicular to the mirror at the point at which the incident wave strikes the mirror's surface is called the NORMAL, or perpendicular. The angle between the incident wave and the normal is called the ANGLE OF INCIDENCE. The angle between the reflected wave and the normal is called the ANGLE OF REFLECTION.

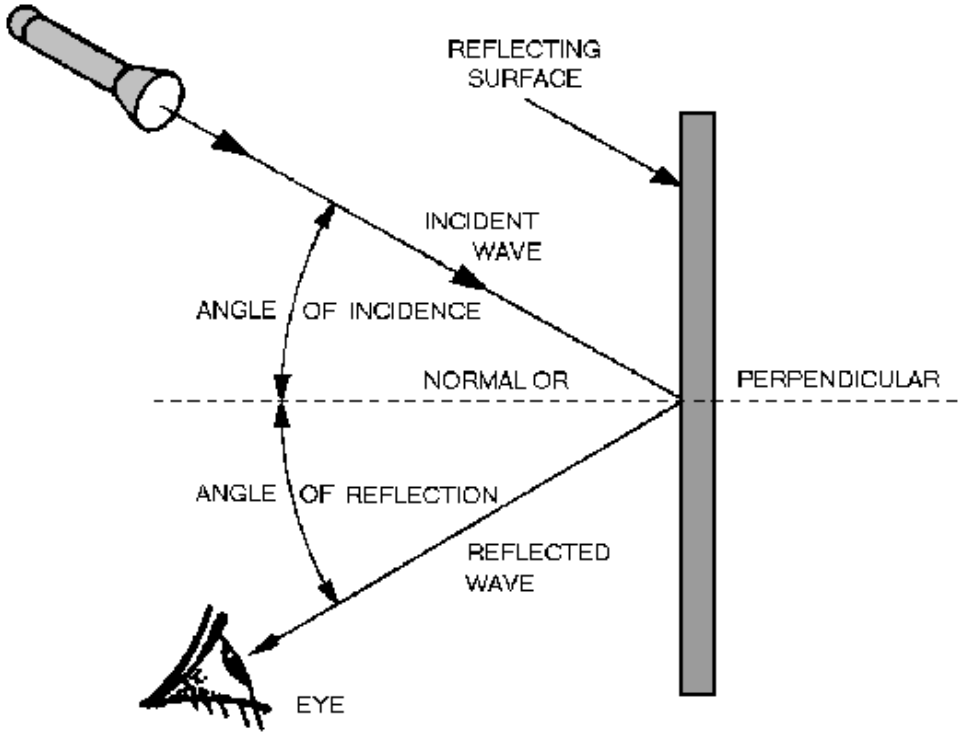

Figure 1-9.—Reflection of a wave.

If the reflecting surface is smooth and polished, the angle between the incident ray and the normal will be the same as the angle between the reflected ray and the normal. This conforms to the law of reflection which states: The angle of incidence is equal to the angle of reflection.

The amount of incident wave energy reflected from a given surface depends on the nature of the surface and the angle at which the wave strikes the surface. As the angle of incidence increases, the amount of wave energy reflected increases. The reflected energy is the greatest when the wave is nearly parallel to the reflecting surface. When the incident wave is perpendicular to the surface, more of the energy is transmitted into the substance and less is reflected. At any incident angle, a mirror reflects almost all of the wave energy, while a dull, black surface reflects very little.

Q11. What is the law of reflection?

Q12. When a wave is reflected from a surface, energy is transferred. When is the transfer of energy greatest?

Q13. When is the transfer of energy minimum?

Refraction

When a wave passes from one medium into another medium that has a different velocity of propagation, a change in the direction of the wave will occur. This changing of direction as the wave enters the second medium is called REFRACTION. As in the discussion of reflection, the wave striking the boundary (surface) is called the INCIDENT WAVE, and the imaginary line perpendicular to the boundary is called the NORMAL. The angle between the incident wave and the normal is called the ANGLE OF INCIDENCE. As the wave passes through the boundary, it is bent either toward or away from the normal. The angle between the normal and the path of the wave through the second medium is the ANGLE OF REFRACTION.

A light wave passing through a block of glass is shown in figure 1-10. The wave moves from point A to B at a constant speed. This is the incident wave. As the wave penetrates the glass boundary at point B, the velocity of the wave is slowed down. This causes the wave to bend toward the normal. The wave then takes the path from point B to C through the glass and becomes BOTH the refracted wave from the top surface and the incident wave to the lower surface. As the wave passes from the glass to the air (the second boundary), it is again refracted, this time away from the normal and takes the path from point C to D. As the wave passes through the last boundary, its velocity increases to the original velocity. As figure 1-10 shows, refracted waves can bend toward or away from the normal. This bending depends on the velocity of the wave through each medium. The broken line between points B and E is the path that the wave would travel if the two mediums (air and glass) had the same density.

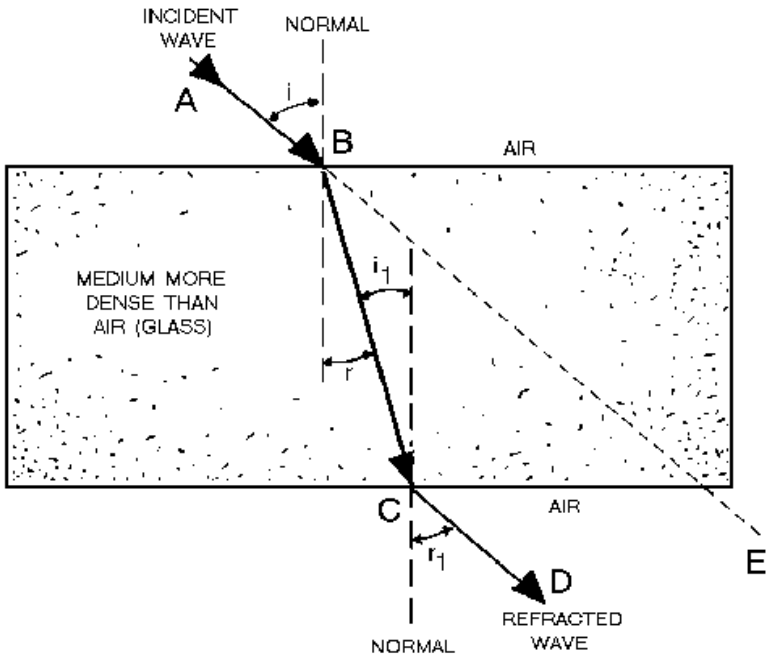

Figure 1-10.—Refraction of a wave.

To summarize what figure 1-10 shows:

1. If the wave passes from a less dense medium to a more dense medium, it is bent toward the normal, and the angle of refraction (r) is less than the angle of incidence (i).

2. If the wave passes from a more dense to a less dense medium, it is bent away from the normal, and the angle of refraction (r_1) is greater than the angle of incidence (i_1).

You can more easily understand refraction by looking at figure 1-11. There is a plowed field in the middle of a parade ground. Think of the incident wave as a company of recruits marching four abreast at an angle across the parade ground to the plowed field, then crossing the plowed field and coming out on the other side onto the parade ground again. As the recruits march diagonally across the parade ground and begin to cross the boundary onto the plowed field, the front line is slowed down. Because the recruits arrive at the boundary at different times, they will begin to slow down at different times (number 1 slows down first and number 4 slows down last in each line). The net effect is a bending action. When the recruits leave the plowed field and reenter the parade ground, the reverse action takes place.

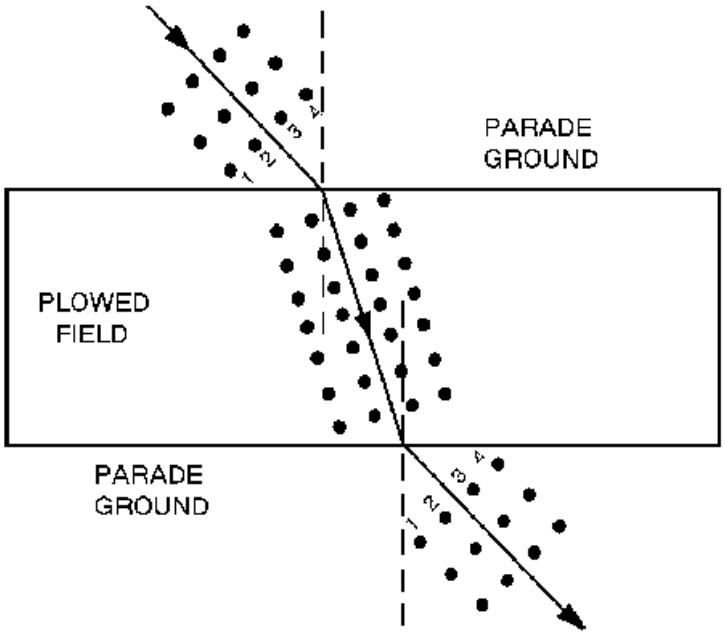

Figure 1-11.—Analogy of refraction.

Q14. A refracted wave occurs when a wave passes from one medium into another medium. What determines the angle of refraction?

Diffraction

DIFFRACTION is the bending of the wave path when the waves meet an obstruction. The amount of diffraction depends on the wavelength of the wave. Higher frequency waves are rarely diffracted in the normal world that surrounds us. Since light waves are high frequency waves, you will rarely see light diffracted. You can, however, observe diffraction in sound waves by listening to music. Suppose you are outdoors listening to a band. If you step behind a solid obstruction, such as a brick wall, you will hear mostly low notes. This is because the higher notes, having short wave lengths, undergo little or no diffraction and pass by or over the wall without wrapping around the wall and reaching your ears. The low notes, having longer wavelengths, wrap around the wall and reach your ears. This leads to the general statement that lower frequency waves tend to diffract more than higher frequency waves. Broadcast band (AM band) radio waves (lower frequency waves) often travel over a mountain to the opposite side from their source because of diffraction, while higher frequency TV and FM signals from the same source tend to be stopped by the mountain.

Doppler Effect

The last, but equally important, characteristic of a wave that we will discuss is the Doppler effect. The DOPPLER EFFECT is the apparent change in frequency or pitch when a sound source moves either toward or away from the listener, or when the listener moves either toward or away from the sound source. This principle, discovered by the Austrian physicist Christian Doppler, applies to all wave motion.

The apparent change in frequency between the source of a wave and the receiver of the wave is because of relative motion between the source and the receiver. To understand the Doppler effect, first assume that the frequency of a sound from a source is held constant. The wavelength of the sound will also remain constant. If both the source and the receiver of the sound remain stationary, the receiver will

hear the same frequency sound produced by the source. This is because the receiver is receiving the same number of waves per second that the source is producing. Now, if either the source or the receiver or both move toward the other, the receiver will perceive a higher frequency sound. This is because the receiver will receive a greater number of sound waves per second and interpret the greater number of waves as a higher frequency sound. Conversely, if the source and the receiver are moving apart, the receiver will receive a smaller number of sound waves per second and will perceive a lower frequency sound. In both cases, the frequency of the sound produced by the source will have remained constant.

For example, the frequency of the whistle on a fast-moving train sounds increasingly higher in pitch as the train is approaching than when the train is departing. Although the whistle is generating sound waves of a constant frequency, and though they travel through the air at the same velocity in all directions, the distance between the approaching train and the listener is decreasing. As a result, each wave has less distance to travel to reach the observer than the wave preceding it. Thus, the waves arrive with decreasing intervals of time between them.

These apparent changes in frequency, called the Doppler effect, affect the operation of equipment used to detect and measure wave energy. In dealing with electromagnetic wave propagation, the Doppler principle is used in equipment such as radar, target detection, weapons control, navigation, and sonar.

Q15. The apparent change in frequency or pitch because of motion is explained by what effect?

SOUND WAVES

The study of sound is important because of the role sound plays in the depth finding equipment (fathometer) and underwater detection equipment (sonar) used by the Navy.

As you know, sound travels through a medium by wave motion. Although sound waves and the electromagnetic waves used in the propagation of radio and radar differ, both types of waves have many of the same characteristics. Studying the principles of sound-wave motion will help you understand the actions of both sound waves and the more complex radio and radar electromagnetic waves. The major differences among sound waves, heat waves, and light waves are (1) their frequencies; (2) their types; the mediums through which they travel; and the velocities at which they travel.

SOUND—WHAT IS IT?

The word SOUND is used in everyday speech to signify a variety of things. One definition of sound is the sensation of hearing. Another definition refers to a stimulus that is capable of producing the sensation of hearing. A third definition limits sound to what is actually heard by the human ear.

In the study of physics, sound is defined as *a range of compression-wave frequencies to which the human ear is sensitive*. For the purpose of this chapter, however, we need to broaden the definition of sound to include compression waves that are not always audible to the human ear. To distinguish frequencies in the audible range from those outside that range, the words SONIC, ULTRASONIC, and INFRASONIC are used. Sounds capable of being heard by the human ear are called SONICS. The normal hearing range extends from about 20 to 20,000 hertz. However, to establish a standard sonic range, the Navy has set an arbitrary upper limit for sonics at 10,000 hertz and a lower limit at 15 hertz. Even though the average person can hear sounds above 10,000 hertz, it is standard practice to refer to sounds above that frequency as *ultrasonic*. Sounds between 15 hertz and 10,000 hertz are called *sonic*, while sounds below 15 hertz are known as *infrasonic* (formerly referred to as subsonic) sounds.

Q16. What term describes sounds capable of being heard by the human ear?

Q17. Are all sounds audible to the human ear? Why?

REQUIREMENTS FOR SOUND

Recall that sound waves are compression waves. The existence of compression waves depends on the transfer of energy. To produce vibrations that become sounds, a mechanical device (the source) must first receive an input of energy. Next, the device must be in contact with a medium that will receive the sound energy and carry it to a receiver. If the device is not in contact with a medium, the energy will not be transferred to a receiver, and there will be no sound.

Thus, three basic elements for transmission and reception of sound must be present before a sound can be produced. They are (1) the source (or transmitter), (2) a medium for carrying the sound (air, water, metal, etc.), and (3) the detector (or receiver).

A simple experiment provides convincing evidence that a medium must be present if sound is to be transferred. In figure 1-12, an electric bell is suspended by rubber bands in a bell jar from which the air can be removed. An external switch is connected from a battery to the bell so the bell may be rung intermittently. As the air is pumped out, the sound from the bell becomes weaker and weaker. If a perfect vacuum could be obtained, and if no sound were conducted out of the jar by the rubber bands, the sound from the bell would be completely inaudible. In other words, sound cannot be transmitted through a vacuum. When the air is admitted again, the sound is as loud as it was at the beginning. This experiment shows that when air is in contact with the vibrating bell, it carries energy to the walls of the jar, which in turn are set in vibration. Thus, the energy passes into the air outside of the jar and then on to the ear of the observer. This experiment illustrates that sound cannot exist in empty space (or a vacuum).

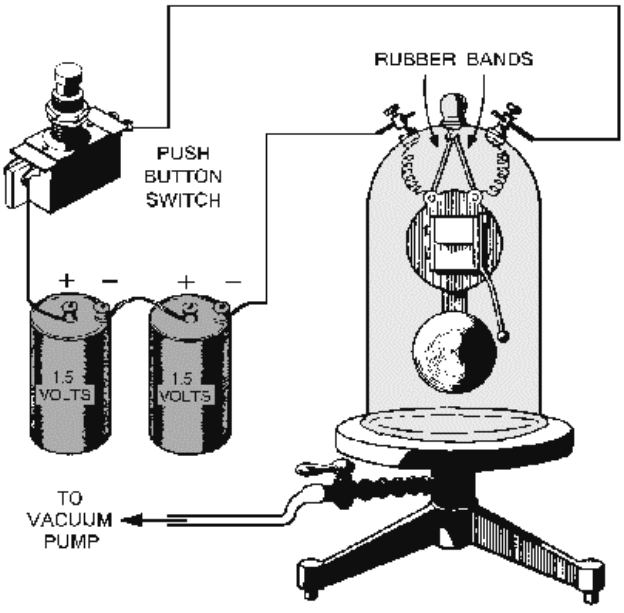

Figure 1-12.—No air, no sound.

Any object that moves rapidly back and forth, or vibrates, and thus disturbs the medium around it may be considered a source for sound. Bells, speakers, and stringed instruments are familiar sound sources.

The material through which sound waves travel is called the *medium*. The density of the medium determines the ease, distance, and speed of sound transmission. The higher the density of the medium, the slower sound travels through it.

The detector acts as the receiver of the sound wave. Because it does not surround the source of the sound wave, the detector absorbs only part of the energy from the wave and sometimes requires an amplifier to boost the weak signal.

As an illustration of what happens if one of these three elements is not present, let's refer to our experiment in which a bell was placed in a jar containing a vacuum. You could see the bell being struck, but you could hear no sound because there was no medium to transmit sound from the bell to you. Now let's look at another example in which the third element, the detector, is missing. You see a source (such as an explosion) apparently producing a sound, and you know the medium (air) is present, but you are too far away to hear the noise. Thus, as far as you are concerned, there is no detector and, therefore, no sound. We must assume, then, that sound can exist only when a source transmits sound through a medium, which passes it to a detector. Therefore, in the absence of any one of the basic elements (source, medium, detector) there can be NO sound.

Q18. Sound waves transmitted from a source are sometimes weak when they reach the detector. What instrument is needed to boost the weak signal?

TERMS USED IN SOUND WAVES

Sound waves vary in length according to their frequency. A sound having a long wavelength is heard at a low pitch (low frequency); one with a short wavelength is heard at a high pitch (high frequency). A complete wavelength is called a cycle. The distance from one point on a wave to the corresponding point on the next wave is a wavelength. The number of cycles per second (hertz) is the frequency of the sound. The frequency of a sound wave is also the number of vibrations per second produced by the sound source.

Q19. What are the three basic requirements for sound?

CHARACTERISTICS OF SOUND

Sound waves travel at great distances in a very short time, but as the distance increases the waves tend to spread out. As the sound waves spread out, their energy simultaneously spreads through an increasingly larger area. Thus, the wave energy becomes weaker as the distance from the source is increased.

Sounds may be broadly classified into two general groups. One group is NOISE, which includes sounds such as the pounding of a hammer or the slamming of a door. The other group is musical sounds, or TONES. The distinction between noise and tone is based on the regularity of the vibrations, the degree of damping, and the ability of the ear to recognize components having a musical sequence. You can best understand the physical difference between these kinds of sound by comparing the waveshape of a musical note, depicted in view A of figure 1-13, with the waveshape of noise, shown in view B. You can see by the comparison of the two waveshapes, that noise makes a very irregular and haphazard curve and a musical note makes a uniform and regular curve.

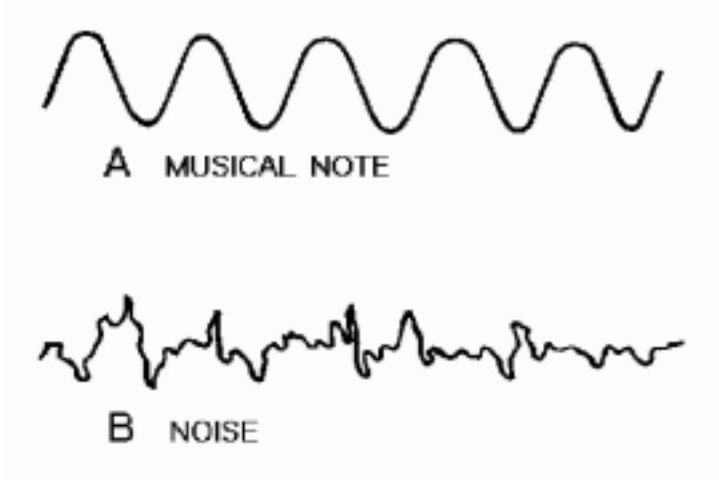

Figure 1-13.—Musical sound versus noise.

Sound has three basic characteristics: pitch, intensity, and quality. Each of these three characteristics is associated with one of the properties of the source or the type of waves which it produces. The pitch depends upon the frequency of the waves; the intensity depends upon the amplitude of the waves; and the quality depends upon the form of the waves. With the proper combination of these characteristics, the tone is pleasant to the ear. With the wrong combination, the sound quality turns into noise.

The Pitch of Sound

The term PITCH is used to describe the frequency of a sound. An object that vibrates many times per second produces a sound with a high pitch, as with a police whistle. The slow vibrations of the heavier strings of a violin cause a low-pitched sound. Thus, the frequency of the wave determines pitch. When the frequency is low, sound waves are long; when it is high, the waves are short. A sound can be so high in frequency that the waves reaching the ear cannot be heard. Likewise, some frequencies are so low that the eardrums do not convert them into sound. The range of sound that the human ear can detect varies with each individual.

The Intensity of Sound

The intensity of sound, at a given distance, depends upon the amplitude of the waves. Thus, a tuning fork gives out more energy in the form of sound when struck hard than when struck gently. You should remember that when a tuning fork is struck, the sound is omnidirectional (heard in all directions), because the sound waves spread out in all directions, as shown in figure 1-14. You can see from the figure that as the distance between the waves and the sound source increases, the energy in each wave spreads over a greater area; hence, the intensity of the sound decreases. The speaking tubes sometimes used aboard a ship prevent the sound waves from spreading in all directions by concentrating them in one desired direction (unidirectional), producing greater intensity. Therefore, the sound is heard almost at its original intensity at the opposite end of the speaking tube. The unidirectional megaphone and the directional loudspeaker also prevent sound waves from spreading in all directions.

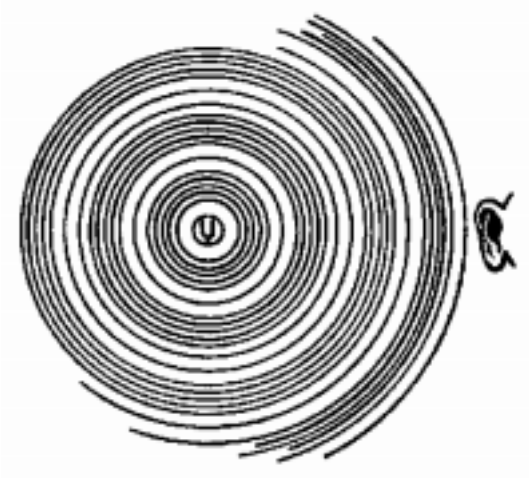

Figure 1-14.—Sound waves spread in all directions.

Sound intensity and loudness are often mistakenly interpreted as having the same meaning. Although they are related, they are not the same. Sound INTENSITY is a measure of the sound energy of a wave. LOUDNESS, on the other hand, is the sensation the intensity (and sometimes frequency) the sound wave produces on the ear. Increasing the intensity causes an increase in loudness but not in a direct proportion. For instance, doubling the loudness of a sound requires about a tenfold increase in the intensity of the sound.

Sound Quality

Most sounds, including musical notes, are not pure tones. They are a mixture of different frequencies (tones). A tuning fork, when struck, produces a pure tone of a specific frequency. This pure tone is produced by regular vibrations of the source (tines of the tuning fork). On the other hand, scraping your fingernails across a blackboard only creates noise, because the vibrations are irregular. Each individual pipe of a pipe organ is similar to a tuning fork, and each pipe produces a tone of a specific frequency. But sounding two or more pipes at the same time produces a complex waveform. A tone that closely imitates any of the vowel sounds can be produced by selecting the proper pipes and sounding them at the same time. Figure 1-15 illustrates the combining of two pure tones to make a COMPLEX WAVE.

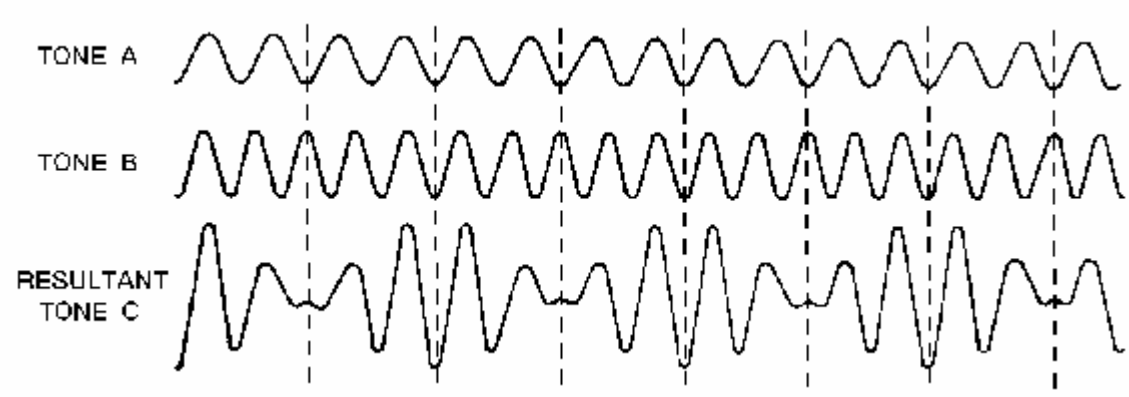

Figure 1-15.—Combination of tones.

The QUALITY of a sound depends on the complexity of its sound waves, such as the waves shown in tone C of figure 1-15. Almost all sounds (musical and vocal included) have complicated (complex)

waveforms. Tone A is a simple wave of a specific frequency that can be produced by a tuning fork, piano, organ, or other musical instrument. Tone B is also a simple wave but at a different frequency. When the two tones are sounded together, the complex waveform in tone C is produced. Note that tone C has the same frequency as tone A with an increase in amplitude. The human ear could easily distinguish between tone A and tone C because of the quality. Therefore, we can say that quality distinguishes tones of like pitch and loudness when sounded on different types of musical instruments. It also distinguishes the voices of different persons.

Q20. What are the two general groups of sound?

Q21. What are the three basic characteristics of sound?

Q22. What is the normal audible range of the human ear?

Q23. What is intensity as it pertains to sound?

Q24. What characteristic of sound enables a person to distinguish one musical instrument from another, if they are all playing the same note?

ELASTICITY AND DENSITY AND VELOCITY OF TRANSMISSION

Sound waves travel through any medium to a velocity that is controlled by the medium. Varying the frequency and intensity of the sound waves will not affect the speed of propagation. The ELASTICITY and DENSITY of a medium are the two basic physical properties that govern the velocity of sound through the medium.

Elasticity is the ability of a strained body to recover its shape after deformation, as from a vibration or compression. The measure of elasticity of a body is the force it exerts to return to its original shape.

The *density* of a medium or substance is the mass per unit volume of the medium or substance. Raising the temperature of the medium (which decreases its density) has the effect of increasing the velocity of sound through the medium.

The velocity of sound in an elastic medium is expressed by the formula:

$$v = \sqrt{\frac{E}{d}}$$

Even though solids such as steel and glass are far more dense than air, their elasticity's are so much greater that the velocities of sound in them are 15 times greater than the velocity of sound in air. Using elasticity as a rough indication of the speed of sound in a given medium, we can state as a general rule that *sound travels faster in harder materials* (such as steel), *slower in liquids, and slowest in gases*. Density has the opposite effect on the velocity of sound, that is, with other factors constant, a denser material (such as lead) passes sound slower.

At a given temperature and atmospheric pressure, all sound waves travel in air at the same speed. Thus the velocity that sound will travel through air at 32º F (0º C) is 1,087 feet per second. But for practical purposes, the speed of sound in air may be considered as 1,100 feet per second. Table 1-1 gives a comparison of the velocity of sound in various mediums.

Table 1-1.—Comparison of Velocity of Sound in Various Mediums

MEDIUM	TEMPERATURE		VELOCITY
	ºF	ºC	(FT/SEC)
AIR	32	0	1,087
AIR	68	20	1,127
ALUMINUM	68	20	16,700
CARBON DIOXIDE	32	0	856
FRESH WATER	32	0	4,629
FRESH WATER	68	20	4,805
HYDROGEN	32	0	4,219
LEAD	32	20	4,030
SALT WATER	32	0	4,800
SALT WATER	68	20	4,953
STEEL	32	0	16,410
STEEL	68	20	16,850

Q25. How does density and temperature affect the velocity of sound?

ACOUSTICS

The science of sound is called ACOUSTICS. This subject could fill volumes of technical books, but we will only scratch the surface in this chapter. We will present important points that you will need for a better understanding of sound waves.

Acoustics, like sound, relates to the sense of hearing. It also deals with the production, control, transmission, reception, and the effects of sound. For the present, we are concerned only with the last relationship—the effects of sound. These same effects will be used throughout your study of wave propagation.

Echo

An ECHO is the reflection of the original sound wave as it bounces off a distant surface. Just as a rubber ball bounces back when it is thrown against a hard surface, sound waves also bounce off most surfaces. As you have learned from the study of the law of conservation of energy, a rubber ball never bounces back with as much energy as the initial bounce. Similarly, a reflected sound wave is not as loud as the original sound wave. In both cases, some of the energy is absorbed by the reflecting surface. Only a portion of the original sound is reflected, and only a portion of the reflected sound returns to the listener. For this reason, an echo is never as loud as the original sound.

Sound reflections (echoes) have many applications in the Navy. The most important of these applications can be found in the use of depth finding equipment (the fathometer) and sonar. The fathometer sends sound-wave pulses from the bottom of the ship and receives echoes from the ocean floor to indicate the depth of the ocean beneath the ship. The sonar transmits a pulse of sound energy and receives the echo to indicate range and bearing of objects or targets in the ocean depths.

Refraction

When sound waves traveling at different velocities pass obliquely (at an angle) from one medium into another, the waves are refracted; that is, their line of travel is bent. Refraction occurs gradually when one part of a sound wave is traveling faster than the other parts. For example, the wind a few feet above

the surface of the earth has a greater velocity than that near the surface because friction retards the lower layers (see figure 1-16). The velocity of the wind is added to the velocity of the sound through the air. The result is that the upper portion of the sound wave moves faster than the lower portion and causes a gradual change in the direction of travel of the wave. Refraction causes sound to travel farther with the wind than against it.

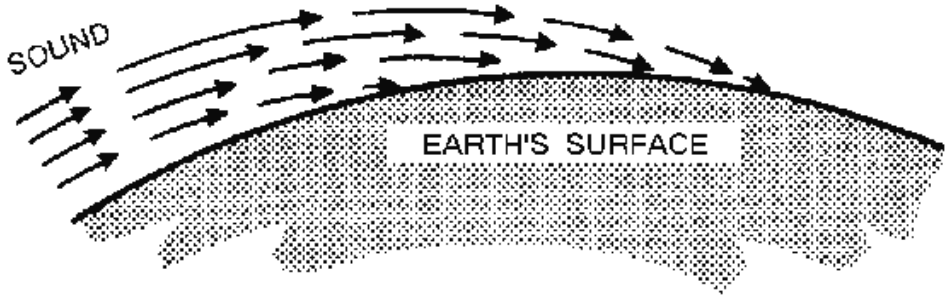

Figure 1-16.—Refraction of sound.

Reverberation

In empty rooms or other confined spaces, sound may be reflected several times to cause what is known as reverberation. REVERBERATION is the multiple reflections of sound waves. Reverberations seem to prolong the time during which a sound is heard. Examples of this often occur in nature. For instance, the discharge of lightning causes a sharp, quick sound. By the time this sound has reached the ears of a distant observer, it is usually drawn out into a prolonged roar by reverberations that we call thunder. A similar case often arises with underwater sound equipment. Reverberations from nearby points may continue for such a long time that they interfere with the returning echoes from targets.

Interference

Any disturbance, man-made or natural, that causes an undesirable response or the degradation of a wave is referred to as INTERFERENCE.

Two sound waves moving simultaneously through the same medium will advance independently, each producing a disturbance as if the other were not present. If the two waves have the same frequency—in phase with each other—and are moving in the same direction, they are additive and are said to interfere constructively. If the two waves have the same frequency and are moving in the same direction, but out of phase with each other, they are subtractive and are said to interfere destructively. If these two subtractive waves have equal amplitudes, the waves cancel each other. This addition or subtraction of waves is often called interference.

Resonance

At some time during your life you probably observed someone putting his or her head into an empty barrel or other cavity and making noises varying in pitch. When that person's voice reached a certain pitch, the tone produced seemed much louder than the others. The reason for this phenomenon is that at that a certain pitch the frequency of vibrations of the voice matched the resonant (or natural) frequency of the cavity. The resonant frequency of a cavity is the frequency at which the cavity body will begin to vibrate and create sound waves. When the resonant frequency of the cavity was reached, the sound of the voice was reinforced by the sound waves created by the cavity, resulting in a louder tone.

This phenomenon occurs whenever the frequency of vibrations is the same as the natural frequency of a cavity, and is called RESONANCE.

Noise

The most complex sound wave that can be produced is noise. Noise has no tonal quality. It distracts and distorts the sound quality that was intended to be heard. NOISE is generally an unwanted disturbance caused by spurious waves originating from man-made or natural sources, such as a jet breaking the sound barrier, or thunder.

Q26. What term is used in describing the science of sound?

Q27. A sound wave that is reflected back toward the source is known as what type of sound?

Q28. What is the term for multiple reflections of sound waves?

Q29. A cavity that vibrates at its natural frequency produces a louder sound than at other frequencies. What term is used to describe this phenomenon?

Q30. What do we call a disturbance that distracts or distorts the quality of sound?

LIGHT WAVES

Technicians maintain equipment that use frequencies from one end of the electromagnetic spectrum to the other—from low-frequency radio waves to high-frequency X-rays and cosmic rays. Visible light is a small but very important part of this electromagnetic spectrum.

Most of the important terms that pertain to the behavior of waves, such as reflection, refraction, diffraction, etc., were discussed earlier in this chapter. We will now discuss how these terms are used in understanding light and light waves. The relationship between light and light waves (rays) is the same as sound and sound waves.

Light is a form of energy. It can be produced by various means (mechanical, electrical, chemical, etc.). We can see objects because the light rays they give off or reflect reach our eyes. If the object is the source of light energy, it is called luminous. If the object is not the source of light but reflects light, it is called an illuminated body.

PROPAGATION OF LIGHT

The exact nature of light is not fully understood, although scientists have been studying the subject for many centuries. Some experiments seem to show that light is composed of tiny particles, and some suggest that it is made up of waves.

One theory after another attracted the approval and acceptance of physicists. Today, some scientific phenomena can be explained only by the wave theory and others only by the particle theory. Physicists, constantly searching for some new discovery that would bring these two theories into agreement, gradually have come to accept a theory that combines the principles of the two theories.

According to the view now generally accepted, light is a form of electromagnetic radiation; that is, light and similar forms of radiation are made up of moving electric and magnetic fields. These two fields will be explained thoroughly later in this chapter.

ELECTROMAGNETIC THEORY OF LIGHT

James Clark Maxwell, a brilliant Scottish scientist Of the middle l9th century, showed, by constructing an oscillating electrical circuit, that electromagnetic waves could move through empty space. Light eventually was proved to be electromagnetic.

Current light theory says that light is made up of very small packets of electromagnetic energy called PHOTONS (the smallest unit of radiant energy). These photons move at a constant speed in the medium through which they travel. Photons move at a faster speed through a vacuum than they do in the atmosphere, and at a slower speed through water than air.

The electromagnetic energy of light is a form of electromagnetic radiation. Light and similar forms of radiation are made up of moving electric and magnetic forces and move as waves. Electromagnetic waves move in a manner similar to the waves produced by the pebble dropped in the pool of water discussed earlier in this chapter. The transverse waves of light from a light source spread out in expanding circles much like the waves in the pool. However, the waves in the pool are very slow and clumsy in comparison with light, which travels approximately 186,000 miles per second.

Light radiates from its source in all directions until absorbed or diverted by some substance (fig. 1-17). The lines drawn from the light source (a light bulb in this instance) to any point on one of these waves indicate the direction in which the waves are moving. These lines, called radii of the spheres, are formed by the waves and are called LIGHT RAYS.

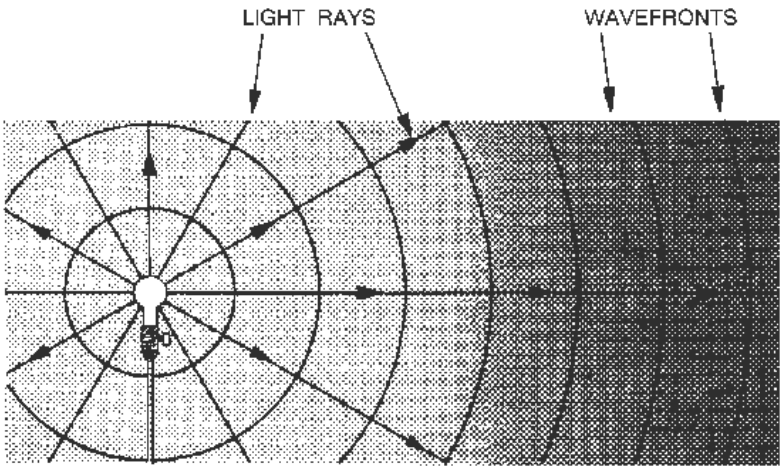

Figure 1-17.—Waves and radii from a nearby light source.

Although single rays of light do not exist, light "rays" as used in illustrations are a convenient method used to show the direction in which light is traveling at any point.

A large volume of light is called a beam; a narrow beam is called a pencil; and the smallest portion of a pencil is called a light ray. A ray of light, can be illustrated as a straight line. This straight line drawn from a light source will represent an infinite number of rays radiating in all directions from the source.

Q31. What are three means of producing light?

Q32. What is the smallest unit of radiant energy?

FREQUENCIES AND WAVELENGTHS

Compared to sound waves, the frequency of light waves is very high and the wavelength is very short. To measure these wavelengths more conveniently, a special unit of measure called an ANGSTROM UNIT, or more usually, an ANGSTROM (Å) was devised. Another common unit used to measure these waves is the millimicron (mμ), which is one millionth of a millimeter. One mF equals ten angstroms. One angstrom equals 1055^{-10}m.

Q33. What unit is used to measure the different wavelengths of light?

FREQUENCIES AND COLOR

For our discussion of light wave waves, we will use the millimicron measurement. The wavelength of a light determines the color of the light. Figure 1-18 indicates that light with a wavelength of 700 millimicrons is red, and that light with a wavelength of 500 millimicrons is blue-green. This illustration shows approximate wavelengths of the different colors in the visible spectrum. In actual fact, the color of light depends on its frequency, not its wavelength. However, light is measured in wavelengths.

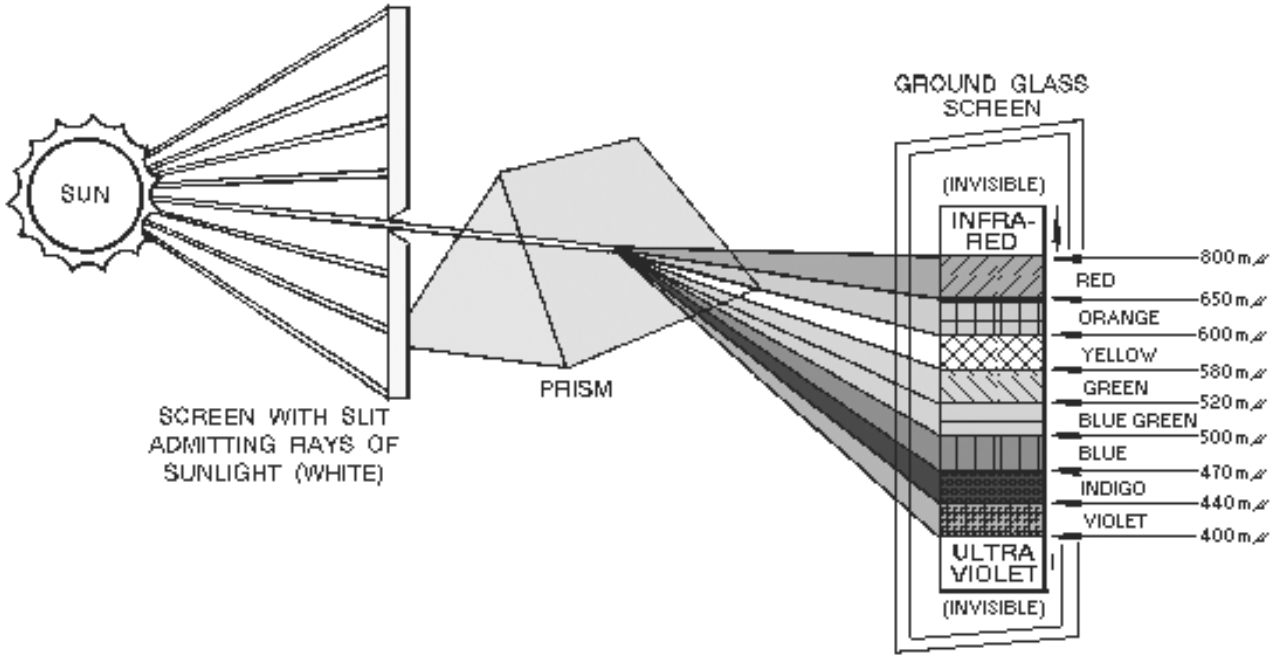

Figure 1-18.—Use of a prism to split white light into different colors.

When the wavelength of 700 millimicrons is measured in a medium such as air, it produces the color red, but the same wave measured in a different medium will have a different wavelength. When red light which has been traveling in air enters glass, it loses speed. Its wavelength becomes shorter or compressed, but it continues to be red. This illustrates that the color of light depends on frequency and not on wavelength. The color scale in figure 1-18 is based on the wavelengths in air.

When a beam of white light (sunlight) is passed through a PRISM, as shown in figure 1-18, it is refracted and dispersed (the phenomenon is known as DISPERSION) into its component wavelengths. Each of these wavelengths causes a different reaction of the eye, which sees the various colors that compose the visible spectrum. The visible spectrum is recorded as a mixture of red, orange, yellow, green, blue, indigo, and violet. White light results when the PRIMARIES (red, green, and blue) are mixed

together in overlapping beams of light. (NOTE: These are not the primaries used in mixing pigments, such as in paint.) Furthermore, the COMPLEMENTARY or SECONDARY colors (magenta, yellow, and cyan) may be shown with equal ease by mixing any two of the primary colors in overlapping beams of light. Thus, red and green light mixed in equal intensities will make yellow light; green and blue will produce cyan (blue-green light); and blue and red correctly mixed will produce magenta (a purplish red light).

LIGHT AND COLOR

All objects absorb some of the light that falls on them. An object appears to be a certain color because it absorbs all of the light waves except those whose frequency corresponds to that particular color. Those waves are reflected from the surface, strike your eye, and cause you to see the particular color. The color of an object therefore depends on the frequency of the electromagnetic wave reflected.

LUMINOUS BODIES

Certain bodies, such as the sun, a gas flame, and an electric light filament, are visible because they are light sources. They are called SELF-LUMINOUS bodies. Objects other than self-luminous bodies become visible only when they are in the presence of light from luminous bodies.

Most NONLUMINOUS bodies are visible because they diffuse or reflect the light that falls on them. A good example of a nonluminous diffusing body is the moon, which shines only because the sunlight falling onto its surface is diffused.

Black objects do not diffuse or reflect light. They are visible only when outlined against a background of light from a luminous or diffusing body.

PROPERTIES OF LIGHT

When light waves, which travel in straight lines, encounter any substance, they are either transmitted, refracted, reflected, or absorbed. This is illustrated in figure 1-19. When light strikes a substance, some absorption and some reflection always take place. No substance completely transmits, reflects, or absorbs all of the light rays that reach its surface. Substances that transmit almost all the light waves that fall upon them are said to be TRANSPARENT. A transparent substance is one through which you can see clearly. Clear glass is transparent because it transmits light rays without diffusing them (view A of figure 1-20). There is no known perfectly transparent substance, but many substances are nearly so. Substances through which some light rays can pass but through which objects cannot be seen clearly because the rays are diffused are called TRANSLUCENT (view B of figure 1-20). The frosted glass of a light bulb and a piece of oiled paper are examples of translucent materials. Substances that do not transmit any light rays are called OPAQUE (view C of figure 1-20). Opaque substances can either reflect or absorb all of the light rays that fall upon them.

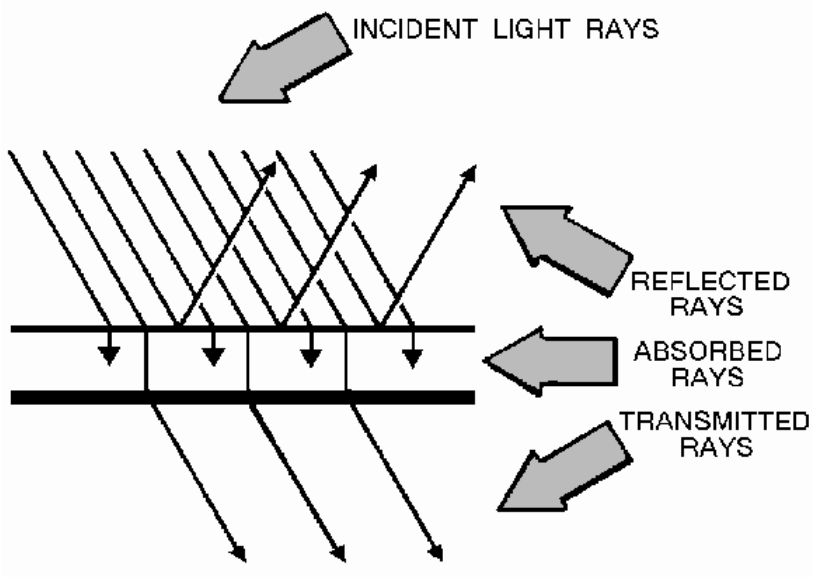

Figure 1-19.—Light waves reflected, absorbed, and transmitted.

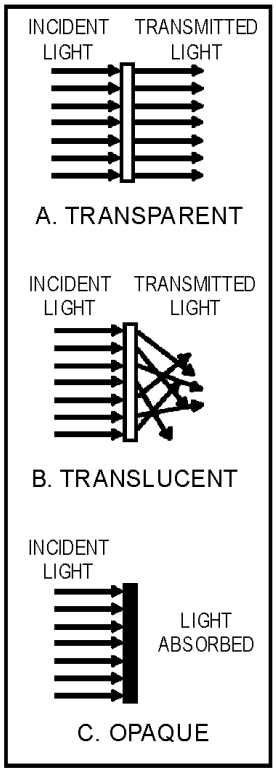

Figure 1-20.—Transparent, translucent, and opaque substances.

Q34. What are the three primary colors of light?

Q35. What are the three secondary colors of light?

Q36. White light falls upon a dull, rough, dark-brown object. Will the light primarily be reflected, diffused, or absorbed by the object?

Q37. What color will be emitted by a dull, rough, black object when white light falls upon it?

Q38. A substance that transmits light but through which an object cannot be seen clearly is known as what kind of substance?

Speed of Light

You probably have heard people say, "quick as lightning" or "fast as light" to describe rapid motion; nevertheless, it is difficult to realize how fast light actually travels. Not until recent years have scientists been able to measure accurately the speed of light.

Prior to the middle 17th century, scientists thought that light required no time at all to pass from the source to the observer. Then in 1675, Ole Roemer, a Danish astronomer, discovered that light travels approximately 186,000 miles per second in space. At this velocity, a light beam can circle the earth 7 1/2 times in one second.

The speed of light depends on the medium through which the light travels. In empty space, the speed is 186,000 (1.86×10^5) miles per second. It is almost the same in air. In water, it slows down to approximately 140,000 (1.4×10^5) miles per second. In glass, the speed of light is 124,000 (1.24×10^5) miles per second. In other words, the speed of light decreases as the density of the substance through which the light passes increases.

The velocity of light, which is the same as the velocity of other electromagnetic waves, is considered to be constant, at 186,000 miles per second. If expressed in meters, it is 300,000,000 meters per second.

Reflection of Light

Light waves obey the law of reflection in the same manner as other types of waves. Consider the straight path of a light ray admitted through a narrow slit into a darkened room. The straight path of the beam is made visible by illuminated dust particles suspended in the air. If the light beam is made to fall onto the surface of a mirror or other reflecting surface, however, the direction of the beam changes sharply. The light can be reflected in almost any direction depending on the angle at which the mirror is held.

As shown earlier in figure 1-9, if a light beam strikes a mirror, the angle at which the beam is reflected depends on the angle at which it strikes the mirror. The beam approaching the mirror is the INCIDENT or striking beam, and the beam leaving the mirror is the REFLECTED beam.

The term "reflected light" simply refers to light waves that are neither transmitted nor absorbed, but are thrown back from the surface of the medium they encounter.

You will see this application used in our discussion of radio waves (chapter 2) and antennas (chapter 4).

Q39. At what speed does light travel?

Refraction of Light

The change of direction that occurs when a ray of light passes from one transparent substance into another of different density is called refraction. Refraction is due to the fact that light travels at various

speeds in different transparent substances. For example, water never appears as deep as it really is, and objects under water appear to be closer to the surface than they really are. A bending of the light rays causes these impressions.

Another example of refraction is the apparent bending of a spoon when it is immersed in a cup of water. The bending seems to take place at the surface of the water, or exactly at the point where there is a change of density. Obviously, the spoon does not bend from the pressure of the water. The light forming the image of the spoon is bent as it passes from the water (a medium of high density) to the air (a medium of comparatively low density).

Without refraction, light waves would pass in straight lines through transparent substances without any change of direction. Refer back to figure 1-10, which shows refraction of a wave. As you can see, all rays striking the glass at any angle other than perpendicular are refracted. However, the perpendicular ray, which enters the glass normal to the surface, continues through the glass and into the air in a straight line no refraction takes place.

Diffusion of Light

When light is reflected from a mirror, the angle of reflection of each ray equals the angle of incidence. When light is reflected from a piece of plain white paper, however, the reflected beam is scattered, or DIFFUSED, as shown in figure 1-21. Because the surface of the paper is not smooth, the reflected light is broken up into many light beams that are reflected in all directions.

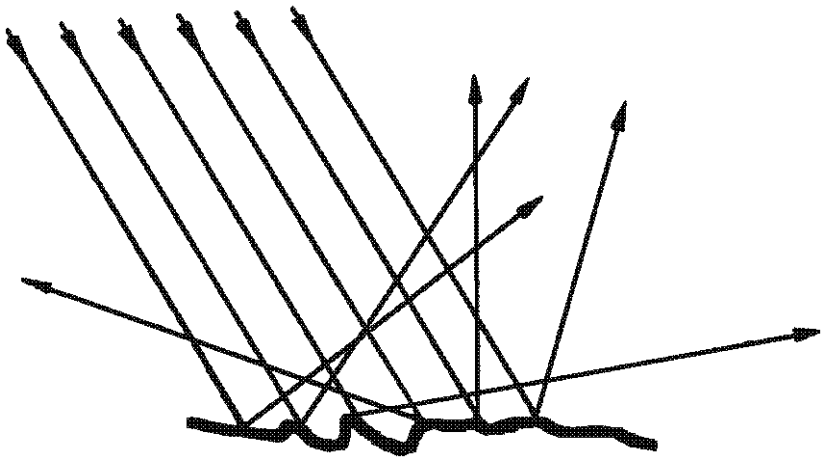

Figure 1-21.—Diffusion of light.

Absorption of Light

You have just seen that a light beam is reflected and diffused when it falls onto a piece of white paper. If a light beam falls onto a piece of black paper, the black paper absorbs most of the light rays and very little light is reflected from the paper. If the surface on which the light beam falls is perfectly black, there is no reflection; that is, the light is totally absorbed. No matter what kind of surface light falls on, however, some of the light is absorbed.

Q40. A light wave enters a sheet of glass at a perfect right angle to the surface. Is the majority of the wave reflected, refracted, transmitted, or absorbed?

Q41. When light strikes a piece of white paper, the light is reflected in all directions. What do we call this scattering of light?

COMPARISON OF LIGHT WAVES WITH SOUND WAVES

There are two main differences between sound waves and light waves. The first difference is in velocity. Sound waves travel through air at the speed of approximately 1,100 feet per second; light waves travel through air and empty space at a speed of approximately 186,000 miles per second. The second difference is that sound is composed of longitudinal waves (alternate compressions and expansions of matter) and light is composed of transverse waves in an electromagnetic field.

Although both are forms of wave motion, sound requires a solid, liquid, or gaseous medium; whereas light travels through empty space. The denser the medium, the greater the speed of sound. The opposite is true of light. Light travels approximately one-third slower in water than in air. Sound travels through all substances, but light cannot pass through opaque materials.

Frequency affects both sound and light. A certain range of sound frequencies produces sensations that you can hear. A slow vibration (low frequency) in sound gives the sensation of a low note. A more rapid sound vibration (higher frequency) produces a higher note. Likewise, a certain range of light frequencies produces sensations that you can see. Violet light is produced at the high-frequency end of the light spectrum, while red light is produced at the low-frequency end of the light spectrum. A change in frequency of sound waves causes an audible sensation—a difference in pitch. A change in the frequency of a light wave causes a visual sensation—a difference in color.

For a comparison of light waves with sound waves, see table 1-2.

Table 1-2.—Comparison of Light Waves and Sound Waves

	SOUND WAVES	LIGHT WAVES
VELOCITY IN AIR	APPROXIMATELY 1,100 FEET PER SECOND	APPROXIMATELY 186,000 MILES PER SECOND
FORM	A FORM OF WAVE MOTION	A FORM OF WAVE MOTION
WAVE COMPOSITION	LONGITUDINAL	TRANSVERSE
TRANSMITTING MEDIUM	ALL SUBSTANCES	EMPTY SPACE AND ALL SUBSTANCES EXCEPT OPAQUE MATERIALS
RELATION OF TRANSMITTING MEDIUM VELOCITY TO VELOCITY	THE DENSER THE MEDIUM, THE GREATER THE SPEED	THE DENSER THE MEDIUM, THE SLOWER THE SPEED
SENSATIONS PRODUCED	HEARING	SEEING
VARIATIONS IN SENSATIONS PRODUCED	A LOW FREQUENCY CAUSES A LOW NOTE; A HIGH FREQUENCY, A HIGH NOTE	A LOW FREQUENCY CAUSES RED LIGHT; A HIGH FREQUENCY, VIOLET LIGHT

Q42. What three examples of electromagnetic energy are mentioned in the text?

Q43. What is the main difference between the bulk of the electromagnetic spectrum and the visual spectrum?

ELECTROMAGNETIC SPECTRUM

Light is one kind of electromagnetic energy. There are many other types, including heat energy and radio energy. The only difference between the various types of electromagnetic energy is the frequency of their waves (rate of vibration). The term SPECTRUM is used to designate the entire range of electromagnetic waves arranged in order of their frequencies. The VISIBLE SPECTRUM contains only those waves which stimulate the sense of sight. You, as a technician, might be expected to maintain equipment that uses electromagnetic waves within, above, and below the visible spectrum.

There are neither sharp dividing lines nor gaps in the ELECTROMAGNETIC SPECTRUM. Figure 1-22 illustrates how portions of the electromagnetic spectrum overlap. Notice that only a small portion of the electromagnetic spectrum contains visible waves, or light, which can be seen by the human eye.

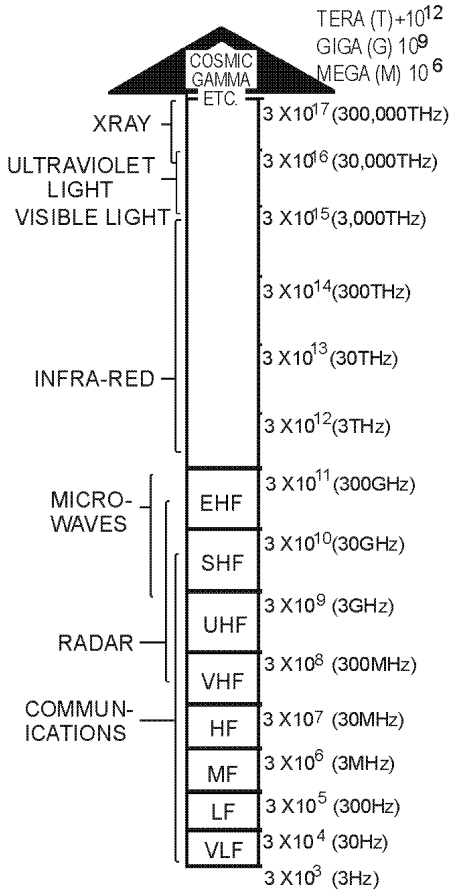

Figure 1-22.—Electromagnetic spectrum.

ELECTROMAGNETIC WAVES

In general, the same principles and properties of light waves apply to the communications electromagnetic waves you are about to study. The electromagnetic field is used to transfer energy (as communications) from point to point. We will introduce the basic ANTENNA as the propagation source of these electromagnetic waves.

THE BASIC ANTENNA

The study of antennas and electromagnetic wave propagation is essential to a complete understanding of radio communication, radar, loran, and other electronic systems. Figure 1-23 shows a simple radio communication system. In the illustration, the transmitter is an electronic device that generates radio-frequency energy. The energy travels through a transmission line (we will discuss this in chapter 3) to an antenna. The antenna converts the energy into radio waves that radiate into space from the antenna at the speed of light. The radio waves travel through the atmosphere or space until they are either reflected by an object or absorbed. If another antenna is placed in the path of the radio waves, it absorbs part of the waves and converts them to energy. This energy travels through another transmission line and is fed to a receiver. From this example, you can see that the requirements for a simple communications system are (1) transmitting equipment, (2) transmission line, (3) transmitting antenna, (4) medium, (5) receiving antenna, and (6) receiving equipment.

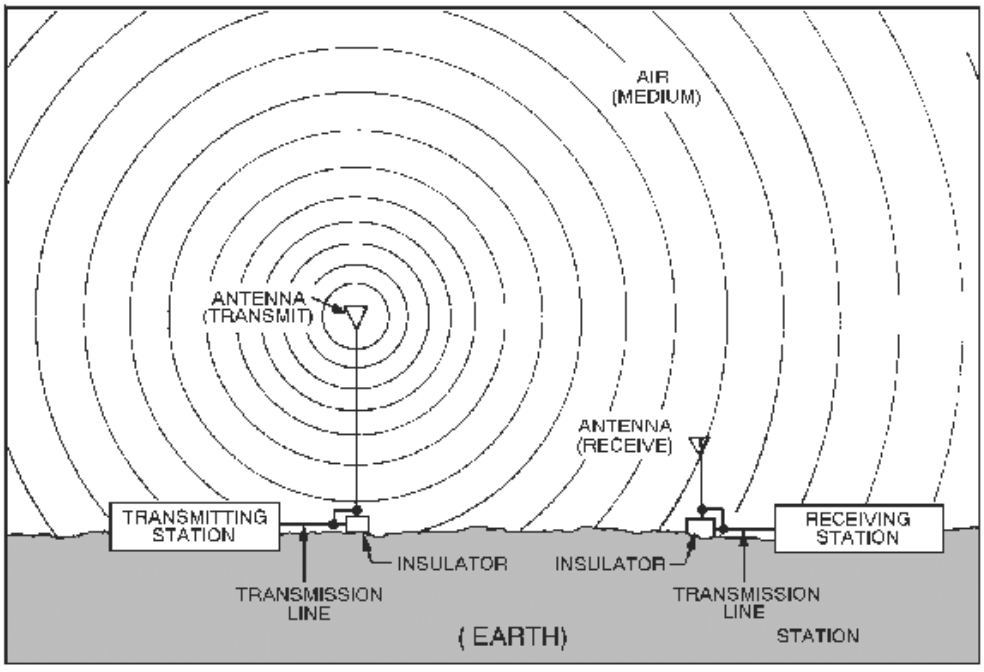

Figure 1-23.—Simple radio communication system.

An antenna is a conductor or a set of conductors used either to radiate electromagnetic energy into space or to collect this energy from space. Figure 1-24 shows an antenna. View A is a drawing of an actual antenna; view B is a cut-away view of the antenna; and view C is a simplified diagram of the antenna.

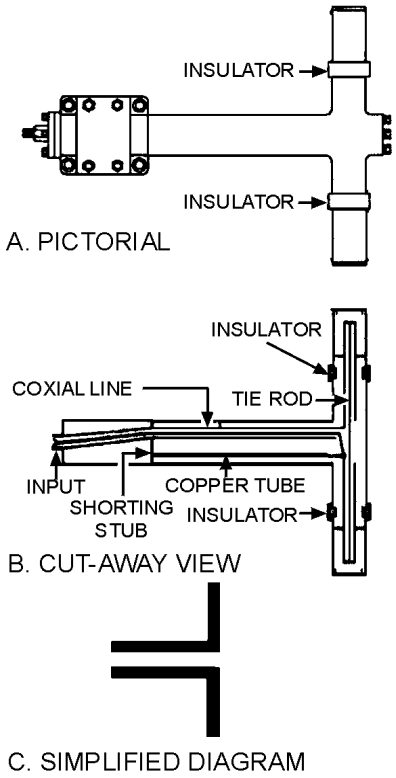

Figure 1-24.—Antenna.

COMPONENTS OF THE ELECTROMAGNETIC WAVE

An electromagnetic wave consists of two primary components—an ELECTRIC FIELD and a MAGNETIC FIELD. The electric field results from the force of voltage, and the magnetic field results from the flow of current.

Although electromagnetic fields that are radiated are commonly considered to be waves, under certain circumstances their behavior makes them appear to have some of the properties of particles. In general, however, it is easier to picture electromagnetic radiation in space as horizontal and vertical lines of force oriented at right angles to each other. These lines of force are made up of an electric field (E) and a magnetic field (H), which together make up the electromagnetic field in space.

The electric and magnetic fields radiated from an antenna form the electromagnetic field. This field is responsible for the transmission and reception of electromagnetic energy through free space. An antenna, however, is also part of the electrical circuit of a transmitter or a receiver and is equivalent to a circuit containing inductance, capacitance, and resistance. Therefore, the antenna can be expected to display definite voltage and current relationships with respect to a given input. A current through the antenna produces a magnetic field, and a charge on the antenna produces an electric field. These two fields combine to form the INDUCTION field. To help you gain a better understanding of antenna theory, we must review some basic electrical concepts. We will review voltage and its electric field, current and its magnetic field, and their relationship to propagation of electrical energy.

Q44. What are the two components (fields) that make up the electromagnetic wave?

Q45. What do we call a conductor (or set of conductors) that radiates electromagnetic energy into space?

Electric Field

Around every electrically charged object is a force field that can be detected and measured. This force field can cause electric charges to move in the field. When an object is charged electrically, there is either a greater or a smaller concentration of electrons than normal. Thus, a difference of potential exists between a charged object and an uncharged object. An electric field is, therefore, associated with a difference of potential, or a voltage.

This invisible field of force is commonly represented by lines that are drawn to show the paths along which the force acts. The lines representing the electric field are drawn in the direction that a single positive charge would normally move under the influence of that field. A large electric force is shown by a large concentration of lines; a weak force is indicated by a few lines.

When a capacitor is connected across a source of voltage, such as a battery, it is charged by a particular amount, depending on the voltage and the value of capacitance. (See figure 1-25.) Because of the emf (electromotive force) of the battery, negative charges flow to the lower plate, leaving the upper plate positively charged. Along with the growth of charge, the electric field is also building up. The flux lines are directed from the positive to the negative charges and at right angles to the plates. When the capacitor is fully charged, the voltage of the capacitor is equal to the voltage of the source and opposite in polarity. The charged capacitor stores the energy in the form of an electric field. It can be said, therefore, that an electric field indicates voltage.

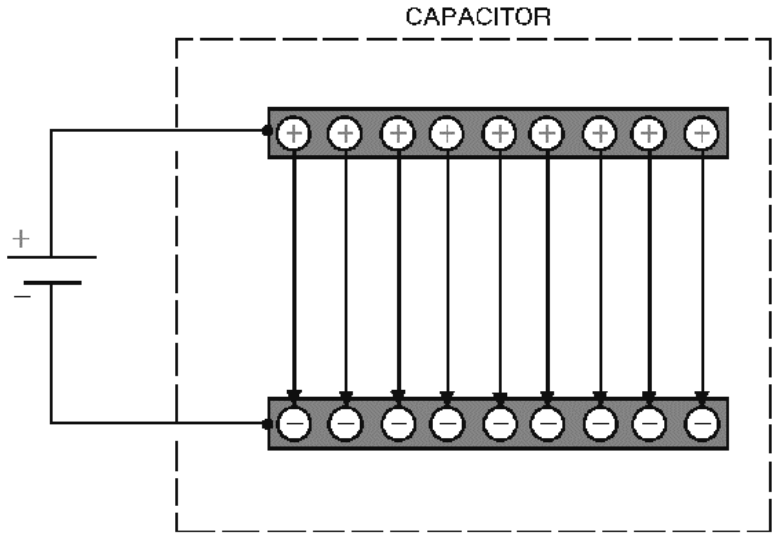

Figure 1-25.—Electric fields between plates.

If the two plates of the capacitor are spread farther apart, the electric field must curve to meet the plates at right angles (fig. 1-26). The straight lines in view A of figure 1-26 become arcs in view B, and approximately semicircles in view C, where the plates are in a straight line. Instead of flat metal plates, as in the capacitor, the two elements can take the form of metal rods or wires and form the basic antenna.

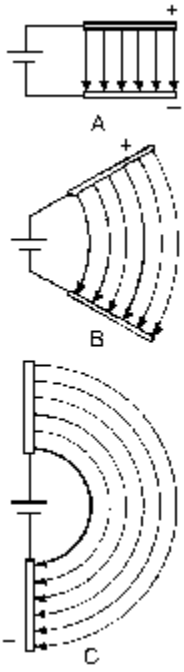

Figure 1-26.—Electric fields between plates at different angles.

In figure 1-27, two rods replace the plates of the capacitor, and the battery is replaced by an ac source generating a 60-hertz signal. On the positive alternation of the 60-hertz generator, the electric field extends from the positively charged rod to the negatively charged rod, as shown. On the negative alternation, the charge is reversed. The previous explanation of electrons moving from one plate to the other of the capacitor in figure 1-25 can also be applied to the rods in figure 1-27.

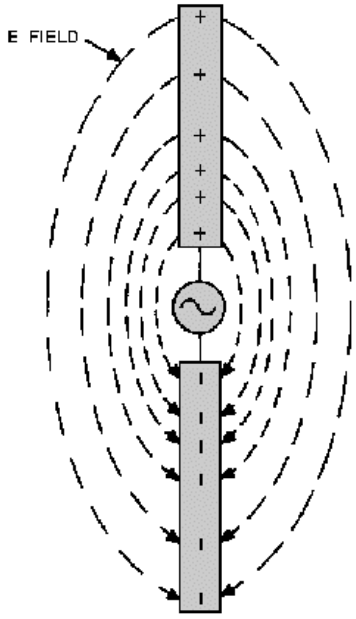

Figure 1-27.—Electric fields between elements.

The polarity of charges and the direction of the electric fields will reverse polarity and direction periodically at the frequency of the voltage source. The electric field will build up from zero to maximum in one direction and then collapse back to zero. Next, the field will build up to maximum in the opposite direction and then collapse back to zero. This complete reversal occurs during a single cycle of the source voltage. The HALF-WAVE DIPOLE ANTENNA (two separate rods in line as illustrated in figure 1-27) is the fundamental element normally used as a starting point of reference in any discussion concerning the radiation of electromagnetic energy into space. If rf energy from the ac generator (or transmitter) is supplied to the element of an antenna, the voltage across the antenna lags the current by 90 degrees. The antenna acts as if it were a capacitor.

Magnetic Field

When current flows through a conductor, a magnetic field is set up in the area surrounding the conductor. In fact, any moving electrical charge will create a magnetic field. The magnetic field is a region in space where a magnetic force can be detected and measured. There are two other fields involved—an INDUCTION FIELD, which exists close to the conductor carrying the current, and the RADIATION FIELD, which becomes detached from the current-carrying rod and travels through space.

To represent the magnetic field, lines of force are again used to illustrate the energy. Magnetic lines are not drawn between the rods, nor between high- and low-potential points, as the E lines that were discussed earlier. Magnetic lines are created by the flow of current rather than the force of voltage. The magnetic lines of force, therefore, are drawn at right angles to the direction of current flow.

The magnetic fields that are set up around two parallel rods, as shown in figure 1-28 view A, are in maximum opposition. Rod 1 contains a current flowing from the generator, while rod 2 contains a current flowing toward the generator. As a result, the direction of the magnetic field surrounding rod 1 is opposite the direction of the magnetic field surrounding rod 2. This will cause cancellation of part or all of both magnetic fields with a resultant decrease in radiation of the electromagnetic energy. View B illustrates the fact that if the far ends of rods 1 and 2 are separated from each other while the rods are still connected to the generator at the near ends, more space, and consequently less opposition, will occur between the magnetic fields of the two rods. View C illustrates the fact that placing the rods in line makes the currents through both rods flow in the same direction. Therefore, the two magnetic fields are in the same direction; thus, maximum electromagnetic radiation into space can be obtained.

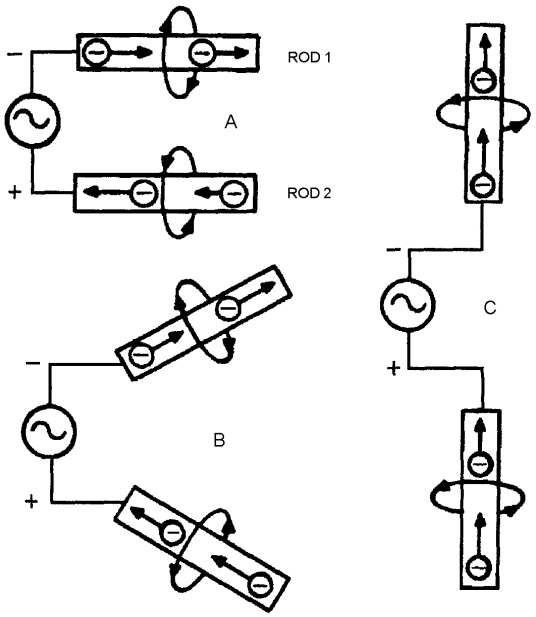

Figure 1-28.—Magnetic fields around elements.

Magnetic lines of force are indicated by the letter H and are called H lines. The direction of the magnetic lines may be determined by use of the left-hand rule for a conductor: If you grasp the conductor in your left hand with the thumb extended in the direction of the current flow, your fingers will point in the direction of the magnetic lines of force. In view C of figure 1-28, the direction of current flow is upward along both halves of the elements (conductors). The lines of magnetic force (flux) form concentric loops that are perpendicular to the direction of current flow. The arrowheads on the loops indicate the direction of the field. The left-hand rule is used to determine the direction of the magnetic field and is illustrated in figure 1-29. If the thumb of the left hand is extended in the direction of current flow and the fingers clenched, then the rough circles formed by the fingers indicate the direction of the magnetic field.

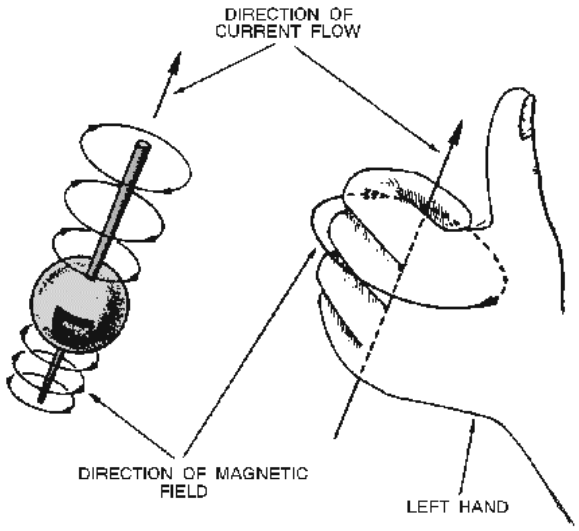

Figure 1-29.—Left-hand rule for conducting elements.

Q46. What do we call the field that is created between two rods when a voltage is applied to them?

Q47. When current flows through a conductor, a field is created around the conductor. What do we call this field?

Combined Electric and Magnetic Fields

The generator, shown in figure 1-30, provides the voltage, which creates an electric field, and current, which creates a magnetic field. This source voltage and current build up to maximum values in one direction during one half-cycle, and then build up to maximum values in the other direction during the next half-cycle. Both the electric and magnetic fields alternate from minimum through maximum values in synchronization with the changing voltage and current. The electric and magnetic fields reach their maximum intensity a quarter-cycle apart. These fields form the induction field. Since the current and voltage that produce these E and H fields are 90 degrees out of phase.

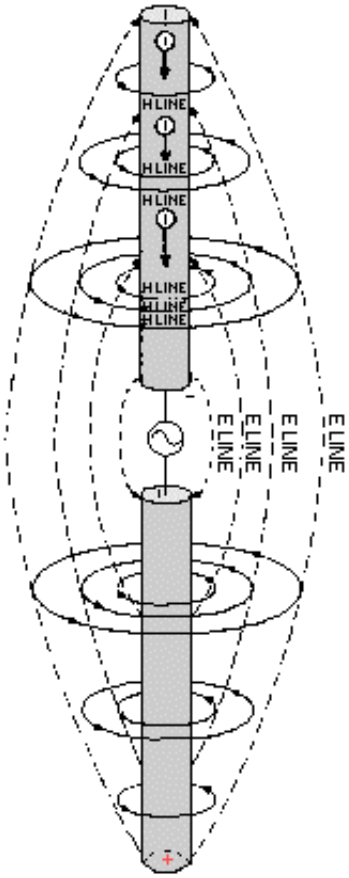

Figure 1-30.—Relationship of E-lines, and current flow.

Q48. An induction field is created around a conductor when current flows through it. What do we call the field that detaches itself from the conductor and travels through space?

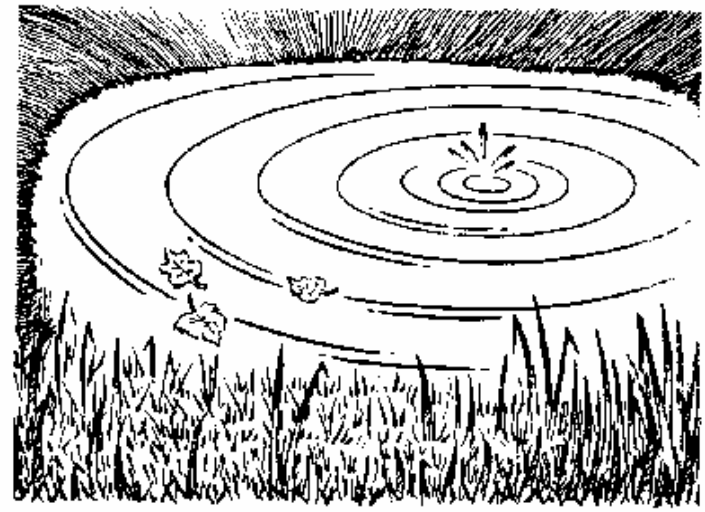
SUMMARY

Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas you have learned. You should have a thorough understanding of these principles before moving on to chapter 2.

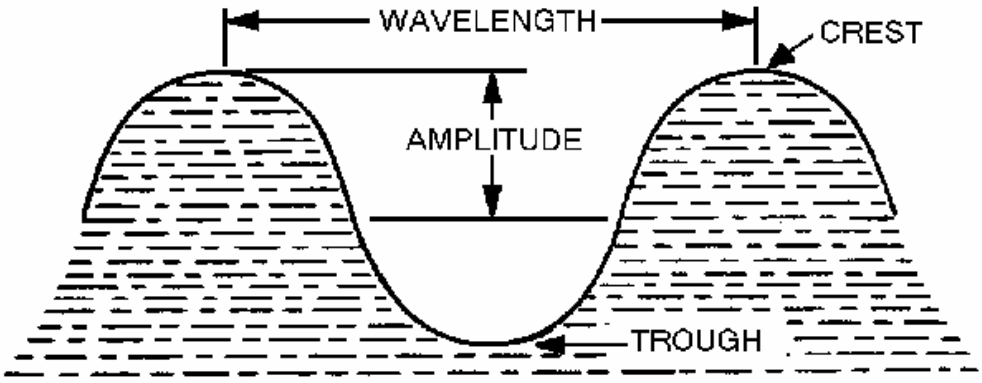
WAVE PROPAGATION is an invisible force that enables man to communicate over long distances. Wave transmission can take many forms, such as **LIGHT**, **SOUND**, and **RADIO**.

LIGHT is a form of wave motion that can be seen. Heat cannot normally be seen, but can be felt. Radio waves cannot be seen or felt.

WAVE MOTION can be seen in action by throwing a pebble into a pool of still water. The ripples that move toward the edge of the pool demonstrate the **PROPAGATION** theory.

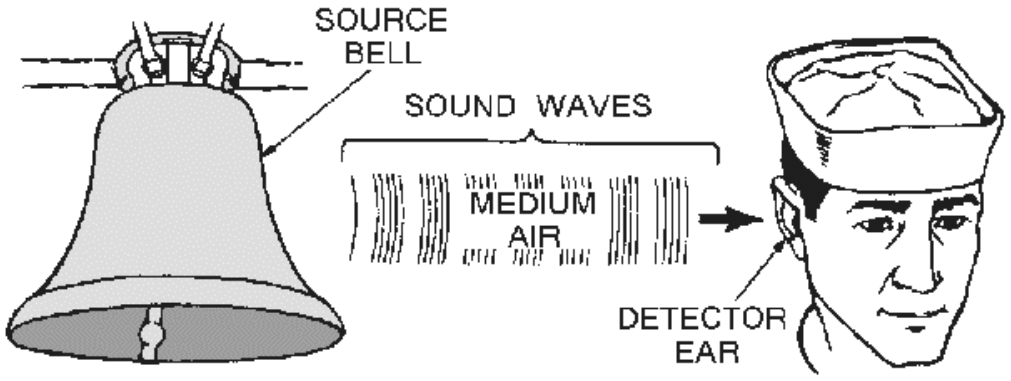


The **TRANSVERSE WAVE** is a type of wave motion. Radio, light, and heat waves are examples of transverse waves.



The **LONGITUDINAL WAVE** is another type of wave motion. The sound wave is the only example of a longitudinal wave given in this text.

SOURCE, MEDIUM, AND DETECTOR (RECEIVER) are the three requirements for all wave motion.



A **SOURCE** can be anything that emits or expends energy (waves).

The **MEDIUM** is the vehicle for carrying waves from one point to another. Water, air, metal, empty space, etc., are examples of a medium. Empty space is considered a medium for electro-magnetic waves but not a medium for sound waves.

The **SOUND DETECTOR** absorbs the waves emitted by the source. The human ear is an example of a detector.

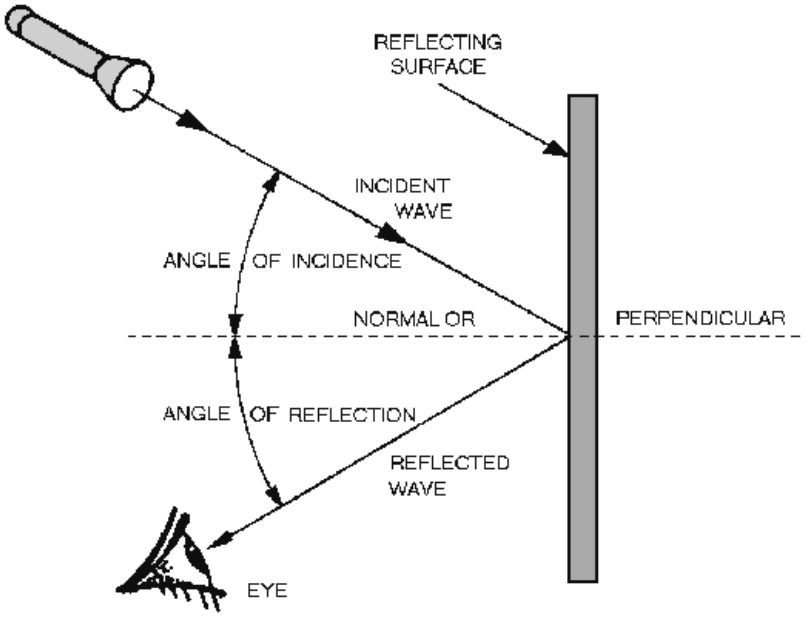
HERTZ, which is abbreviated **Hz**, is used in lieu of "cycle per second" when referring to radio frequencies.

VELOCITY OF PROPAGATION is the speed (or rate) at which the crest of a wave moves through a medium. Velocity can be calculated by using the formula:

$$V = \lambda f$$

Where v is velocity of propagation and is expressed in feet (meters) per second, λ is the wavelength in feet (meters), and f is the frequency in hertz.

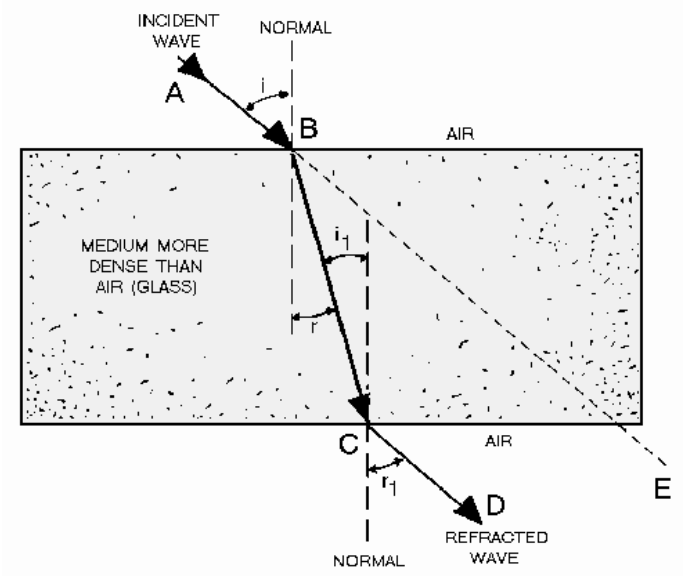
REFLECTION occurs when a wave strikes an object and bounces back (toward the source). The wave that moves from the source to the object is called the **INCIDENT WAVE**, and the wave that moves away from the object is called the **REFLECTED WAVE**.



The **LAW OF REFLECTION** states:

The angle of incidence is equal to the angle of reflection.

REFRACTION occurs when a wave traveling through two different mediums passes through the **BOUNDARY** of the mediums and bends toward or away from the **NORMAL**.



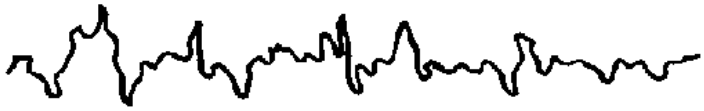
DIFFRACTION can account for the ability of the AM radio waves (due to their low frequency) to travel over a mountain, while FM and TV signals (due to their higher frequencies) are blocked.

The **DOPPLER EFFECT** is the apparent change in frequency of a source as it moves toward or away from a detector. It can affect the operation of equipment used to detect and measure wave energy.

SOUND can be audible to the human ear or it can be outside the hearing range.

NOISE AND TONES are the two general groups that broadly classify ALL sounds.

A MUSICAL NOTE



B NOISE

PITCH, INTENSITY, AND QUALITY are the three basic characteristics of sound. Pitch describes the frequency of sound. Intensity describes how much energy is transmitted. Quality enables us to distinguish one sound from another.

The **DENSITY** of a **MEDIUM**, **TEMPERATURE**, and **ATMOSPHERIC PRESSURE** affect the velocity of sound. If temperature, density, or pressure increases, the velocity of sound increases and vice versa.

ACOUSTICS is the science of sound and relates to the sense of hearing.

ECHO is an example of reflection. Sound echoes are used in sonar and depth finders to determine or measure the range of an object or the depth of the ocean bottom.

REVERBERATION is the multiple reflections of sound waves. The prolonged roar of thunder is caused by reverberations. With underwater sound equipment, reverberations of nearby objects may interfere with returning echoes from actual targets.

INTERFERENCE occurs when two waves move simultaneously through a medium. They can interfere constructively, destructively, or produce a resultant of zero.

RESONANCE occurs when an objects vibrates (or resonates) at its natural frequency. When different frequencies are produced inside a cavity, the sound from the cavity sounds louder at its resonant frequency than at all other frequencies.

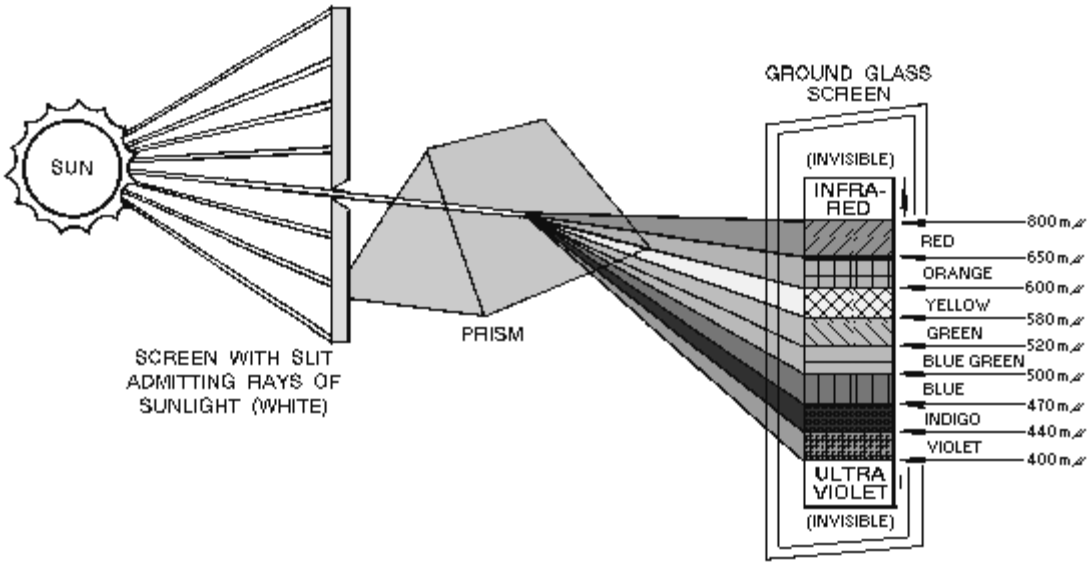
NOISE is any disturbance that distracts from or distorts the quality of sound.

A **PHOTON** is the smallest unit of radiant energy that makes up light waves and radio waves.

ANGSTROM (Å) units are used for measuring the wavelength of light. One angstrom = 1055^{-10} m.

The **VISIBLE SPECTRUM** contains all the colors between infrared and ultraviolet. **INFRA-RED** and **ULTRA-VIOLET** are invisible to the human eye.

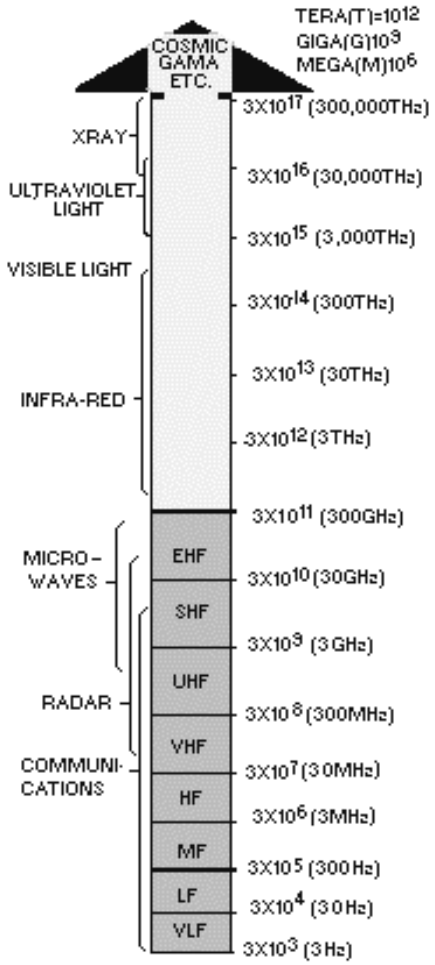
The **PRIMARY COLORS** of light are red, green, and blue. These primaries can be mixed to make any color between red and violet. If the three colors are mixed equally, they produce white light.



The **COMPLEMENTARY COLORS** of light are magenta, yellow, and cyan. They are produced by mixing any two of the primary colors together in overlapping beams.

The **SPEED OF LIGHT** in empty space is considered to be 186,000 miles per second (or 300,000,000 meters per second). This speed varies in different mediums, but the constant of 186,000 miles per second is always used as the speed of light.

The **ELECTROMAGNETIC SPECTRUM** is the complete range of electromagnetic frequencies from 3 kHz to beyond 300,000 THz. Audio frequencies (15 Hz-20 kHz) are not electromagnetic energy and are not included in the electromagnetic spectrum.



The **ELECTROMAGNETIC FIELD** consists of an **ELECTRIC FIELD** and a **MAGNETIC FIELD**. These fields are responsible for the transmission and reception of electromagnetic energy through free space.

ANSWERS TO QUESTIONS Q1. THROUGH Q48.

A1. Propagation means spreading out.

A2. A wave is a disturbance which moves through a medium.

A3. A means of transferring energy from one place to another.

A4. Sound waves, light waves, radio waves, heat waves, water waves.

A5. Transverse waves.

A6. Radio waves, light waves, and heat waves.

A7. A sound wave.

A8. A source, medium, and detector (receiver).

A9. A sequence of events, such as the positive and negative alternation of electrical current.

A10. The space occupied by one cycle of a radio wave at any given instant.

A11. The law of reflection states: The angle of incidence is equal to the angle of reflection.

A12. When the incident wave is nearly parallel with the surface.

A13. When the incident wave is perpendicular to the surface. Also a dull (or black) surface reflects very little regardless of the angle.

A14. The density of the two mediums, and the velocity of the waves.

A15. The Doppler effect.

A16. Sonics.

A17. No. The average human ear cannot hear all sounds in the infrasonic and ultrasonic regions.

A18. An amplifier.

A19. A source, medium, and detector (receiver).

A20. Noise and tones.

A21. Pitch, intensity, and quality.

A22. 20 Hz to 20 kHz.

A23. The amount of energy transmitted from a source.

A24. Quality.

A25. Velocity increases as density decreases and temperature increases.

A26. Acoustics.

A27. Echo.

A28. Reverberation.

A29. Resonance.

A30. Noise.

A31. Mechanical, electrical, and chemical.

A32. A photon.

A33. Angstrom unit.

A34. Red, green and blue.

CHAPTER 2

RADIO WAVE PROPAGATION

LEARNING OBJECTIVES

Upon completion of this unit, you should be able to:

1. State what the electromagnetic field is and what components make up the electromagnetic field.
2. State the difference between the induction field and the radiation field.
3. State what radio waves are.
4. List the components of a radio wave and define the terms cycle, frequency, harmonics, period, wavelength, and velocity as applied to radio wave propagation.
5. Compute the wavelength of radio waves.
6. State how radio waves are polarized, vertically and horizontally.
7. State what reflection, refraction, and diffraction are as applied to radio waves.
8. State what influence the Earth's atmosphere has on radio waves and list the different layers of the Earth's atmosphere.
9. Identify a ground wave, a sky wave, and state the effects of the ionosphere on the sky wave.
10. Identify the structure of the ionosphere.
11. Define density of layer, frequency, angle of incidence, skip distance, and skip zone.
12. Describe propagation paths.
13. Describe fading, multipath fading, and selective fading. Describe propagation paths.
14. State how transmission losses affect radio wave propagation.
15. State how electromagnetic interference, man-made/natural interference, and ionospheric disturbances affect radio wave propagation. State how transmission losses affect radio wave propagation.
16. Identify variations in the ionosphere.
17. Identify the maximum, optimum, and lowest usable frequencies of radio waves.
18. State what temperature inversion is, how frequency predictions are made, and how weather affects frequency.
19. State what tropospheric scatter is and how it affects radio wave propagation.

ELECTROMAGNETIC FIELDS

The way energy is propagated into free space is a source of great dispute among people concerned with it. Although many theories have been proposed, the following theory adequately explains the phenomena and has been widely accepted. There are two basic fields associated with every antenna; an INDUCTION FIELD and a RADIATION FIELD. The field associated with the energy stored in the antenna is the induction field. This field is said to provide no part in the transmission of electromagnetic energy through free space. However, without the presence of the induction field, there would be no energy radiated.

INDUCTION FIELD

Figure 2-1, a low-frequency generator connected to an antenna, will help you understand how the induction field is produced. Let's follow the generator through one cycle of operation.

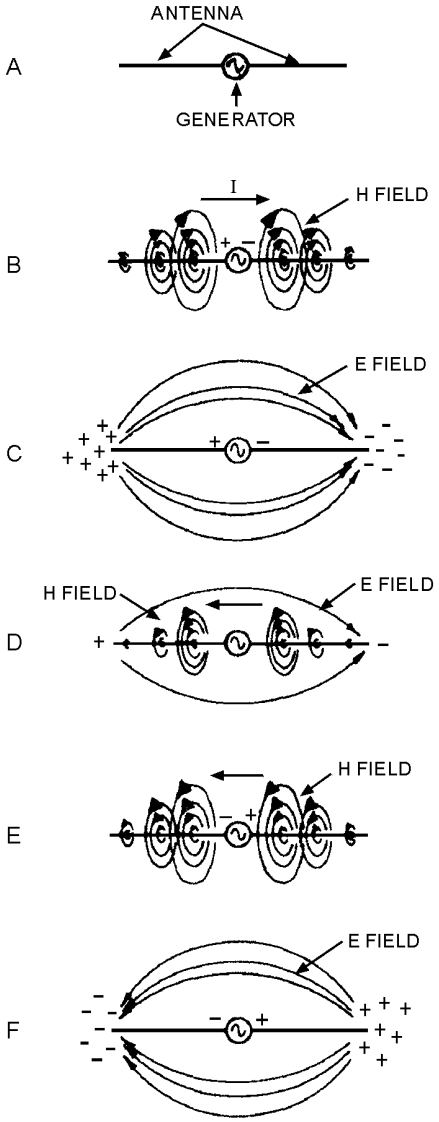


Figure 2-1.—Induction field about an antenna.

Initially, you can consider that the generator output is zero and that no fields exist about the antenna, as shown in view A. Now assume that the generator produces a slight potential and has the instantaneous polarity shown in view B. Because of this slight potential, the antenna capacitance acts as a short, allowing a large flow of current (I) through the antenna in the direction shown. This current flow, in turn, produces a large magnetic field about the antenna. Since the flow of current at each end of the antenna is minimum, the corresponding magnetic fields at each end of the antenna are also minimum. As time passes, charges, which oppose antenna current and produce an electrostatic field (E field), collect at each end of the antenna. Eventually, the antenna capacitance becomes fully charged and stops current flow through the antenna. Under this condition, the electrostatic field is maximum, and the magnetic field (H field) is fully collapsed, as shown in view C.

As the generator potential decreases back to zero, the potential of the antenna begins to discharge. During the discharging process, the electrostatic field collapses and the direction of current flow reverses, as shown in view D. When the current again begins to flow, an associated magnetic field is generated. Eventually, the electrostatic field completely collapses, the generator potential reverses, and current is maximum, as shown in view E. As charges collect at each end of the antenna, an electrostatic field is produced and current flow decreases. This causes the magnetic field to begin collapsing. The collapsing magnetic field produces more current flow, a greater accumulation of charge, and a greater electrostatic field. The antenna gradually reaches the condition shown in view F, where current is zero and the collected charges are maximum.

As the generator potential again decreases toward zero, the antenna begins to discharge and the electrostatic field begins to collapse. When the generator potential reaches zero, discharge current is maximum and the associated magnetic field is maximum. A brief time later, generator potential reverses, and the condition shown in view B recurs.

NOTE: The electric field (E field) and the electrostatic field (E field) are the same. They will be used interchangeably throughout this text.

The graph shown in figure 2-2 shows the relationship between the magnetic (H) field and the electric (E) field plotted against time. Note that the two fields are 90 degrees out of phase with each other. If you compare the graph in figure 2-2 with figure 2-1, you will notice that the two fields around the antenna are displaced 90 degrees from each other in space. (The H field exists in a plane perpendicular to the antenna. The E field exists in a plane parallel with the antenna, as shown in figure 2-1.)

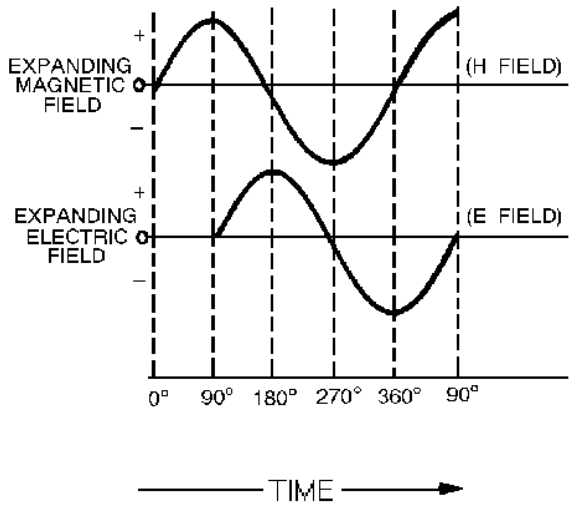

Figure 2-2.—Phase relationship of induction field components.

All the energy supplied to the induction field is returned to the antenna by the collapsing E and H fields. No energy from the induction field is radiated from the antenna. Therefore, the induction field is considered a local field and plays no part in the transmission of electromagnetic energy. The induction field represents only the stored energy in the antenna and is responsible only for the resonant effects that the antenna reflects to the generator.

RADIATION FIELDS

The E and H fields that are set up in the transfer of energy through space are known collectively as the radiation field. This radiation field is responsible for electromagnetic radiation from the antenna. The radiation field decreases as the distance from the antenna is increased. Because the decrease is linear, the radiation field reaches great distances from the antenna.

Let's look at a half-wave antenna to illustrate how this radiation actually takes place. Simply stated, a half-wave antenna is one that has an electrical length equal to half the wavelength of the signal being transmitted. Assume, for example, that a transmitter is operating at 30 megahertz. If a half-wave antenna is used with the transmitter, the antenna's electrical length would have to be at least 16 feet long. (The formula used to compute the electrical length of an antenna will be explained in chapter 4.) When power is delivered to the half-wave antenna, both an induction field and a radiation field are set up by the fluctuating energy. At the antenna, the intensities of these fields are proportional to the amount of power delivered to the antenna from a source such as a transmitter. At a short distance from the antenna and beyond, only the radiation field exists. This radiation field is made up of an electric component and a magnetic component at right angles to each other in space and varying together in intensity.

With a high-frequency generator (a transmitter) connected to the antenna, the induction field is produced as described in the previous section. However, the generator potential reverses before the electrostatic field has had time to collapse completely. The reversed generator potential neutralizes the remaining antenna charges, leaving a resultant E field in space.

Figure 2-3 is a simple picture of an E field detaching itself from an antenna. (The H field will not be considered, although it is present.) In view A the voltage is maximum and the electric field has maximum intensity. The lines of force begin at the end of the antenna that is positively charged and extend to the end of the antenna that is negatively charged. Note that the outer E lines are stretched away from the inner lines. This is because of the repelling force that takes place between lines of force in the same direction. As the voltage drops (view B), the separated charges come together, and the ends of the lines move toward the center of the antenna. But, since lines of force in the same direction repel each other, the centers of the lines are still being held out.

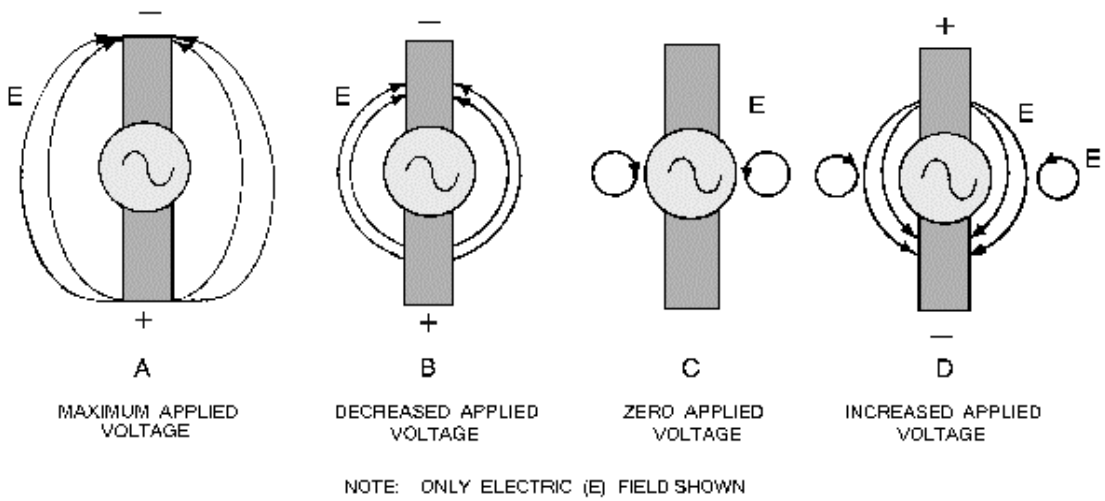

Figure 2-3.—Radiation from an antenna.

As the voltage approaches zero (view B), some of the lines collapse back into the antenna. At the same time, the ends of other lines begin to come together to form a complete loop. Notice the direction of these lines of force next to the antenna in view C. At this point the voltage on the antenna is zero. As the charge starts to build up in the opposite direction (view D), electric lines of force again begin at the positive end of the antenna and stretch to the negative end of the antenna. These lines of force, being in the same direction as the sides of the closed loops next to the antenna, repel the closed loops and force them out into space at the speed of light. As these loops travel through space, they generate a magnetic field in phase with them.

Since each successive E field is generated with a polarity that is opposite the preceding E field (that is, the lines of force are opposite), an oscillating electric field is produced along the path of travel. When an electric field oscillates, a magnetic field having an intensity that varies directly with that of the E field is produced. The variations in magnetic field intensity, in turn, produce another E field. Thus, the two varying fields sustain each other, resulting in electromagnetic wave propagation.

During this radiation process, the E and H fields are in phase in time but physically displaced 90 degrees in space. Thus, the varying magnetic field produces a varying electric field; and the varying electric field, in turn, sustains the varying magnetic field. Each field supports the other, and neither can be propagated by itself. Figure 2-4 shows a comparison between the induction field and the radiation field.

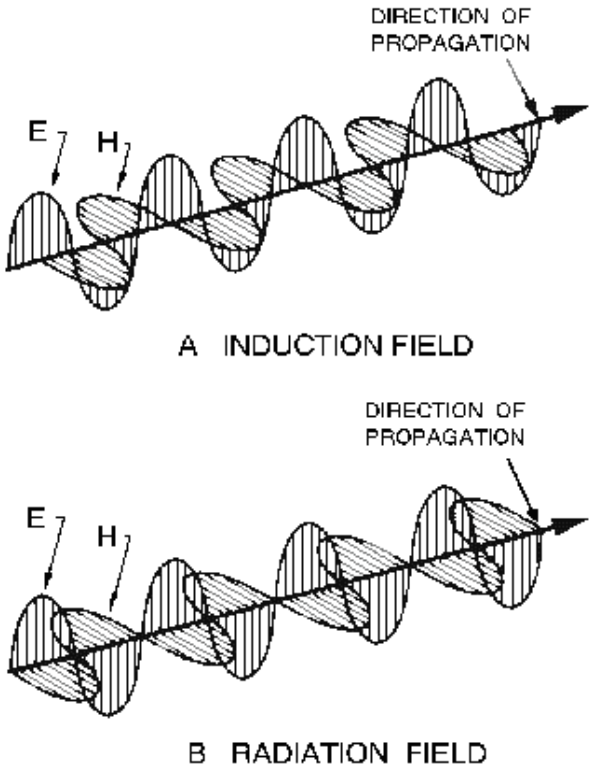

Figure 2-4.—E and H components of induction and radiation fields.

Q1. Which two composite fields (composed of E and H fields) are associated with every antenna?

Q2. What composite field (composed of E and H fields) is found stored in the antenna?

Q3. What composite field (composed of E and H fields) is propagated into free space?

RADIO WAVES

An energy wave generated by a transmitter is called a RADIO WAVE. The radio wave radiated into space by the transmitting antenna is a very complex form of energy containing both electric and magnetic fields. Because of this combination of fields, radio waves are also referred to as ELECTROMAGNETIC RADIATION.

This discussion will explain the Earth's atmosphere and its effect on radio waves. All the principles of wave motion that were discussed in chapter 1 also apply to radio waves.

NOTE: The term *radio wave* is not limited to communications equipment alone. The term applies to all equipment that generate signals in the form of electromagnetic energy.

COMPONENTS OF RADIO WAVES

The basic shape of the wave generated by a transmitter is that of a sine wave. The wave radiated out into space, however, may or may not retain the characteristics of the sine wave.

A sine wave can be one cycle or many cycles. Recall from chapter 1 that the number of cycles of a sine wave that are completed in 1 second is known as the *frequency* of the sine wave. For example, 60 cycles of ordinary house current occur each second, so house current is said to have a frequency of 60 cycles per second or 60 hertz.

The frequencies falling between 3000 hertz (3 kHz) and 300,000,000,000 hertz (300 GHz) are called RADIO FREQUENCIES (abbreviated rf) since they are commonly used in radio communications. This part of the radio frequency spectrum is divided into bands, each band being 10 times higher in frequency than the one immediately below it. This arrangement serves as a convenient way to remember the range of each band. The rf bands are shown in table 2-1. The usable radio-frequency range is roughly 10 kilohertz to 100 gigahertz.

Table 2-1.—Radio Frequency Bands

DESCRIPTION	ABBREVIATION	FREQUENCY
Very low	VLF	3 to 30 KHz
Low	LF	30 to 300 KHz
Medium	MF	300 to 3000 KHz
High	HF	3 to 30 MHz
Very high	VHF	30 to 300 MHz
Ultrahigh	UHF	300 to 3000 MHz
Super high	SHF	3 to 30 GHz
Extremely high	EHF	30 to 300 GHz

Any frequency that is a whole number multiple of a smaller basic frequency is known as a HARMONIC of that basic frequency. The basic frequency itself is called the first harmonic or, more commonly, the FUNDAMENTAL FREQUENCY. A frequency that is twice as great as the fundamental frequency is called the second harmonic; a frequency three times as great is the third harmonic; and so on. For example:

First harmonic (Fundamental frequency)	3000 kHz
Second harmonic	6000 kHz
Third harmonic	9000 kHz

The PERIOD of a radio wave is simply the amount of time required for the completion of one full cycle. If a sine wave has a frequency of 2 hertz, each cycle has a duration, or period, of one-half second. If the frequency is 10 hertz, the period of each cycle is one-tenth of a second. Since the frequency of a radio wave is the number of cycles that are completed in one second, you should be able to see that as the frequency of a radio wave increases, its period decreases.

A wavelength is the space occupied by one full cycle of a radio wave at any given instant. Wavelengths are expressed in meters (1 meter is equal to 3.28 feet). You need to have a good understanding of frequency and wavelength to be able to select the proper antenna(s) for use in successful

communications. The relationship between frequency, wavelength, and antennas will be discussed in chapter 4 of this module.

The velocity (or speed) of a radio wave radiated into free space by a transmitting antenna is equal to the speed of light—186,000 miles per second or 300,000,000 meters per second. Because of various factors, such as barometric pressure, humidity, molecular content, etc., radio waves travel inside the Earth's atmosphere at a speed slightly less than the speed of light. Normally, in discussions of the velocity of radio waves, the velocity referred to is the speed at which radio waves travel in free space.

The frequency of a radio wave has nothing to do with its velocity. A 5-megahertz wave travels through space at the same velocity as a 10-megahertz wave. However, the velocity of radio waves is an important factor in making wavelength-to-frequency conversions, the subject of our next discussion.

Q4. What is the term used to describe the basic frequency of a radio wave?

Q5. What is the term used to describe a whole number multiple of the basic frequency of a radio wave?

WAVELENGTH-TO-FREQUENCY CONVERSIONS

Radio waves are often referred to by their wavelength in meters rather than by frequency. For example, most people have heard commercial radio stations make announcements similar to the following: "Station WXYZ operating on 240 meters..." To tune receiving equipment that is calibrated by frequency to such a station, you must first convert the designated wavelength to its equivalent frequency.

As discussed earlier, a radio wave travels 300,000,000 meters a second (speed of light); therefore, a radio wave of 1 hertz would have traveled a distance (or wavelength) of 300,000,000 meters. Obviously then, if the frequency of the wave is increased to 2 hertz, the wavelength will be cut in half to 150,000,000 meters. This illustrates the principle that the HIGHER THE FREQUENCY, the SHORTER THE WAVELENGTH.

Wavelength-to-frequency conversions of radio waves are really quite simple because wavelength and frequency are reciprocals: Either one divided into the velocity of a radio wave yields the other. Remember, the formula for wavelength is:

$$\lambda = \frac{v}{f} \quad \text{or} \quad f = \frac{v}{\lambda}$$

Where:

λ = wavelength in meters

v = velocity of radio wave (speed of light)

f = frequency of radio wave (in Hz, kHz or Mhz)

The wavelength in meters divided into 300,000,000 yields the frequency of a radio wave in hertz. Likewise, the wavelength divided into 300,000 yields the frequency of a radio wave in kilohertz, and the wavelength divided into 300 yields the frequency in megahertz.

Now, let us apply the formula to determine the frequency to which the receiving equipment must be tuned to receive station WXYZ operating on 240 meters. Radio wave frequencies are normally expressed in kilohertz or megahertz.

To find the frequency in hertz, use the formula:

$$f = \frac{v}{\lambda}$$

Given:

$v = 300{,}000{,}000$ meters per second

$\lambda = 240$ meters

Solution:

$$f = \frac{300{,}000{,}000 \text{ meters per second}}{240 \text{ meters}}$$

$f = 1{,}250{,}000$ Hz

To find the frequency in kilohertz, use the formula:

$$f_{[kHz]} = \frac{300{,}000}{\lambda}$$

Given:

$\lambda = 240$ meters

Solution:

$$f_{[kHz]} = \frac{300{,}000}{240 \text{ meters}}$$

$f = 1250$kHz

To find the frequency in megahertz, use the formula:

$$f_{[MHz]} = \frac{300}{\lambda}$$

Given:

$\lambda = 240$ meters

Solution:

$$f_{[MHz]} = \frac{300}{240 \text{ meters}}$$

$f = 1.25$MHz

Q6. It is known that WWV operates on a frequency of 10 megahertz. What is the wavelength of WWV?

Q7. A station is known to operate at 60-meters. What is the frequency of the unknown station?

POLARIZATION

For maximum absorption of energy from the electromagnetic fields, the receiving antenna must be located in the plane of polarization. This places the conductor of the antenna at right angles to the magnetic lines of force moving through the antenna and parallel to the electric lines, causing maximum induction.

Normally, the plane of polarization of a radio wave is the plane in which the E field propagates with respect to the Earth. If the E field component of the radiated wave travels in a plane perpendicular to the Earth's surface (vertical), the radiation is said to be VERTICALLY POLARIZED, as shown in figure 2-5, view A. If the E field propagates in a plane parallel to the Earth's surface (horizontal), the radiation is said to be HORIZONTALLY POLARIZED, as shown in view B.

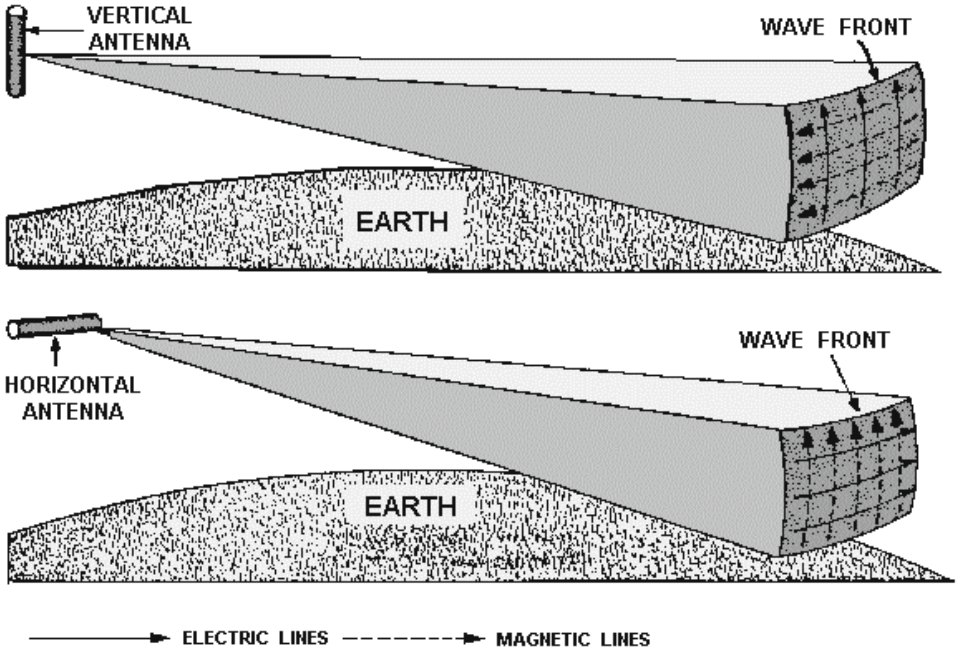

Figure 2-5.—Vertical and horizontal polarization.

The position of the antenna in space is important because it affects the polarization of the electromagnetic wave. When the transmitting antenna is close to the ground, vertically polarized waves cause a greater signal strength along the Earth's surface. On the other hand, antennas high above the ground should be horizontally polarized to get the greatest possible signal strength to the Earth's surface. Vertically and horizontally polarized antennas will be discussed in more detail in chapter 4.

The radiated energy from an antenna is in the form of an expanding sphere. Any small section of this sphere is perpendicular to the direction the energy travels and is called a WAVEFRONT. All energy on a wavefront is in phase. Usually all points on the wavefront are at equal distances from the antenna. The farther the wavefront is from the antenna, the less spherical the wave appears. At a considerable distance the wavefront can be considered as a plane surface at a right angle to the direction of propagation.

If you know the directions of the E and H components, you can use the "right-hand rule" (see figure 2-6) to determine the direction of wave propagation. This rule states that if the thumb, forefinger, and middle finger of the right hand are extended so they are mutually perpendicular, the middle finger will point in the direction of wave propagation if the thumb points in the direction of the E field and the forefinger points in the direction of the H field. Since both the E and H fields reverse directions simultaneously, propagation of a particular wavefront is always in the same direction (away from the antenna).

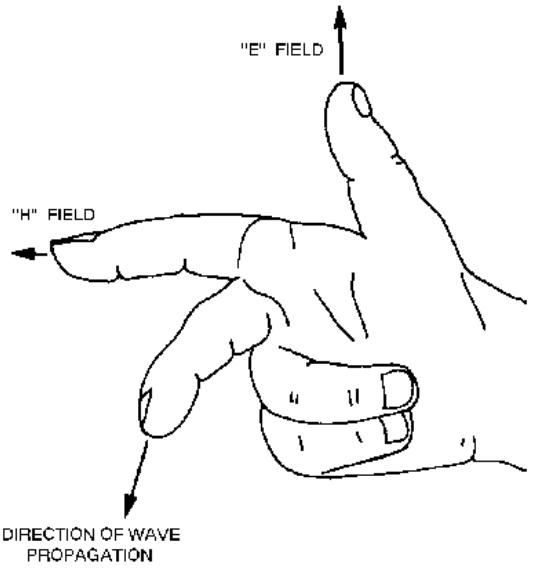

Figure 2-6.—Right-hand rule for propagation.

Q8. If a transmitting antenna is placed close to the ground, how should the antenna be polarized to give the greatest signal strength?

Q9. In the right-hand rule for propagation, the thumb points in the direction of the E field and the forefinger points in the direction of the H field. In what direction does the middle finger point?

ATMOSPHERIC PROPAGATION

Within the atmosphere, radio waves can be reflected, refracted, and diffracted like light and heat waves.

Reflection

Radio waves may be reflected from various substances or objects they meet during travel between the transmitting and receiving sites. The amount of reflection depends on the reflecting material. Smooth metal surfaces of good electrical conductivity are efficient reflectors of radio waves. The surface of the Earth itself is a fairly good reflector. The radio wave is not reflected from a single point on the reflector but rather from an area on its surface. The size of the area required for reflection to take place depends on the wavelength of the radio wave and the angle at which the wave strikes the reflecting substance.

When radio waves are reflected from flat surfaces, a phase shift in the alternations of the wave occurs. Figure 2-7 shows two radio waves being reflected from the Earth's surface. Notice that the positive and negative alternations of radio waves (A) and (B) are in phase with each other in their paths toward the Earth's surface. After reflection takes place, however, the waves are approximately 180 degrees out of phase from their initial relationship. The amount of phase shift that occurs is not constant.

It depends on the polarization of the wave and the angle at which the wave strikes the reflecting surface. Radio waves that keep their phase relationships after reflection normally produce a stronger signal at the receiving site. Those that are received out of phase produce a weak or fading signal. The shifting in the phase relationships of reflected radio waves is one of the major reasons for fading. Fading will be discussed in more detail later in this chapter.

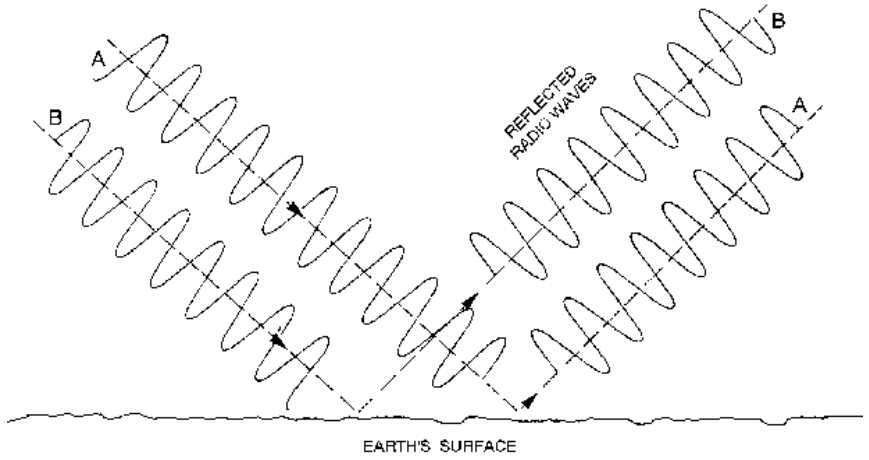

Figure 2-7.—Phase shift of reflected radio waves.

Refraction

Another phenomenon common to most radio waves is the bending of the waves as they move from one medium into another in which the velocity of propagation is different. This bending of the waves is called refraction. For example, suppose you are driving down a smoothly paved road at a constant speed and suddenly one wheel goes off onto the soft shoulder. The car tends to veer off to one side. The change of medium, from hard surface to soft shoulder, causes a change in speed or velocity. The tendency is for the car to change direction. This same principle applies to radio waves as changes occur in the medium through which they are passing. As an example, the radio wave shown in figure 2-8 is traveling through the Earth's atmosphere at a constant speed. As the wave enters the dense layer of electrically charged ions, the part of the wave that enters the new medium first travels faster than the parts of the wave that have not yet entered the new medium. This abrupt increase in velocity of the upper part of the wave causes the wave to bend back toward the Earth. This bending, or change of direction, is always toward the medium that has the lower velocity of propagation.

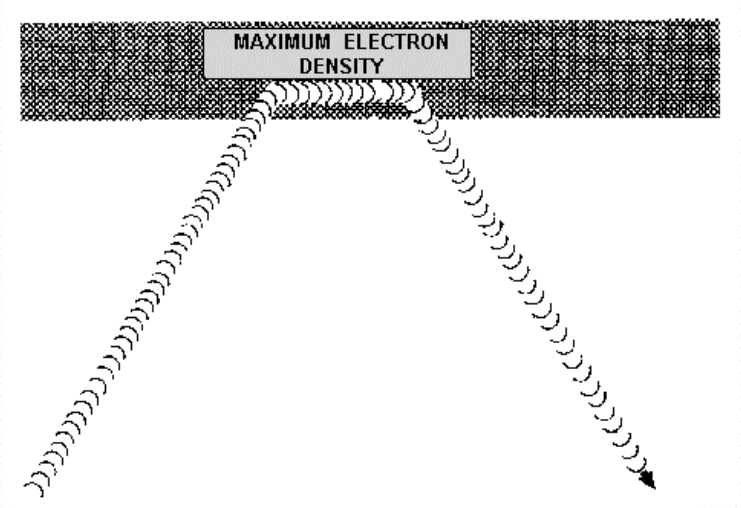

Figure 2-8.—Radio wave refraction.

Radio waves passing through the atmosphere are affected by certain factors, such as temperature, pressure, humidity, and density. These factors can cause the radio waves to be refracted. This effect will be discussed in greater detail later in this chapter.

Diffraction

A radio wave that meets an obstacle has a natural tendency to bend around the obstacle as illustrated in figure 2-9. The bending, called diffraction, results in a change of direction of part of the wave energy from the normal line-of-sight path. This change makes it possible to receive energy around the edges of an obstacle as shown in view A or at some distances below the highest point of an obstruction, as shown in view B. Although diffracted rf energy usually is weak, it can still be detected by a suitable receiver. The principal effect of diffraction extends the radio range beyond the visible horizon. In certain cases, by using high power and very low frequencies, radio waves can be made to encircle the Earth by diffraction.

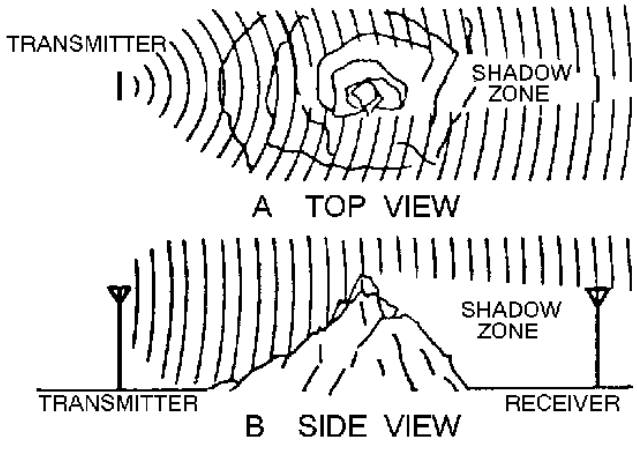

Figure 2-9.—Diffraction around an object.

Q10. What is one of the major reasons for the fading of radio waves which have been reflected from a surface?

THE EFFECT OF THE EARTH'S ATMOSPHERE ON RADIO WAVES

This discussion of electromagnetic wave propagation is concerned mainly with the properties and effects of the medium located between the transmitting antenna and the receiving antenna. While radio waves traveling in free space have little outside influence affecting them, radio waves traveling within the Earth's atmosphere are affected by varying conditions. The influence exerted on radio waves by the Earth's atmosphere adds many new factors to complicate what at first seems to be a relatively simple problem. These complications are because of a lack of uniformity within the Earth's atmosphere. Atmospheric conditions vary with changes in height, geographical location, and even with changes in time (day, night, season, year). A knowledge of the composition of the Earth's atmosphere is extremely important for understanding wave propagation.

The Earth's atmosphere is divided into three separate regions, or layers. They are the TROPOSPHERE, the STRATOSPHERE, and the IONOSPHERE. The layers of the atmosphere are illustrated in figure 2-10.

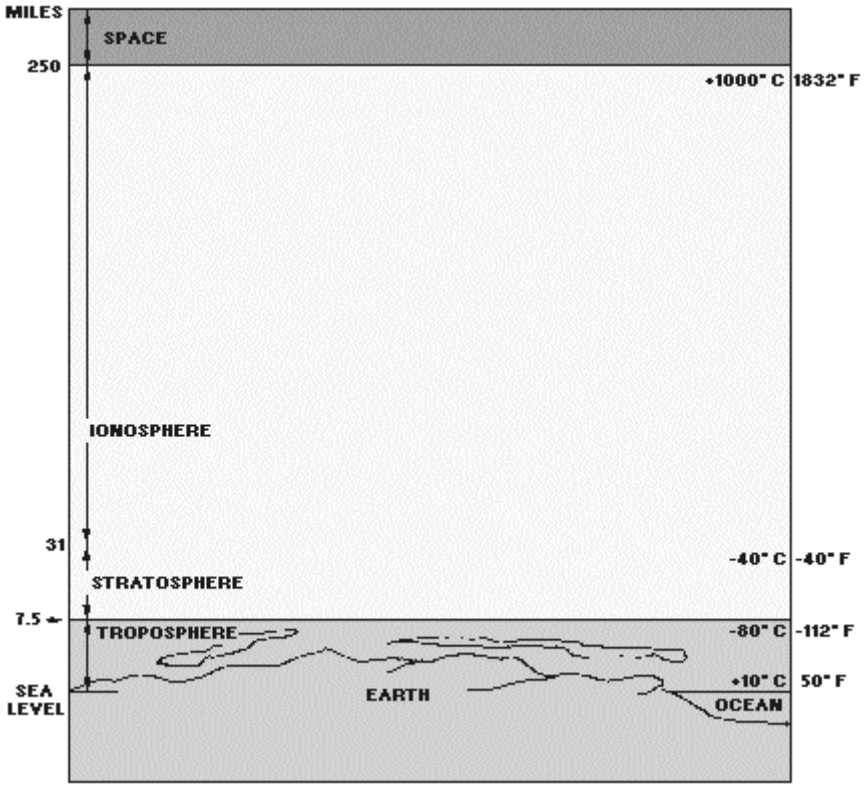

Figure 2-10.—Layers of the earth's atmosphere.

TROPOSPHERE

The troposphere is the portion of the Earth's atmosphere that extends from the surface of the Earth to a height of about 3.7 miles (6 km) at the North Pole or the South Pole and 11.2 miles (18 km) at the

equator. Virtually all weather phenomena take place in the troposphere. The temperature in this region decreases rapidly with altitude, clouds form, and there may be much turbulence because of variations in temperature, density, and pressure. These conditions have a great effect on the propagation of radio waves, which will be explained later in this chapter.

STRATOSPHERE

The stratosphere is located between the troposphere and the ionosphere. The temperature throughout this region is considered to be almost constant and there is little water vapor present. The stratosphere has relatively little effect on radio waves because it is a relatively calm region with little or no temperature changes.

IONOSPHERE

The ionosphere extends upward from about 31.1 miles (50 km) to a height of about 250 miles (402 km). It contains four cloud-like layers of electrically charged ions, which enable radio waves to be propagated to great distances around the Earth. This is the most important region of the atmosphere for long distance point-to-point communications. This region will be discussed in detail a little later in this chapter.

Q11. What are the three layers of the atmosphere?

Q12. Which layer of the atmosphere has relatively little effect on radio waves?

RADIO WAVE TRANSMISSION

There are two principal ways in which electromagnetic (radio) energy travels from a transmitting antenna to a receiving antenna. One way is by GROUND WAVES and the other is by SKY WAVES. Ground waves are radio waves that travel near the surface of the Earth (surface and space waves). Sky waves are radio waves that are reflected back to Earth from the ionosphere. (See figure 2-11.)

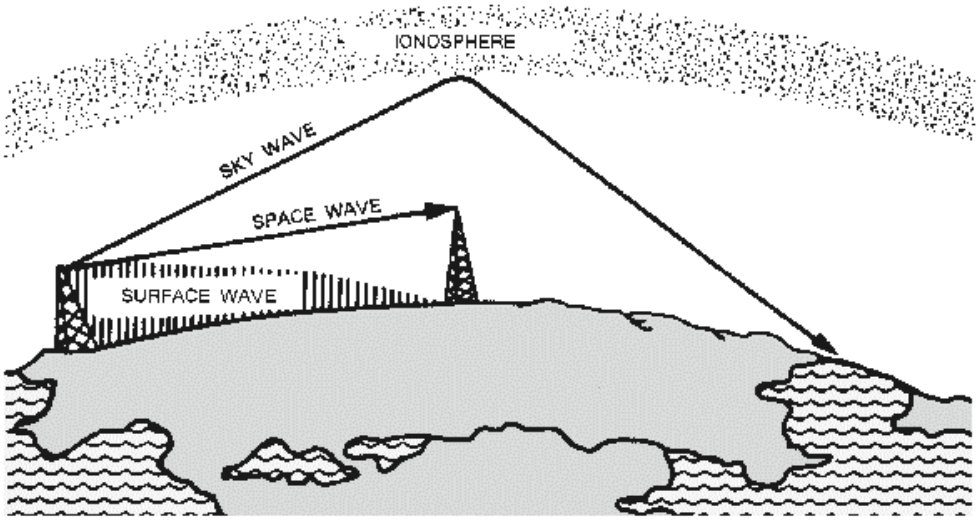

Figure 2-11.—Ground waves and sky waves.

Ground Waves

The ground wave is actually composed of two separate component waves. These are known as the SURFACE WAVE and the SPACE WAVE (fig. 2-11). The determining factor in whether a ground wave component is classified as a space wave or a surface wave is simple. A surface wave travels along the surface of the Earth. A space wave travels over the surface.

SURFACE WAVE.—The surface wave reaches the receiving site by traveling along the surface of the ground as shown in figure 2-12. A surface wave can follow the contours of the Earth because of the process of diffraction. When a surface wave meets an object and the dimensions of the object do not exceed its wavelength, the wave tends to curve or bend around the object. The smaller the object, the more pronounced the diffractive action will be.

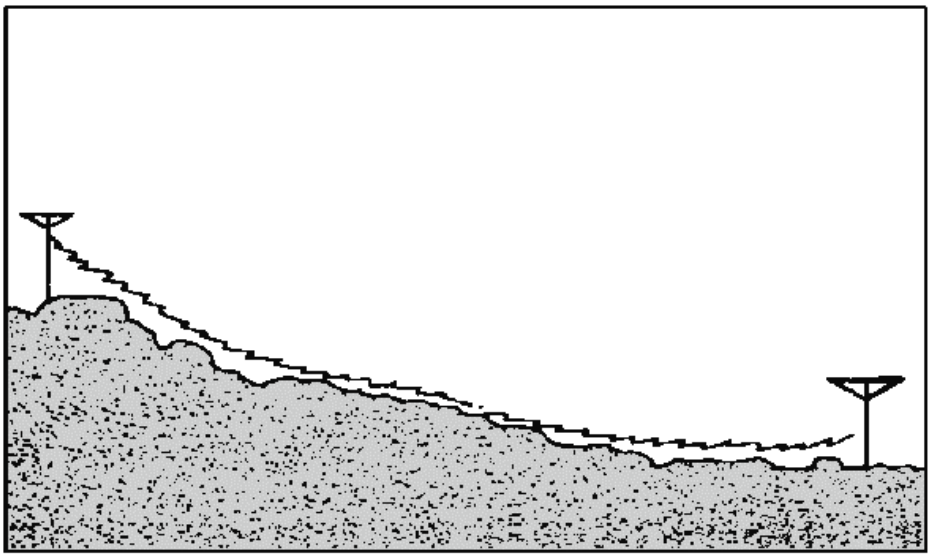

Figure 2-12.—Surface wave propagation.

As a surface wave passes over the ground, the wave induces a voltage in the Earth. The induced voltage takes energy away from the surface wave, thereby weakening, or attenuating, the wave as it moves away from the transmitting antenna. To reduce the attenuation, the amount of induced voltage must be reduced. This is done by using vertically polarized waves that minimize the extent to which the electric field of the wave is in contact with the Earth. When a surface wave is horizontally polarized, the electric field of the wave is parallel with the surface of the Earth and, therefore, is constantly in contact with it. The wave is then completely attenuated within a short distance from the transmitting site. On the other hand, when the surface wave is vertically polarized, the electric field is vertical to the Earth and merely dips into and out of the Earth's surface. For this reason, vertical polarization is vastly superior to horizontal polarization for surface wave propagation.

The attenuation that a surface wave undergoes because of induced voltage also depends on the electrical properties of the terrain over which the wave travels. The best type of surface is one that has good electrical conductivity. The better the conductivity, the less the attenuation. Table 2-2 gives the relative conductivity of various surfaces of the Earth.

Table 2-2.—Surface Conductivity

SURFACE	RELATIVE CONDUCTIVITY
Sea water	Good
Flat, loamy soil	Fair
Large bodies of fresh water	Fair
Rocky terrain	Poor
Desert	Poor
Jungle	Unusable

Another major factor in the attenuation of surface waves is frequency. Recall from earlier discussions on wavelength that the higher the frequency of a radio wave, the shorter its wavelength will be. These high frequencies, with their shorter wavelengths, are not normally diffracted but are absorbed by the Earth at points relatively close to the transmitting site. You can assume, therefore, that as the frequency of a surface wave is increased, the more rapidly the surface wave will be absorbed, or attenuated, by the Earth. Because of this loss by attenuation, the surface wave is impractical for long-distance transmissions at frequencies above 2 megahertz. On the other hand, when the frequency of a surface wave is low enough to have a very long wavelength, the Earth appears to be very small, and diffraction is sufficient for propagation well beyond the horizon. In fact, by lowering the transmitting frequency into the very low frequency (vlf) range and using very high-powered transmitters, the surface wave can be propagated great distances. The Navy's extremely high-powered vlf transmitters are actually capable of transmitting surface wave signals around the Earth and can provide coverage to naval units operating anywhere at sea.

SPACE WAVE.—The space wave follows two distinct paths from the transmitting antenna to the receiving antenna—one through the air directly to the receiving antenna, the other reflected from the ground to the receiving antenna. This is illustrated in figure 2-13. The primary path of the space wave is directly from the transmitting antenna to the receiving antenna. So, the receiving antenna must be located within the radio horizon of the transmitting antenna. Because space waves are refracted slightly, even when propagated through the troposphere, the radio horizon is actually about one-third farther than the line-of-sight or natural horizon.

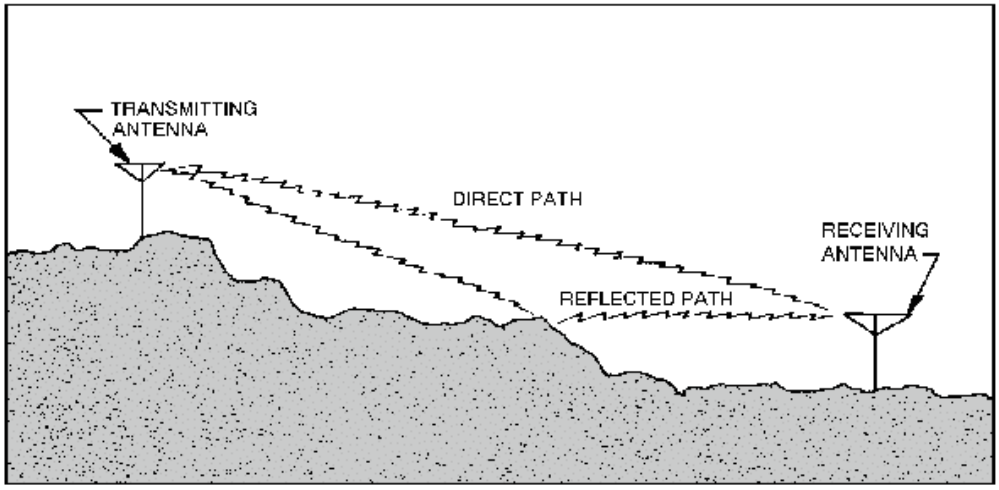

Figure 2-13.—Space wave propagation.

Although space waves suffer little ground attenuation, they nevertheless are susceptible to fading. This is because space waves actually follow two paths of different lengths (direct path and ground reflected path) to the receiving site and, therefore, may arrive in or out of phase. If these two component waves are received in phase, the result is a reinforced or stronger signal. Likewise, if they are received out of phase, they tend to cancel one another, which results in a weak or fading signal.

Q13. What is the determining factor in classifying whether a radio wave is a ground wave or a space wave?

Q14. What is the best type of surface or terrain to use for radio wave transmission?

Q15. What is the primary difference between the radio horizon and the natural horizon?

Q16. What three factors must be considered in the transmission of a surface wave to reduce attenuation?

Sky Wave

The sky wave, often called the ionospheric wave, is radiated in an upward direction and returned to Earth at some distant location because of refraction from the ionosphere. This form of propagation is relatively unaffected by the Earth's surface and can propagate signals over great distances. Usually the high frequency (hf) band is used for sky wave propagation. The following in-depth study of the ionosphere and its effect on sky waves will help you to better understand the nature of sky wave propagation.

STRUCTURE OF THE IONOSPHERE

As we stated earlier, the ionosphere is the region of the atmosphere that extends from about 30 miles above the surface of the Earth to about 250 miles. It is appropriately named the ionosphere because it consists of several layers of electrically charged gas atoms called ions. The ions are formed by a process called ionization.

Ionization

Ionization occurs when high energy ultraviolet light waves from the sun enter the ionospheric region of the atmosphere, strike a gas atom, and literally knock an electron free from its parent atom. A normal atom is electrically neutral since it contains both a positive proton in its nucleus and a negative orbiting electron. When the negative electron is knocked free from the atom, the atom becomes positively charged (called a positive ion) and remains in space along with the free electron, which is negatively charged. This process of upsetting electrical neutrality is known as IONIZATION.

The free negative electrons subsequently absorb part of the ultraviolet energy, which initially freed them from their atoms. As the ultraviolet light wave continues to produce positive ions and negative electrons, its intensity decreases because of the absorption of energy by the free electrons, and an ionized layer is formed. The rate at which ionization occurs depends on the density of atoms in the atmosphere and the intensity of the ultraviolet light wave, which varies with the activity of the sun.

Since the atmosphere is bombarded by ultraviolet light waves of different frequencies, several ionized layers are formed at different altitudes. Lower frequency ultraviolet waves penetrate the atmosphere the least; therefore, they produce ionized layers at the higher altitudes. Conversely, ultraviolet waves of higher frequencies penetrate deeper and produce layers at the lower altitudes.

An important factor in determining the density of ionized layers is the elevation angle of the sun, which changes frequently. For this reason, the height and thickness of the ionized layers vary, depending on the time of day and even the season of the year.

Recombination

Recall that the process of ionization involves ultraviolet light waves knocking electrons free from their atoms. A reverse process called RECOMBINATION occurs when the free electrons and positive ions collide with each other. Since these collisions are inevitable, the positive ions return to their original neutral atom state.

The recombination process also depends on the time of day. Between the hours of early morning and late afternoon, the rate of ionization exceeds the rate of recombination. During this period, the ionized layers reach their greatest density and exert maximum influence on radio waves. During the late afternoon and early evening hours, however, the rate of recombination exceeds the rate of ionization, and the density of the ionized layers begins to decrease. Throughout the night, density continues to decrease, reaching a low point just before sunrise.

Four Distinct Layers

The ionosphere is composed of three layers designated D, E, and F, from lowest level to highest level as shown in figure 2-14. The F layer is further divided into two layers designated F1 (the lower layer) and F2 (the higher layer). The presence or absence of these layers in the ionosphere and their height above the Earth varies with the position of the sun. At high noon, radiation in the ionosphere directly above a given point is greatest. At night it is minimum. When the radiation is removed, many of the particles that were ionized recombine. The time interval between these conditions finds the position and number of the ionized layers within the ionosphere changing. Since the position of the sun varies daily, monthly, and yearly, with respect to a specified point on Earth, the exact position and number of layers present are extremely difficult to determine. However, the following general statements can be made:

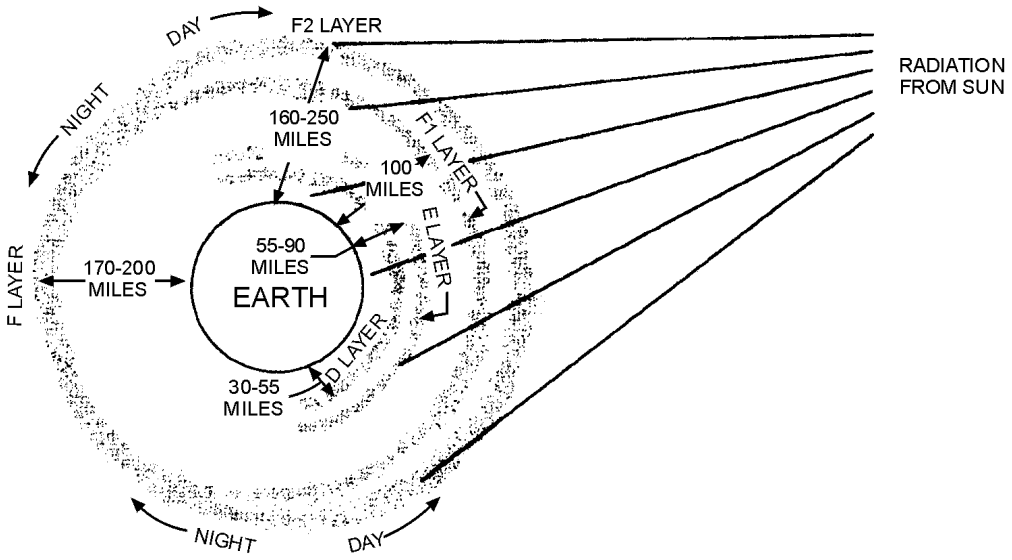

Figure 2-14.—Layers of the ionosphere.

a. The D layer ranges from about 30 to 55 miles. Ionization in the D layer is low because it is the lowest region of the ionosphere. This layer has the ability to refract signals of low frequencies. High frequencies pass right through it and are attenuated. After sunset, the D layer disappears because of the rapid recombination of ions.

b. The E layer limits are from about 55 to 90 miles. This layer is also known as the Kennelly-Heaviside layer, because these two men were the first to propose its existence. The rate of ionic recombination in this layer is rather rapid after sunset and the layer is almost gone by midnight. This layer has the ability to refract signals as high as 20 megahertz. For this reason, it is valuable for communications in ranges up to about 1500 miles.

c. The F layer exists from about 90 to 240 miles. During the daylight hours, the F layer separates into two layers, the F1 and F2 layers. The ionization level in these layers is quite high and varies widely during the day. At noon, this portion of the atmosphere is closest to the sun and the degree of ionization is maximum. Since the atmosphere is rarefied at these heights, recombination occurs slowly after sunset. Therefore, a fairly constant ionized layer is always present. The F layers are responsible for high-frequency, long distance transmission.

Q17. What causes ionization to occur in the ionosphere?

Q18. How are the four distinct layers of the ionosphere designated?

Q19. What is the height of the individual layers of the ionosphere?

REFRACTION IN THE IONOSPHERE

When a radio wave is transmitted into an ionized layer, refraction, or bending of the wave, occurs. As we discussed earlier, refraction is caused by an abrupt change in the velocity of the upper part of a radio wave as it strikes or enters a new medium. The amount of refraction that occurs depends on three main factors: (1) the density of ionization of the layer, (2) the frequency of the radio wave, and (3) the angle at which the wave enters the layer.

Density of Layer

Figure 2-15 illustrates the relationship between radio waves and ionization density. Each ionized layer has a central region of relatively dense ionization, which tapers off in intensity both above and below the maximum region. As a radio wave enters a region of INCREASING ionization, the increase in velocity of the upper part of the wave causes it to be bent back TOWARD the Earth. While the wave is in the highly dense center portion of the layer, however, refraction occurs more slowly because the density of ionization is almost uniform. As the wave enters into the upper part of the layer of DECREASING ionization, the velocity of the upper part of the wave decreases, and the wave is bent AWAY from the Earth.

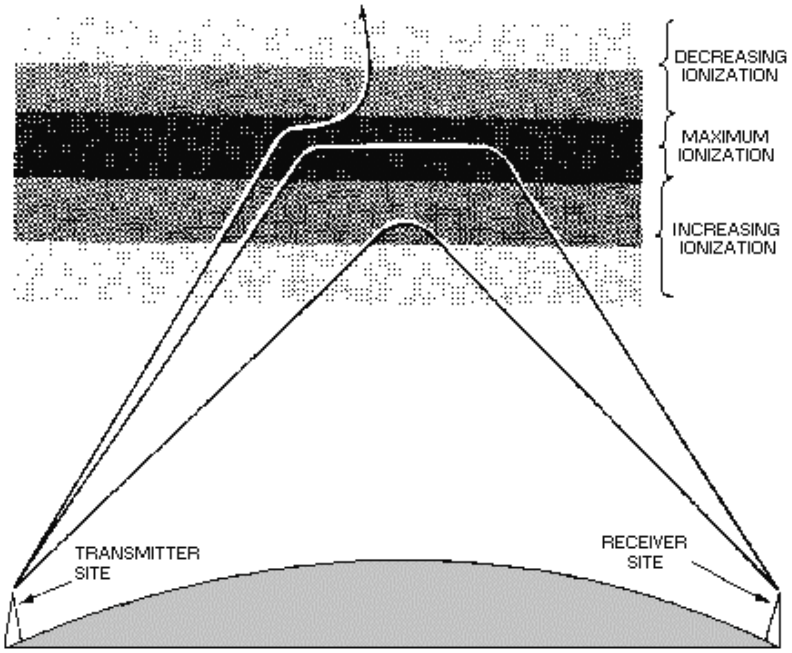

Figure 2-15.—Effects of ionospheric density on radio waves.

If a wave strikes a thin, very highly ionized layer, the wave may be bent back so rapidly that it will appear to have been reflected instead of refracted back to Earth. To reflect a radio wave, the highly ionized layer must be approximately no thicker than one wavelength of the radio wave. Since the ionized layers are often several miles thick, ionospheric reflection is more likely to occur at long wavelengths (low frequencies).

Frequency

For any given time, each ionospheric layer has a maximum frequency at which radio waves can be transmitted vertically and refracted back to Earth. This frequency is known as the CRITICAL FREQUENCY. It is a term that you will hear frequently in any discussion of radio wave propagation. Radio waves transmitted at frequencies higher than the critical frequency of a given layer will pass through the layer and be lost in space; but if these same waves enter an upper layer with a higher critical frequency, they will be refracted back to Earth. Radio waves of frequencies lower than the critical frequency will also be refracted back to Earth unless they are absorbed or have been refracted from a

lower layer. The lower the frequency of a radio wave, the more rapidly the wave is refracted by a given degree of ionization. Figure 2-16 shows three separate waves of different frequencies entering an ionospheric layer at the same angle. Notice that the 5-megahertz wave is refracted quite sharply. The 20-megahertz wave is refracted less sharply and returned to Earth at a greater distance. The 100-megahertz wave is obviously greater than the critical frequency for that ionized layer and, therefore, is not refracted but is passed into space.

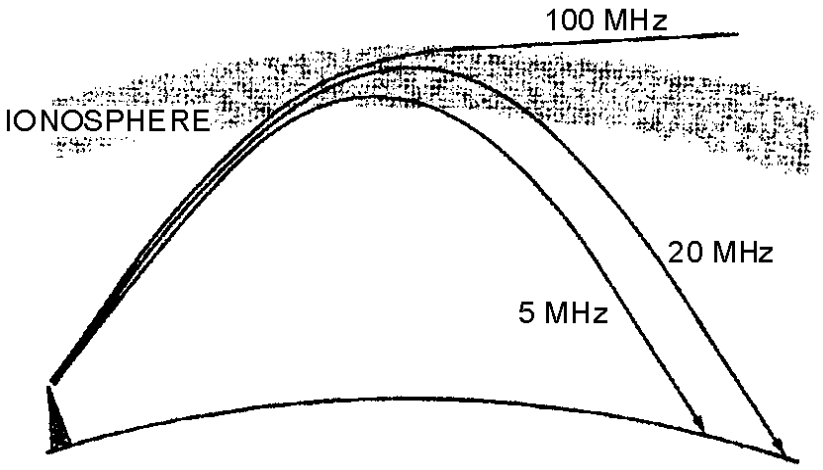

Figure 2-16.—Frequency versus refraction and distance.

Angle of Incidence

The rate at which a wave of a given frequency is refracted by an ionized layer depends on the angle at which the wave enters the layer. Figure 2-17 shows three radio waves of the same frequency entering a layer at different angles. The angle at which wave A strikes the layer is too nearly vertical for the wave to be refracted to Earth. As the wave enters the layer, it is bent slightly but passes through the layer and is lost. When the wave is reduced to an angle that is less than vertical (wave B), it strikes the layer and is refracted back to Earth. The angle made by wave B is called the CRITICAL ANGLE for that particular frequency. Any wave that leaves the antenna at an angle greater than the critical angle will penetrate the ionospheric layer for that frequency and then be lost in space. Wave C strikes the ionosphere at the smallest angle at which the wave can be refracted and still return to Earth. At any smaller angle, the wave will be refracted but will not return to Earth.

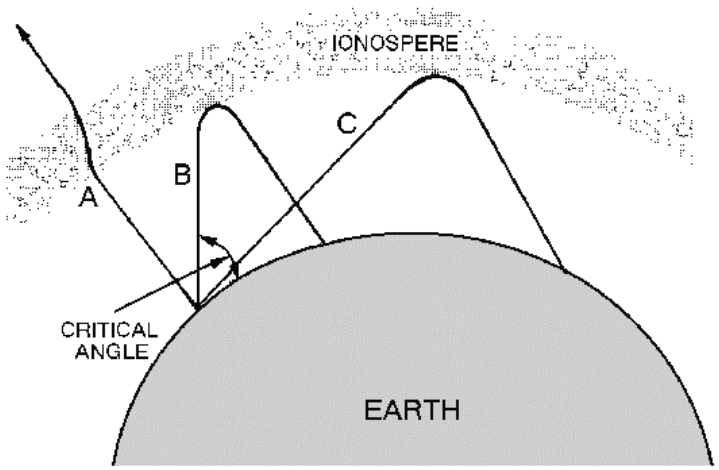

Figure 2-17.—Different incident angles of radio waves.

As the frequency of the radio wave is increased, the critical angle must be reduced for refraction to occur. This is illustrated in figure 2-18. The 2-megahertz wave strikes the layer at the critical angle for that frequency and is refracted back to Earth. Although the 5-megahertz wave (broken line) strikes the ionosphere at a lesser angle, it nevertheless penetrates the layer and is lost. As the angle is lowered from the vertical, however, a critical angle for the 5-megahertz wave is reached, and the wave is then refracted to Earth.

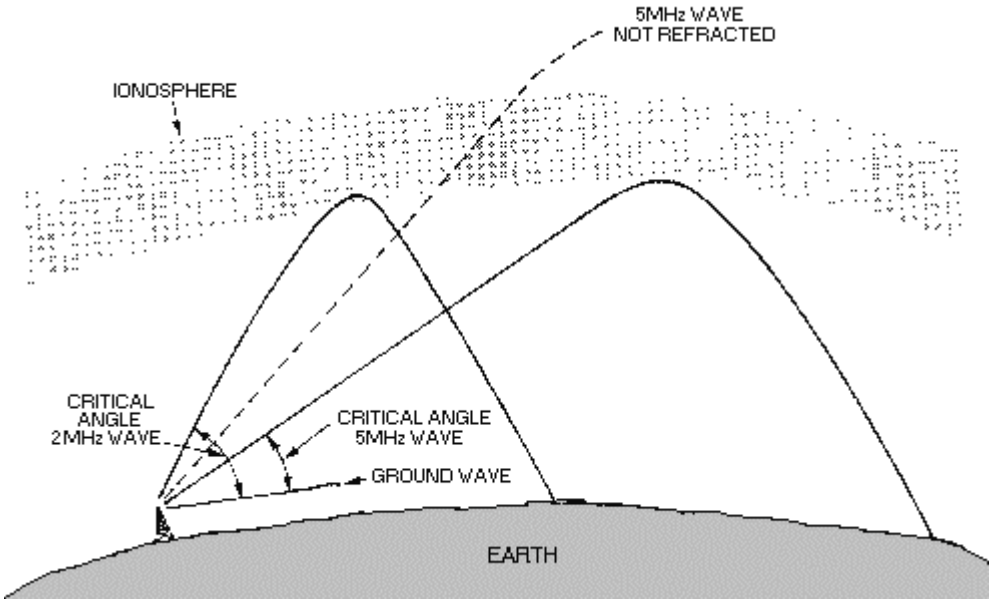

Figure 2-18.—Effects of frequency on the critical angle.

Q20. What factor determines whether a radio wave is reflected or refracted by the ionosphere?

Q21. There is a maximum frequency at which vertically transmitted radio waves can be refracted back to Earth. What is this maximum frequency called?

Q22. What three main factors determine the amount of refraction in the ionosphere?

Skip Distance/Skip Zone

In figure 2-19, note the relationship between the sky wave skip distance, the skip zone, and the ground wave coverage. The SKIP DISTANCE is the distance from the transmitter to the point where the sky wave is first returned to Earth. The size of the skip distance depends on the frequency of the wave, the angle of incidence, and the degree of ionization present.

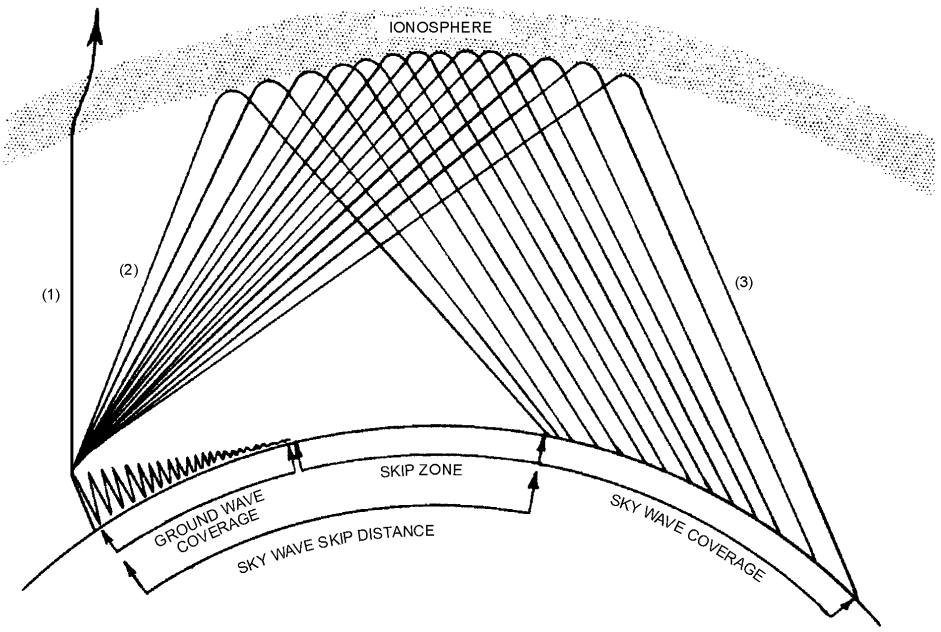

Figure 2-19.—Relationship between skip zone, skip distance, and ground wave.

The SKIP ZONE is a zone of silence between the point where the ground wave becomes too weak for reception and the point where the sky wave is first returned to Earth. The size of the skip zone depends on the extent of the ground wave coverage and the skip distance. When the ground wave coverage is great enough or the skip distance is short enough that no zone of silence occurs, there is no skip zone.

Occasionally, the first sky wave will return to Earth within the range of the ground wave. If the sky wave and ground wave are nearly of equal intensity, the sky wave alternately reinforces and cancels the ground wave, causing severe fading. This is caused by the phase difference between the two waves, a result of the longer path traveled by the sky wave.

PROPAGATION PATHS

The path that a refracted wave follows to the receiver depends on the angle at which the wave strikes the ionosphere. You should remember, however, that the rf energy radiated by a transmitting antenna spreads out with distance. The energy therefore strikes the ionosphere at many different angles rather than a single angle.

After the rf energy of a given frequency enters an ionospheric region, the paths that this energy might follow are many. It may reach the receiving antenna via two or more paths through a single layer. It

may also, reach the receiving antenna over a path involving more than one layer, by multiple hops between the ionosphere and Earth, or by any combination of these paths.

Figure 2-20 shows how radio waves may reach a receiver via several paths through one layer. The various angles at which rf energy strikes the layer are represented by dark lines and designated as rays 1 through 6.

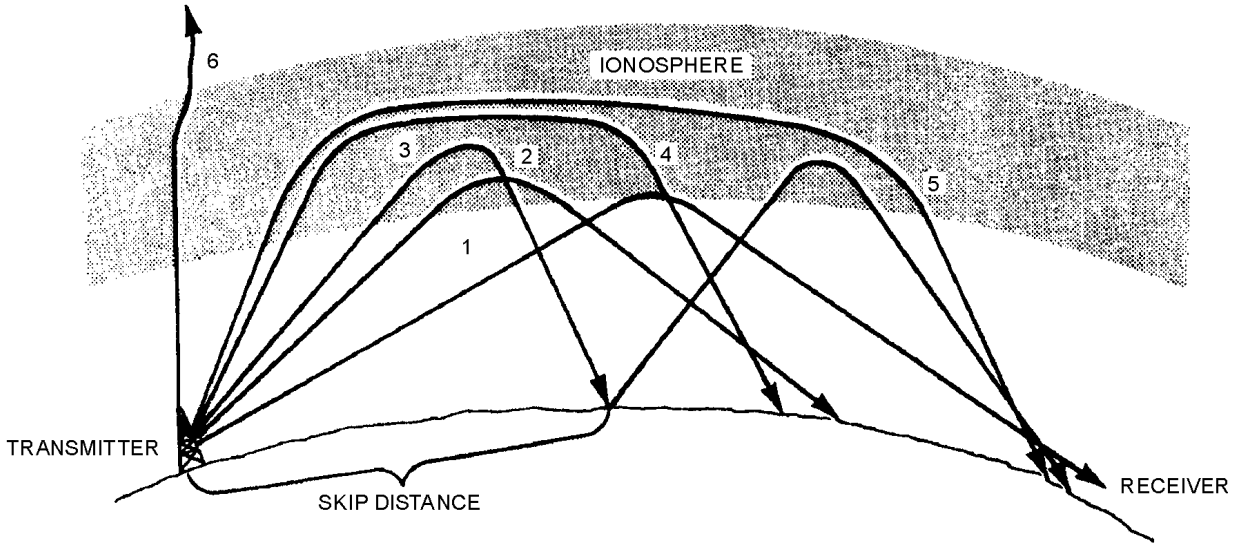

Figure 2-20.—Ray paths for a fixed frequency with varying angles of incidence.

When the angle is relatively low with respect to the horizon (ray 1), there is only slight penetration of the layer and the propagation path is long. When the angle of incidence is increased (rays 2 and 3), the rays penetrate deeper into the layer but the range of these rays decreases. When a certain angle is reached (ray 3), the penetration of the layer and rate of refraction are such that the ray is first returned to Earth at a minimal distance from the transmitter. Notice, however, that ray 3 still manages to reach the receiving site on its second refraction (called a hop) from the ionospheric layer.

As the angle is increased still more (rays 4 and 5), the rf energy penetrates the central area of maximum ionization of the layer. These rays are refracted rather slowly and are eventually returned to Earth at great distances. As the angle approaches vertical incidence (ray 6), the ray is not returned at all, but passes on through the layer.

ABSORPTION IN THE IONOSPHERE

Many factors affect a radio wave in its path between the transmitting and receiving sites. The factor that has the greatest adverse effect on radio waves is ABSORPTION. Absorption results in the loss of energy of a radio wave and has a pronounced effect on both the strength of received signals and the ability to communicate over long distances.

You learned earlier in the section on ground waves that surface waves suffer most of their absorption losses because of ground-induced voltage. Sky waves, on the other hand, suffer most of their absorption losses because of conditions in the ionosphere. Note that some absorption of sky waves may also occur at lower atmospheric levels because of the presence of water and water vapor. However, this becomes important only at frequencies above 10,000 megahertz.

Most ionospheric absorption occurs in the lower regions of the ionosphere where ionization density is greatest. As a radio wave passes into the ionosphere, it loses some of its energy to the free electrons and ions. If these high-energy free electrons and ions do not collide with gas molecules of low energy, most of the energy lost by the radio wave is reconverted into electromagnetic energy, and the wave continues to be propagated with little change in intensity. However, if the high-energy free electrons and ions do collide with other particles, much of this energy is lost, resulting in absorption of the energy from the wave. Since absorption of energy depends on collision of the particles, the greater the density of the ionized layer, the greater the probability of collisions; therefore, the greater the absorption. The highly dense D and E layers provide the greatest absorption of radio waves.

Because the amount of absorption of the sky wave depends on the density of the ionosphere, which varies with seasonal and daily conditions, it is impossible to express a fixed relationship between distance and signal strength for ionospheric propagation. Under certain conditions, the absorption of energy is so great that communicating over any distance beyond the line of sight is difficult.

FADING

The most troublesome and frustrating problem in receiving radio signals is variations in signal strength, most commonly known as FADING. There are several conditions that can produce fading. When a radio wave is refracted by the ionosphere or reflected from the Earth's surface, random changes in the polarization of the wave may occur. Vertically and horizontally mounted receiving antennas are designed to receive vertically and horizontally polarized waves, respectively. Therefore, changes in polarization cause changes in the received signal level because of the inability of the antenna to receive polarization changes.

Fading also results from absorption of the rf energy in the ionosphere. Absorption fading occurs for a longer period than other types of fading, since absorption takes place slowly.

Usually, however, fading on ionospheric circuits is mainly a result of multipath propagation.

Multipath Fading

MULTIPATH is simply a term used to describe the multiple paths a radio wave may follow between transmitter and receiver. Such propagation paths include the ground wave, ionospheric refraction, reradiation by the ionospheric layers, reflection from the Earth's surface or from more than one ionospheric layer, etc. Figure 2-21 shows a few of the paths that a signal can travel between two sites in a typical circuit. One path, XYZ, is the basic ground wave. Another path, XEA, refracts the wave at the E layer and passes it on to the receiver at A. Still another path, XFZFA, results from a greater angle of incidence and two refractions from the F layer. At point Z, the received signal is a combination of the ground wave and the sky wave. These two signals having traveled different paths arrive at point Z at different times. Thus, the arriving waves may or may not be in phase with each other. Radio waves that are received in phase reinforce each other and produce a stronger signal at the receiving site. Conversely, those that are received out of phase produce a weak or fading signal. Small alternations in the transmission path may change the phase relationship of the two signals, causing periodic fading. This condition occurs at point A. At this point, the double-hop F layer signal may be in or out of phase with the signal arriving from the E layer.

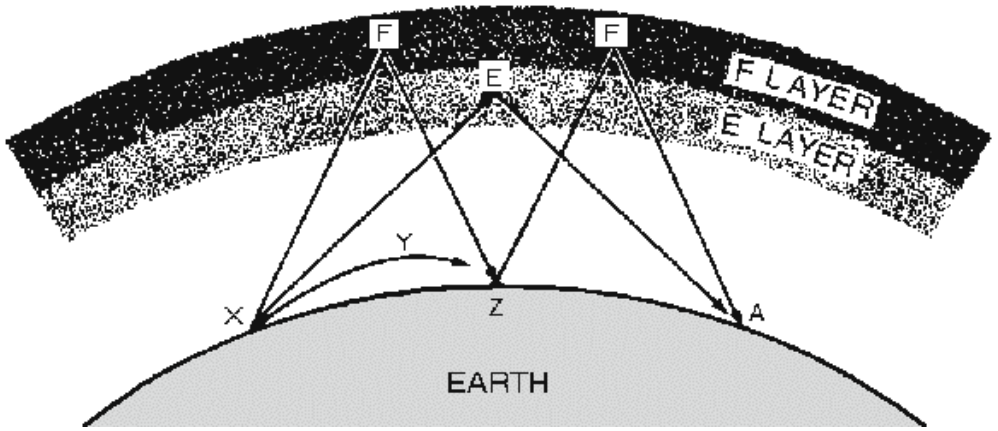

Figure 2-21.—Multipath transmission.

Multipath fading may be minimized by practices called SPACE DIVERSITY and FREQUENCY DIVERSITY. In space diversity, two or more receiving antennas are spaced some distance apart. Fading does not occur simultaneously at both antennas; therefore, enough output is almost always available from one of the antennas to provide a useful signal. In frequency diversity, two transmitters and two receivers are used, each pair tuned to a different frequency, with the same information being transmitted simultaneously over both frequencies. One of the two receivers will almost always provide a useful signal.

Selective Fading

Fading resulting from multipath propagation is variable with frequency since each frequency arrives at the receiving point via a different radio path. When a wide band of frequencies is transmitted simultaneously, each frequency will vary in the amount of fading. This variation is called SELECTIVE FADING. When selective fading occurs, all frequencies of the transmitted signal do not retain their original phases and relative amplitudes. This fading causes severe distortion of the signal and limits the total signal transmitted.

Q23. What is the skip zone of a radio wave?

Q24. Where does the greatest amount of ionospheric absorption occur in the ionosphere?

Q25. What is meant by the term "multipath"?

Q26. When a wide band of frequencies is transmitted simultaneously, each frequency will vary in the amount of fading. What is this variable fading called?

TRANSMISSION LOSSES

All radio waves propagated over ionospheric paths undergo energy losses before arriving at the receiving site. As we discussed earlier, absorption in the ionosphere and lower atmospheric levels account for a large part of these energy losses. There are two other types of losses that also significantly affect the ionospheric propagation of radio waves. These losses are known as ground reflection loss and free space loss. The combined effects of absorption, ground reflection loss, and free space loss account for most of the energy losses of radio transmissions propagated by the ionosphere.

Ground Reflection Loss

When propagation is accomplished via multihop refraction, rf energy is lost each time the radio wave is reflected from the Earth's surface. The amount of energy lost depends on the frequency of the wave, the angle of incidence, ground irregularities, and the electrical conductivity of the point of reflection.

Free space Loss

Normally, the major loss of energy is because of the spreading out of the wavefront as it travels away from the transmitter. As the distance increases, the area of the wavefront spreads out, much like the beam of a flashlight. This means the amount of energy contained within any unit of area on the wavefront will decrease as distance increases. By the time the energy arrives at the receiving antenna, the wavefront is so spread out that the receiving antenna extends into only a very small fraction of the wavefront. This is illustrated in figure 2-22.

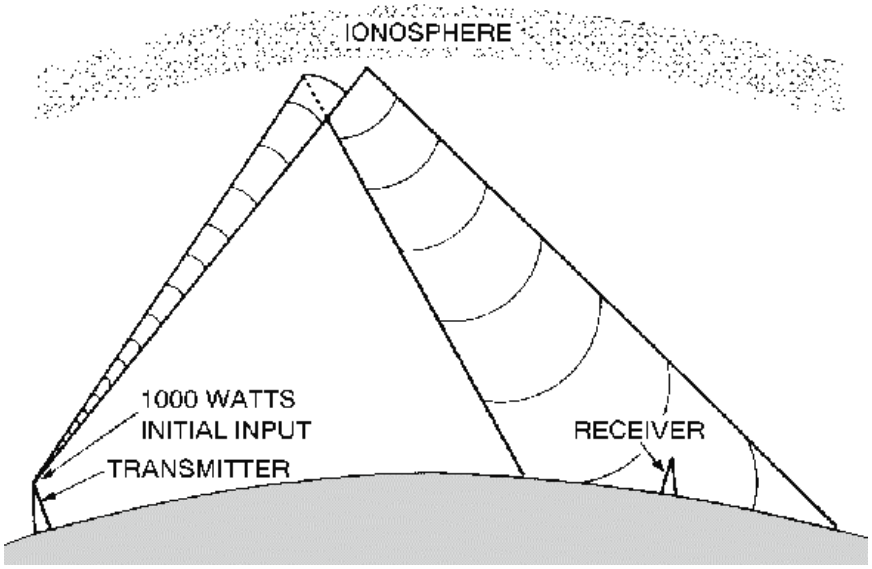

Figure 2-22.—Free space loss principle.

ELECTROMAGNETIC INTERFERENCE (EMI)

The transmission losses just discussed are not the only factors that interfere with communications. An additional factor that can interfere with radio communications is the presence of ELECTROMAGNETIC INTERFERENCE (EMI). This interference can result in annoying or impossible operating conditions. Sources of emi are both man-made and natural.

Man-Made Interference

Man-made interference may come from several sources. Some of these sources, such as oscillators, communications transmitters, and radio transmitters, may be specifically designed to generate radio frequency energy. Some electrical devices also generate radio frequency energy, although they are not specifically designed for this purpose. Examples are ignition systems, generators, motors, switches, relays, and voltage regulators. The intensity of man-made interference may vary throughout the day and drop off to a low level at night when many of these sources are not being used. Man-made interference may be a critical limiting factor at radio receiving sites located near industrial areas.

Natural Interference

Natural interference refers to the static that you often hear when listening to a radio. This interference is generated by natural phenomena, such as thunderstorms, snowstorms, cosmic sources, and the sun. The energy released by these sources is transmitted to the receiving site in roughly the same manner as radio waves. As a result, when ionospheric conditions are favorable for the long distance propagation of radio waves, they are likewise favorable for the propagation of natural interference. Natural interference is very erratic, particularly in the hf band, but generally will decrease as the operating frequency is increased and wider bandwidths are used. There is little natural interference above 30 megahertz.

Control of EMI

Electromagnetic interference can be reduced or eliminated by using various suppression techniques. The amount of emi that is produced by a radio transmitter can be controlled by cutting transmitting antennas to the correct frequency, limiting bandwidth, and using electronic filtering networks and metallic shielding.

Radiated emi during transmission can be controlled by the physical separation of the transmitting and receiving antennas, the use of directional antennas, and limiting antenna bandwidth.

Q27. What are the two main sources of emi with which radio waves must compete?

Q28. Thunderstorms, snowstorms, cosmic sources, the sun, etc., are a few examples of emi sources. What type of emi comes from these sources?

Q29. Motors, switches, voltage regulators, generators, etc., are a few examples of emi sources. What type of emi comes from these sources?

Q30. What are three ways of controlling the amount of transmitter-generated emi?

Q31. What are three ways of controlling radiated emi during transmission?

VARIATIONS IN THE IONOSPHERE

Because the existence of the ionosphere is directly related to radiations emitted from the sun, the movement of the Earth about the sun or changes in the sun's activity will result in variations in the ionosphere. These variations are of two general types: (1) those which are more or less regular and occur in cycles and, therefore, can be predicted in advance with reasonable accuracy, and (2) those which are irregular as a result of abnormal behavior of the sun and, therefore, cannot be predicted in advance. Both regular and irregular variations have important effects on radio wave propagation.

Regular Variations

The regular variations that affect the extent of ionization in the ionosphere can be divided into four main classes: daily, seasonal, 11-year, and 27-day variations.

DAILY.—Daily variations in the ionosphere are a result of the 24-hour rotation of the Earth about its axis. Daily variations of the different layers (fig. 2-14) are summarized as follows:

- The D layer reflects vlf waves; is important for long range vlf communications; refracts lf and mf waves for short range communications; absorbs hf waves; has little effect on vhf and above; and disappears at night.

- In the E layer, ionization depends on the angle of the sun. The E layer refracts hf waves during the day up to 20 megahertz to distances of about 1200 miles. Ionization is greatly reduced at night.

- Structure and density of the F region depend on the time of day and the angle of the sun. This region consists of one layer during the night and splits into two layers during daylight hours.

- Ionization density of the F1 layer depends on the angle of the sun. Its main effect is to absorb hf waves passing through to the F2 layer.

- The F2 layer is the most important layer for long distance hf communications. It is a very variable layer and its height and density change with time of day, season, and sunspot activity.

SEASONAL.—Seasonal variations are the result of the Earth revolving around the sun; the relative position of the sun moves from one hemisphere to the other with changes in seasons. Seasonal variations of the D, E, and F1 layers correspond to the highest angle of the sun; thus the ionization density of these layers is greatest during the summer. The F2 layer, however, does not follow this pattern; its ionization is greatest in winter and least in summer, the reverse of what might be expected. As a result, operating frequencies for F2 layer propagation are higher in the winter than in the summer.

ELEVEN-YEAR SUN SPOT CYCLE.—One of the most notable phenomena on the surface of the sun is the appearance and disappearance of dark, irregularly shaped areas known as SUNSPOTS. The exact nature of sunspots is not known, but scientists believe they are caused by violent eruptions on the sun and are characterized by unusually strong magnetic fields. These sunspots are responsible for variations in the ionization level of the ionosphere. Sunspots can, of course, occur unexpectedly, and the life span of individual sunspots is variable; however, a regular cycle of sunspot activity has also been observed. This cycle has both a minimum and maximum level of sunspot activity that occur approximately every 11 years.

During periods of maximum sunspot activity, the ionization density of all layers increases. Because of this, absorption in the D layer increases and the critical frequencies for the E, F1, and F2 layers are higher. At these times, higher operating frequencies must be used for long distance communications.

27-DAY SUNSPOT CYCLE.—The number of sunspots in existence at any one time is continually subject to change as some disappear and new ones emerge. As the sun rotates on its own axis, these sunspots are visible at 27-day intervals, the approximate period required for the sun to make one complete rotation.

The 27-day sunspot cycle causes variations in the ionization density of the layers on a day-to-day basis. The fluctuations in the F2 layer are greater than for any other layer. For this reason, precise predictions on a day-to-day basis of the critical frequency of the F2 layer are not possible. In calculating frequencies for long-distance communications, allowances for the fluctuations of the F2 layer must be made.

Irregular Variations

Irregular variations in ionospheric conditions also have an important effect on radio wave propagation. Because these variations are irregular and unpredictable, they can drastically affect communications capabilities without any warning.

The more common irregular variations are sporadic E, sudden ionospheric disturbances, and ionospheric storms.

SPORADIC E.—Irregular cloud-like patches of unusually high ionization, called sporadic E, often form at heights near the normal E layer. Exactly what causes this phenomenon is not known, nor can its occurrence be predicted. It is known to vary significantly with latitude, and in the northern latitudes, it appears to be closely related to the aurora borealis or northern lights.

At times the sporadic E is so thin that radio waves penetrate it easily and are returned to earth by the upper layers. At other times, it extends up to several hundred miles and is heavily ionized.

These characteristics may be either harmful or helpful to radio wave propagation. For example, sporadic E may blank out the use of higher, more favorable ionospheric layers or cause additional absorption of the radio wave at some frequencies. Also, it can cause additional multipath problems and delay the arrival times of the rays of rf energy.

On the other hand, the critical frequency of the sporadic E is very high and can be greater than double the critical frequency of the normal ionospheric layers. This condition may permit the long distance transmission of signals at unusually high frequencies. It may also permit short distance communications to locations that would normally be in the skip zone.

The sporadic E can form and disappear in a short time during either the day or night. However, it usually does not occur at the same time at all transmitting or receiving stations.

SUDDEN IONOSPHERIC DISTURBANCES.—The most startling of the ionospheric irregularities is known as a SUDDEN IONOSPHERIC DISTURBANCE (sid). These disturbances may occur without warning and may prevail for any length of time, from a few minutes to several hours. When sid occurs, long distance propagation of hf radio waves is almost totally "blanked out." The immediate effect is that radio operators listening on normal frequencies are inclined to believe their receivers have gone dead.

When sid has occurred, examination of the sun has revealed a bright solar eruption. All stations lying wholly, or in part, on the sunward side of the Earth are affected. The solar eruption produces an unusually intense burst of ultraviolet light, which is not absorbed by the F2, F1, and E layers, but instead causes a sudden abnormal increase in the ionization density of the D layer. As a result, frequencies above 1 or 2 megahertz are unable to penetrate the D layer and are usually completely absorbed by the layer.

IONOSPHERIC STORMS.—Ionospheric storms are disturbances in the Earth's magnetic field. They are associated, in a manner not fully understood, with both solar eruptions and the 27-day intervals, thus corresponding to the rotation of the sun.

Scientists believe that ionospheric storms result from particle radiation from the sun. Particles radiated from a solar eruption have a slower velocity than ultraviolet light waves produced by the eruption. This would account for the 18-hour or so time difference between a sid and an ionospheric storm. An ionospheric storm that is associated with sunspot activity may begin anytime from 2 days before an active sunspot crosses the central meridian of the sun until four days after it passes the central meridian. At times, however, active sunspots have crossed the central region of the sun without any ionospheric storms occurring. Conversely, ionospheric storms have occurred when there were no visible spots on the sun and no preceding sid. As you can see, some correlation between ionospheric storms, sid, and sunspot activity is possible, but there are no hard and fast rules. Ionospheric storms can occur suddenly without warning.

The most prominent effects of ionospheric storms are a turbulent ionosphere and very erratic sky wave propagation. Critical frequencies are lower than normal, particularly for the F2 layer. Ionospheric storms affect the higher F2 layer first, reducing its ion density. Lower layers are not appreciably affected by the storms unless the disturbance is great. The practical effect of ionospheric storms is that the range of

frequencies that can be used for communications on a given circuit is much smaller than normal, and communications are possible only at the lower working frequencies.

Q32. What are the two general types of variations in the ionosphere?

Q33. What is the main difference between these two types of variations?

Q34. What are the four main classes of regular variation which affect the extent of ionization in the ionosphere?

Q35. What are the three more common types of irregular variations in the ionosphere?

FREQUENCY SELECTION CONSIDERATIONS

Up to this point, we have covered various factors that control the propagation of radio waves through the ionosphere, such as the structure of the ionosphere, the incidence angle of radio waves, operating frequencies, etc. There is a very good reason for studying radio wave propagation. You must have a thorough knowledge of radio wave propagation to exercise good judgment when you select transmitting and receiving antennas and operating frequencies. Selection of a suitable operating frequency (within the bounds of frequency allocations and availability) is of prime importance in maintaining reliable communications.

For successful communications between any two specified locations at any given time of the day, there is a maximum frequency, a lowest frequency, and an optimum frequency that can be used.

Maximum Usable Frequency

As we discussed earlier, the higher the frequency of a radio wave, the lower the rate of refraction by an ionized layer. Therefore, for a given angle of incidence and time of day, there is a maximum frequency that can be used for communications between two given locations. This frequency is known as the MAXIMUM USABLE FREQUENCY (muf).

Waves at frequencies above the muf are normally refracted so slowly that they return to Earth beyond the desired location, or pass on through the ionosphere and are lost. You should understand, however, that use of an established muf certainly does not guarantee successful communications between a transmitting site and a receiving site. Variations in the ionosphere may occur at any time and consequently raise or lower the predetermined muf. This is particularly true for radio waves being refracted by the highly variable F2 layer.

The muf is highest around noon when ultraviolet light waves from the sun are the most intense. It then drops rather sharply as recombination begins to take place.

Lowest Usable Frequency

As there is a maximum operating frequency that can be used for communications between two points, there is also a minimum operating frequency. This is known as the LOWEST USABLE FREQUENCY (luf).

As the frequency of a radio wave is lowered, the rate of refraction increases. So a wave whose frequency is below the established luf is refracted back to Earth at a shorter distance than desired, as shown in figure 2-23.

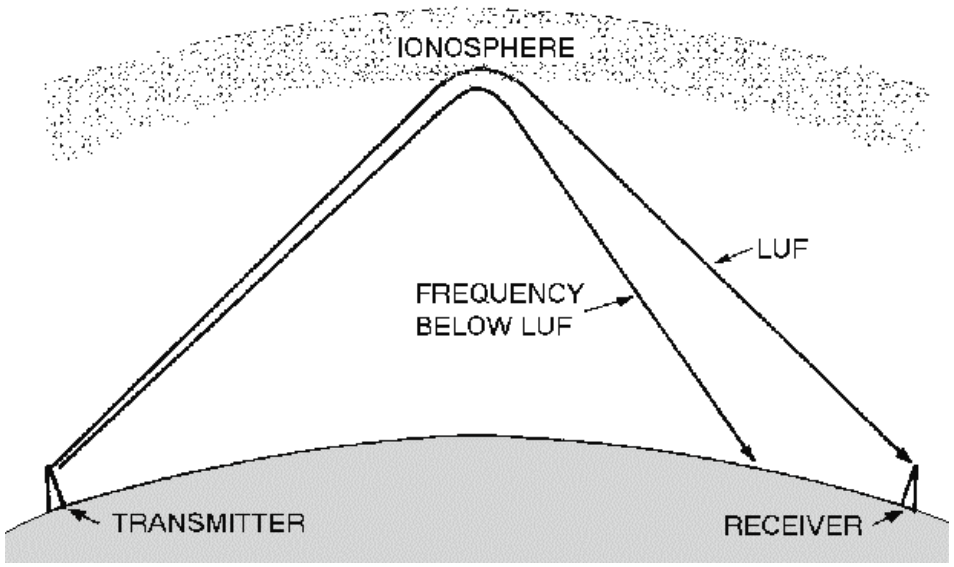

Figure 2-23.—Refraction of frequency below the lowest usable frequency (luf).

The transmission path that results from the rate of refraction is not the only factor that determines the luf. As a frequency is lowered, absorption of the radio wave increases. A wave whose frequency is too low is absorbed to such an extent that it is too weak for reception. Likewise, atmospheric noise is greater at lower frequencies; thus, a low-frequency radio wave may have an unacceptable signal-to-noise ratio.

For a given angle of incidence and set of ionospheric conditions, the luf for successful communications between two locations depends on the refraction properties of the ionosphere, absorption considerations, and the amount of atmospheric noise present.

Optimum Working Frequency

Neither the muf nor the luf is a practical operating frequency. While radio waves at the luf can be refracted back to Earth at the desired location, the signal-to-noise ratio is still much lower than at the higher frequencies, and the probability of multipath propagation is much greater. Operating at or near the muf can result in frequent signal fading and dropouts when ionospheric variations alter the length of the transmission path.

The most practical operating frequency is one that you can rely on with the least amount of problems. It should be high enough to avoid the problems of multipath, absorption, and noise encountered at the lower frequencies; but not so high as to result in the adverse effects of rapid changes in the ionosphere.

A frequency that meets the above criteria has been established and is known as the OPTIMUM WORKING FREQUENCY. It is abbreviated "fot" from the initial letters of the French words for optimum working frequency, "frequence optimum de travail." The fot is roughly about 85 percent of the muf but the actual percentage varies and may be either considerably more or less than 85 percent.

Q36. What do the letters muf, luf, and fot stand for?

Q37. When is muf at its highest and why?

Q38. What happens to the radio wave if the luf is too low?

Q39. What are some disadvantages of operating transmitters at or near the luf?

Q40. What are some disadvantages of operating a transmitter at or near the muf?

Q41. What is fot?

WEATHER VERSUS PROPAGATION

Weather is an additional factor that affects the propagation of radio waves. In this section, we will explain how and to what extent the various weather phenomena affect wave propagation.

Wind, air temperature, and water content of the atmosphere can combine in many ways. Certain combinations can cause radio signals to be heard hundreds of miles beyond the ordinary range of radio communications. Conversely, a different combination of factors can cause such attenuation of the signal that it may not be heard even over a normally satisfactory path. Unfortunately, there are no hard and fast rules on the effects of weather on radio transmissions since the weather is extremely complex and subject to frequent change. We will, therefore, limit our discussion on the effects of weather on radio waves to general terms.

PRECIPITATION ATTENUATION

Calculating the effect of weather on radio wave propagation would be comparatively simple if there were no water or water vapor in the atmosphere. However, some form of water (vapor, liquid, or solid) is always present and must be considered in all calculations. Before we begin discussing the specific effects that individual forms of precipitation (rain, snow, fog) have on radio waves, you should understand that attenuation because of precipitation is generally proportionate to the frequency and wavelength of the radio wave. For example, rain has a pronounced effect on waves at microwave frequencies. However, rain hardly affects waves with long wavelengths (hf range and below). You can assume, then, that as the wavelength becomes shorter with increases in frequency, precipitation has an increasingly important attenuation effect on radio waves. Conversely, you can assume that as the wavelength becomes longer with decreases in frequency, precipitation has little attenuation effect.

Rain

Attenuation because of raindrops is greater than attenuation because of other forms of precipitation. Attenuation may be caused by absorption, in which the raindrop, acting as a poor dielectric, absorbs power from the radio wave and dissipates the power by heat loss or by scattering (fig. 2-24). Raindrops cause greater attenuation by scattering than by absorption at frequencies above 100 megahertz. At frequencies above 6 gigahertz, attenuation by raindrop scatter is even greater.

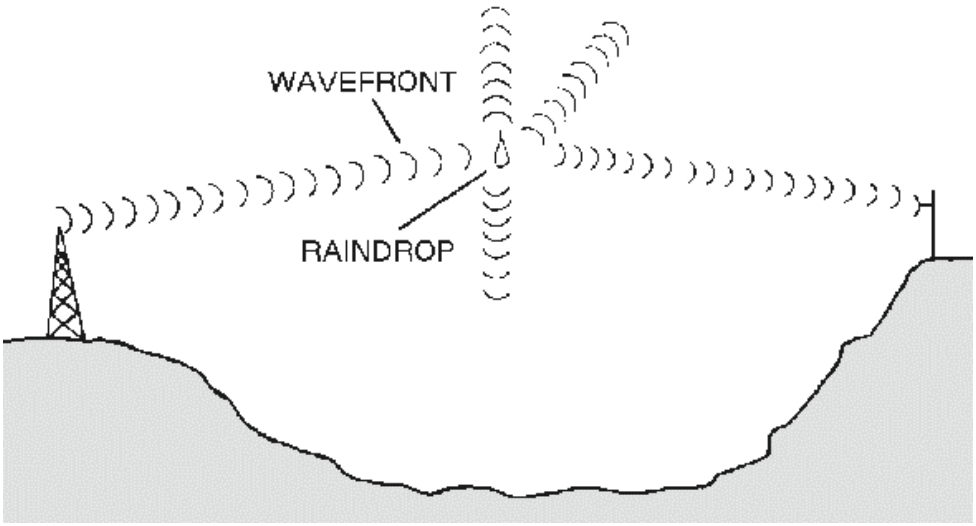

Figure 2-24.—Rf energy losses from scattering.

Fog

In the discussion of attenuation, fog may be considered as another form of rain. Since fog remains suspended in the atmosphere, the attenuation is determined by the quantity of water per unit volume and by the size of the droplets. Attenuation because of fog is of minor importance at frequencies lower than 2 gigahertz. However, fog can cause serious attenuation by absorption, at frequencies above 2 gigahertz.

Snow

The scattering effect because of snow is difficult to compute because of irregular sizes and shapes of the flakes. While information on the attenuating effect of snow is limited, scientists assume that attenuation from snow is less than from rain falling at an equal rate. This assumption is borne out by the fact that the density of rain is eight times the density of snow. As a result, rain falling at 1 inch per hour would have more water per cubic inch than snow falling at the same rate.

Hail

Attenuation by hail is determined by the size of the stones and their density. Attenuation of radio waves by scattering because of hailstones is considerably less than by rain.

TEMPERATURE INVERSION

Under normal atmospheric conditions, the warmest air is found near the surface of the Earth. The air gradually becomes cooler as altitude increases. At times, however, an unusual situation develops in which layers of warm air are formed above layers of cool air. This condition is known as TEMPERATURE INVERSION. These temperature inversions cause channels, or ducts, of cool air to be sandwiched between the surface of the Earth and a layer of warm air, or between two layers of warm air.

If a transmitting antenna extends into such a duct of cool air, or if the radio wave enters the duct at a very low angle of incidence, vhf and uhf transmissions may be propagated far beyond normal line-of-sight distances. When ducts are present as a result of temperature inversions, good reception of vhf and uhf television signals from a station located hundreds of miles away is not unusual. These long

distances are possible because of the different densities and refractive qualities of warm and cool air. The sudden change in density when a radio wave enters the warm air above a duct causes the wave to be refracted back toward Earth. When the wave strikes the Earth or a warm layer below the duct, it is again reflected or refracted upward and proceeds on through the duct with a multiple-hop type of action. An example of the propagation of radio waves by ducting is shown in figure 2-25.

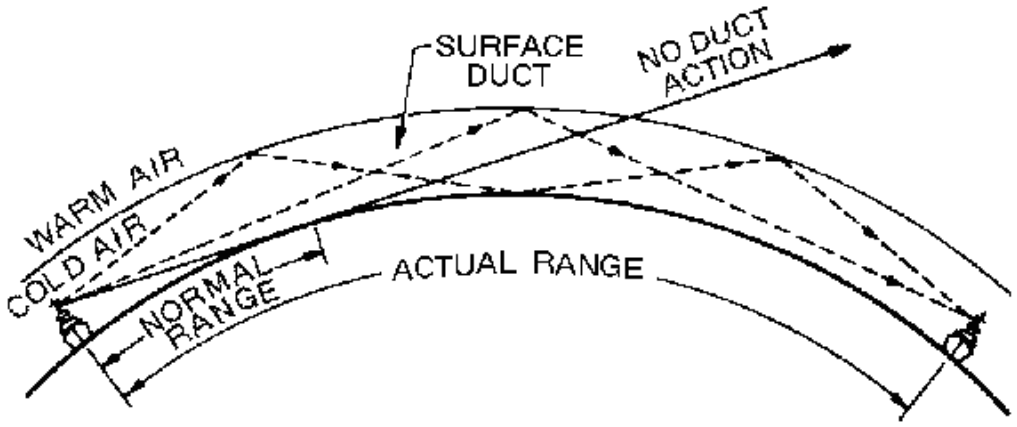

Figure 2-25.—Duct effect caused by temperature inversion.

Q42. How do raindrops affect radio waves?

Q43. How does fog affect radio waves at frequencies above 2 gigahertz?

Q44. How is the term "temperature inversion" used when referring to radio waves?

Q45. How does temperature inversion affect radio transmission?

TROPOSPHERIC PROPAGATION

As the lowest region of the Earth's atmosphere, the troposphere extends from the Earth's surface to a height of slightly over 7 miles. Virtually all weather phenomena occur in this region. Generally, the troposphere is characterized by a steady decrease in both temperature and pressure as height is increased. However, the many changes in weather phenomena cause variations in humidity and an uneven heating of the Earth's surface. As a result, the air in the troposphere is in constant motion. This motion causes small turbulences, or eddies, to be formed, as shown by the bouncing of aircraft entering turbulent areas of the atmosphere. These turbulences are most intense near the Earth's surface and gradually diminish with height. They have a refractive quality that permits the refracting or scattering of radio waves with short wavelengths. This scattering provides enhanced communications at higher frequencies.

Recall that in the relationship between frequency and wavelength, wavelength decreases as frequency increases and vice versa. Radio waves of frequencies below 30 megahertz normally have wavelengths longer than the size of weather turbulences. These radio waves are, therefore, affected very little by the turbulences. On the other hand, as the frequency increases into the vhf range and above, the wavelengths decrease in size, to the point that they become subject to tropospheric scattering. The usable frequency range for tropospheric scattering is from about 100 megahertz to 10 gigahertz.

TROPOSPHERIC SCATTERING

When a radio wave passing through the troposphere meets a turbulence, it makes an abrupt change in velocity. This causes a small amount of the energy to be scattered in a forward direction and returned to Earth at distances beyond the horizon. This phenomenon is repeated as the radio wave meets other turbulences in its path. The total received signal is an accumulation of the energy received from each of the turbulences.

This scattering mode of propagation enables vhf and uhf signals to be transmitted far beyond the normal line-of-sight. To better understand how these signals are transmitted over greater distances, you must first consider the propagation characteristics of the space wave used in vhf and uhf line-of-sight communications. When the space wave is transmitted, it undergoes very little attenuation within the line-of-sight horizon. When it reaches the horizon, the wave is diffracted and follows the Earth's curvature. Beyond the horizon, the rate of attenuation increases very rapidly and signals soon become very weak and unusable.

Tropospheric scattering, on the other hand, provides a usable signal at distances beyond the point where the diffracted space wave drops to an unusable level. This is because of the height at which scattering takes place. The turbulence that causes the scattering can be visualized as a relay station located above the horizon; it receives the transmitted energy and then reradiates it in a forward direction to some point beyond the line-of-sight distance. A high gain receiving antenna aimed toward this scattered energy can then capture it.

The magnitude of the received signal depends on the number of turbulences causing scatter in the desired direction and the gain of the receiving antenna. The scatter area used for tropospheric scatter is known as the *scatter volume*. The angle at which the receiving antenna must be aimed to capture the scattered energy is called the *scatter angle*. The scatter volume and scatter angle are shown in figure 2-26.

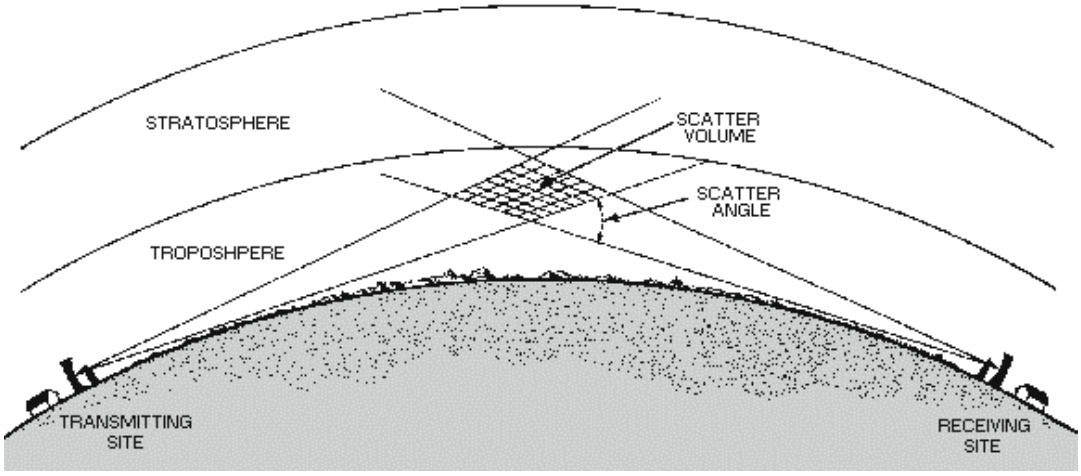

Figure 2-26.—Tropospheric scattering propagation.

The signal take-off angle (transmitting antenna's angle of radiation) determines the height of the scatter volume and the size of the scatter angle. A low signal take-off angle produces a low scatter volume, which in turn permits a receiving antenna that is aimed at a low angle to the scatter volume to capture the scattered energy.

As the signal take-off angle is increased, the height of the scatter volume is increased. When this occurs, the amount of received energy decreases. There are two reasons for this: (1) scatter angle

increases as the height of the scatter volume is increased; (2) the amount of turbulence decreases with height. As the distance between the transmitting and receiving antennas is increased, the height of the scatter volume must also be increased. The received signal level, therefore, decreases as circuit distance is increased.

The tropospheric region that contributes most strongly to tropospheric scatter propagation lies near the midpoint between the transmitting and receiving antennas and just above the radio horizon of the antennas.

Since tropospheric scatter depends on turbulence in the atmosphere, changes in atmospheric conditions have an effect on the strength of the received signal. Both daily and seasonal variations in signal strength occur as a result of changes in the atmosphere. These variations are called *long-term fading*.

In addition to long-term fading, the tropospheric scatter signal often is characterized by very rapid fading because of multipath propagation. Since the turbulent condition is constantly changing, the path lengths and individual signal levels are also changing, resulting in a rapidly changing signal. Although the signal level of the received signal is constantly changing, the average signal level is stable; therefore, no complete fade out occurs.

Another characteristic of a tropospheric scatter signal is its relatively low power level. Since very little of the scattered energy is reradiated toward the receiver, the efficiency is very low and the signal level at the final receiver point is low. Initial input power must be high to compensate for the low efficiency in the scatter volume. This is accomplished by using high-power transmitters and high-gain antennas, which concentrate the transmitted power into a beam, thus increasing the intensity of energy of each turbulence in the volume. The receiver must also be very sensitive to detect the low-level signals.

APPLICATION OF TROPOSPHERIC SCATTERING

Tropospheric scatter propagation is used for point-to-point communications. A correctly designed tropospheric scatter circuit will provide highly reliable service for distances ranging from 50 miles to 500 miles. Tropospheric scatter systems may be particularly useful for communications to locations in rugged terrain that are difficult to reach with other methods of propagation. One reason for this is that the tropospheric scatter circuit is not affected by ionospheric and auroral disturbances.

Q46. In what layer of the atmosphere does virtually all weather phenomena occur?

Q47. Which radio frequency bands use the tropospheric scattering principle for propagation of radio waves?

Q48. Where is the tropospheric region that contributes most strongly to tropospheric scatter propagation?

SUMMARY

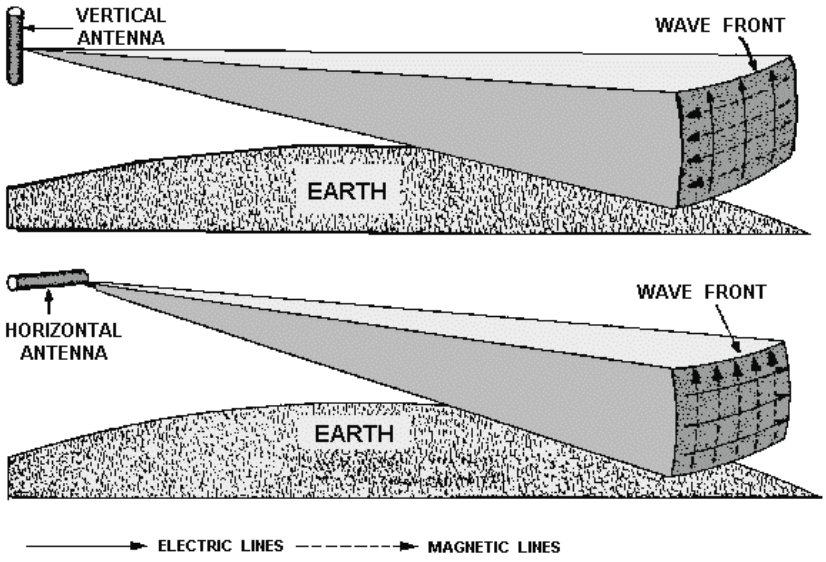
Now that you have completed this chapter, let's review some of the new terms, concepts, and ideas that you have learned. You should have a thorough understanding of these principles before moving on to chapter 3.

The **INDUCTION FIELD** contains an E field and an H field and is localized near the antenna. The E and H fields of the induction field are 90 degrees out of phase with each other.

The **RADIATION FIELD** contains E and H fields that are propagated from the antenna into space in the form of electromagnetic waves. The E and H fields of the radiation field are in phase with each other.

A **HARMONIC FREQUENCY** is any frequency that is a whole number multiple of a smaller basic frequency. For example, a radio wave transmitted at a fundamental frequency of 3000 hertz can have a second harmonic of 6000 hertz, a third harmonic frequency of 9000 hertz, etc., transmitted at the same time.

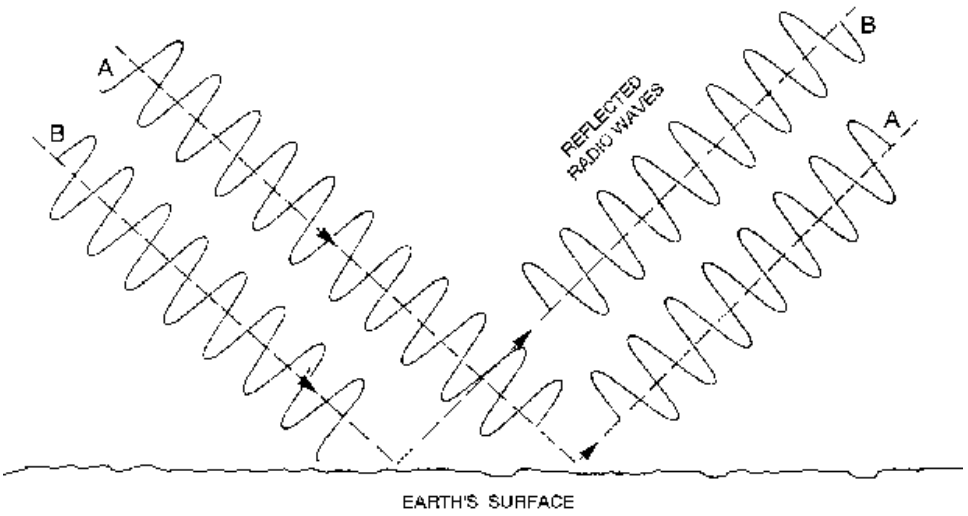
A **VERTICALLY POLARIZED** antenna transmits an electromagnetic wave with the E field perpendicular to the Earth's surface. A **HORIZONTALLY POLARIZED** antenna transmits a radio wave with the E field parallel to the Earth's surface.



A **WAVEFRONT** is a small section of an expanding sphere of radiated energy and is perpendicular to the direction of travel from the antenna.

RADIO WAVES are electromagnetic waves that can be reflected, refracted, and diffracted in the atmosphere like light and heat waves.

REFLECTED RADIO WAVES are waves that have been reflected from a surface and are 180 degrees out of phase with the initial wave.



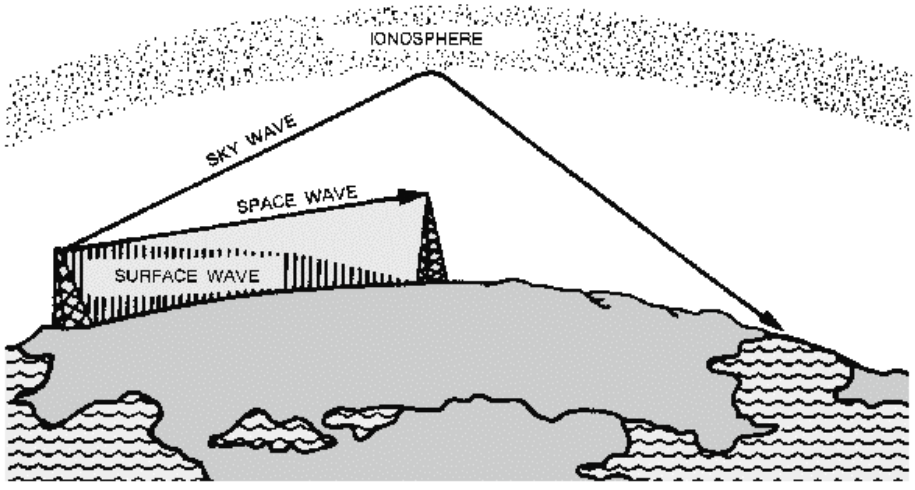
The Earth's atmosphere is divided into three separate layers: The **TROPOSPHERE**, **STRATOSPHERE**, and **IONOSPHERE**.

The **TROPOSPHERE** is the region of the atmosphere where virtually all weather phenomena take place. In this region, rf energy is greatly affected.

The **STRATOSPHERE** has a constant temperature and has little effect on radio waves.

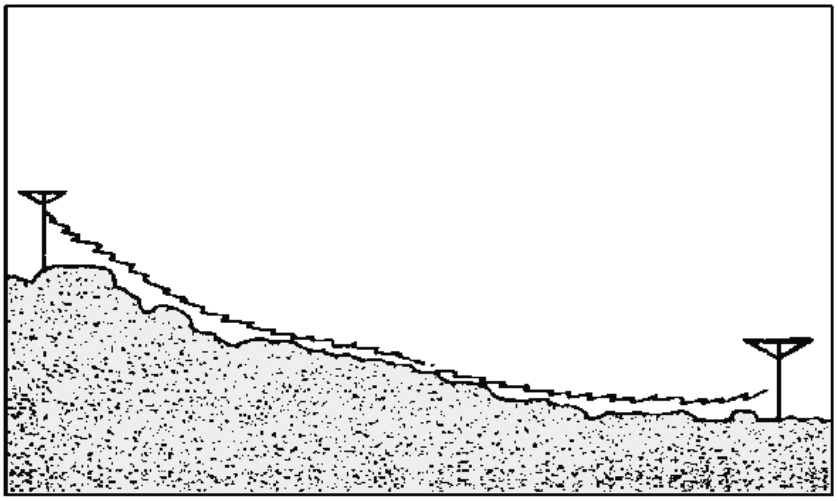
The **IONOSPHERE** contains four cloud-like layers of electrically charged ions which aid in long distance communications.

GROUND WAVES and **SKY WAVES** are the two basic types of radio waves that transmit energy from the transmitting antenna to the receiving antenna.

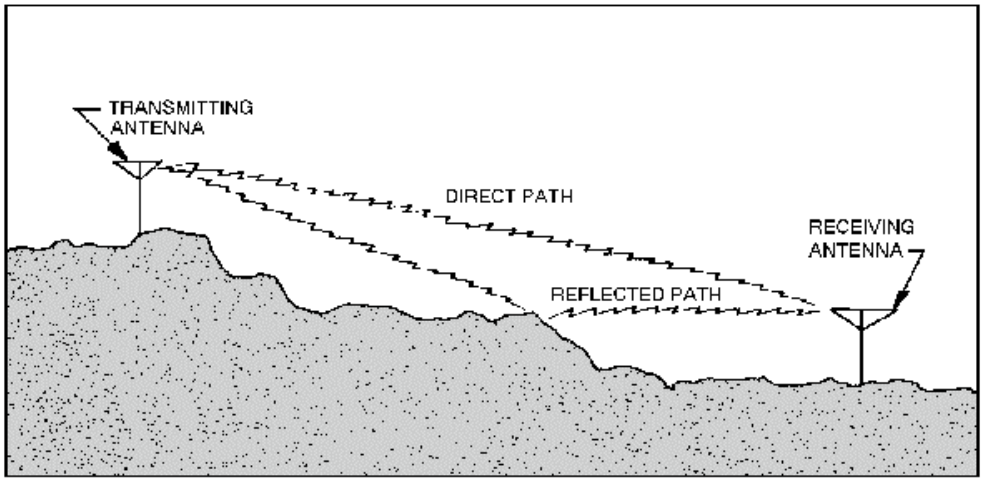


GROUND WAVES are composed of two separate component waves: the **SURFACE WAVE** and the **SPACE WAVE**.

SURFACE WAVES travel along the contour of the Earth by diffraction.



SPACE WAVES can travel through the air directly to the receiving antenna or can be reflected from the surface of the Earth.



SKY WAVES, often called ionospheric waves, are radiated in an upward direction and returned to Earth at some distant location because of refraction.

NATURAL HORIZON is the line-of-sight horizon.

RADIO HORIZON is one-third farther than the natural horizon.

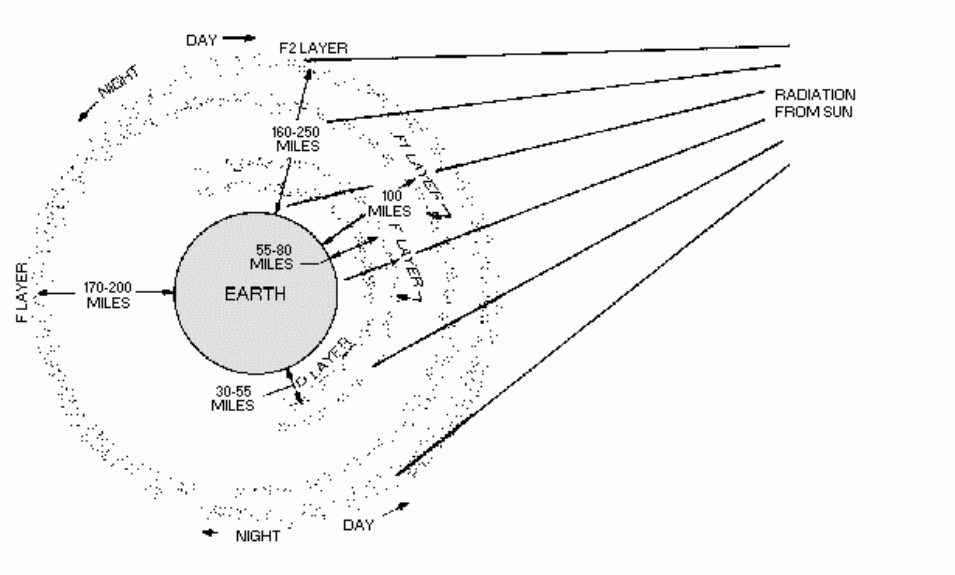
The **IONOSPHERE** consists of several layers of ions, formed by the process called ionization.

IONIZATION is the process of knocking electrons free from their parent atom, thus upsetting electrical neutrality.

RECOMBINATION is the opposite of ionization; that is, the free ions combine with positive ions, causing the positive ions to return to their original neutral atom state.

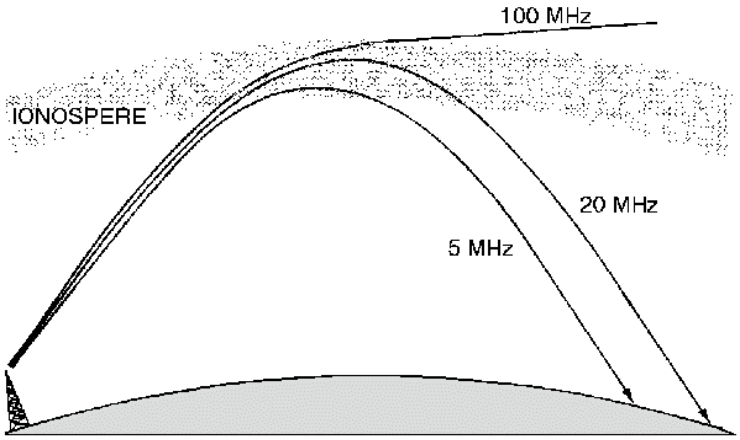
The **D LAYER** is the lowest region of the ionosphere and refracts signals of low frequencies back to Earth.

The **E LAYER** is present during the daylight hours; refracts signals as high as 20 megahertz back to Earth; and is used for communications up to 1500 miles.

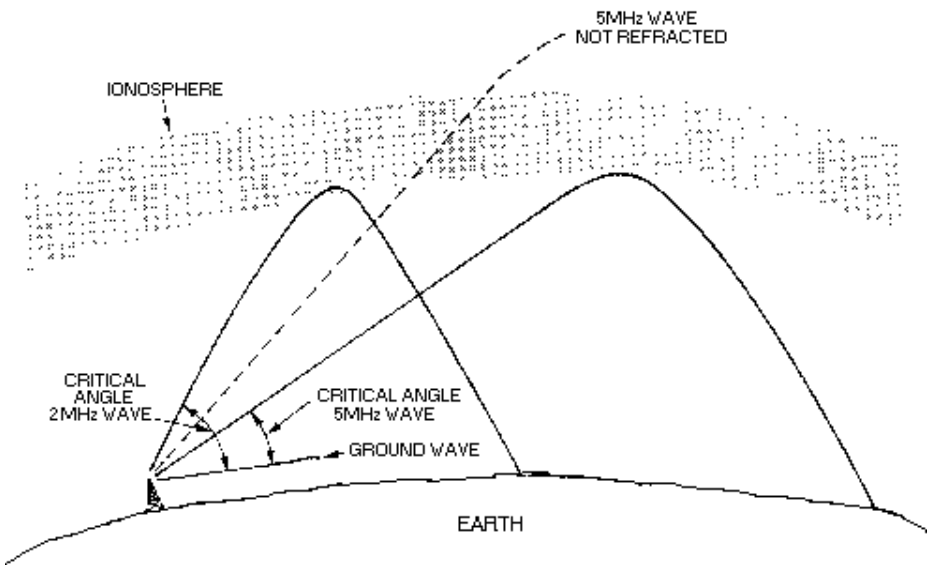


The **F LAYER** is divided into the F1 and F2 layers during the day but combine at night to form one layer. This layer is responsible for high-frequency, long-range transmission.

The **CRITICAL FREQUENCY** is the maximum frequency that a radio wave can be transmitted vertically and still be refracted back to Earth.

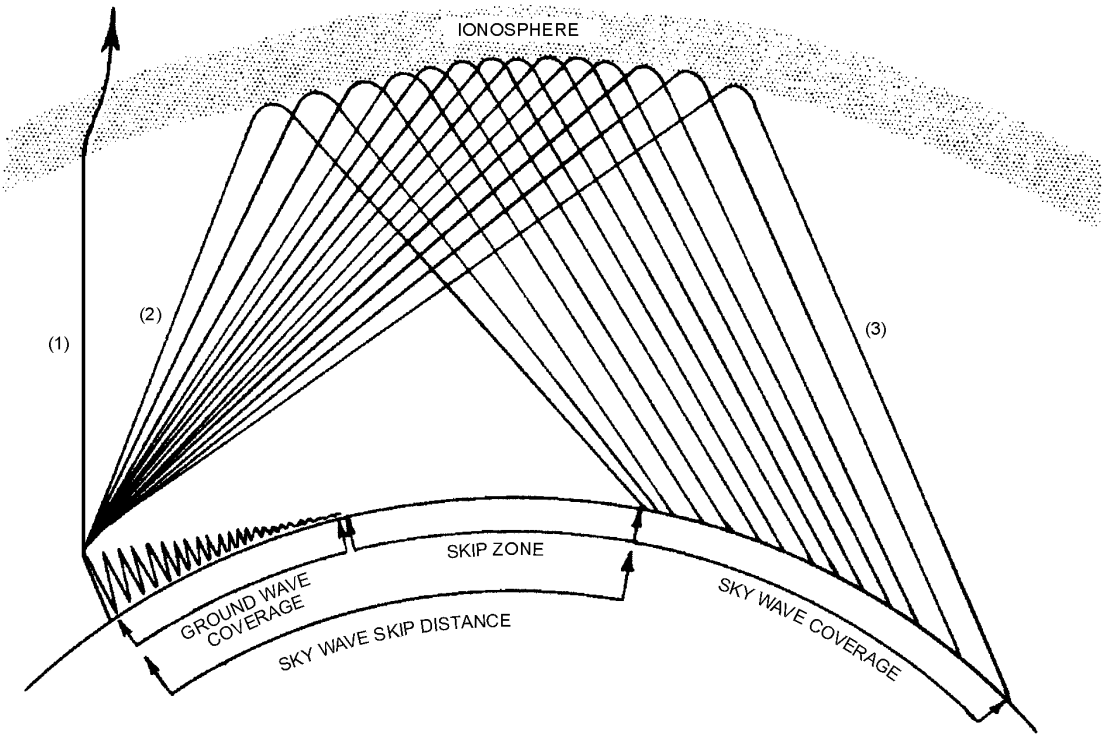


The **CRITICAL ANGLE** is the maximum and/or minimum angle that a radio wave can be transmitted and still be refracted back to Earth.



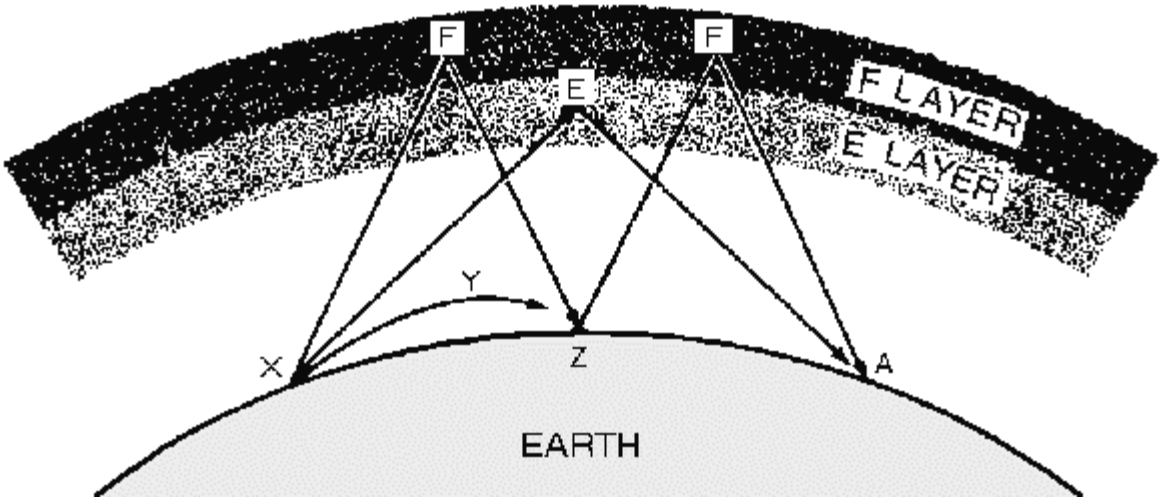
SKIP DISTANCE is the distance between the transmitter and the point where the sky wave first returns to Earth.

SKIP ZONE is the zone of silence between the point where the ground wave becomes too weak for reception and the point where the sky wave is first returned to Earth.



FADING is caused by variations in signal strength, such as absorption of the rf energy by the ionosphere.

MULTIPATH FADING occurs when a transmitted signal divides and takes more than one path to a receiver and some of the signals arrive out of phase, resulting in a weak or fading signal.

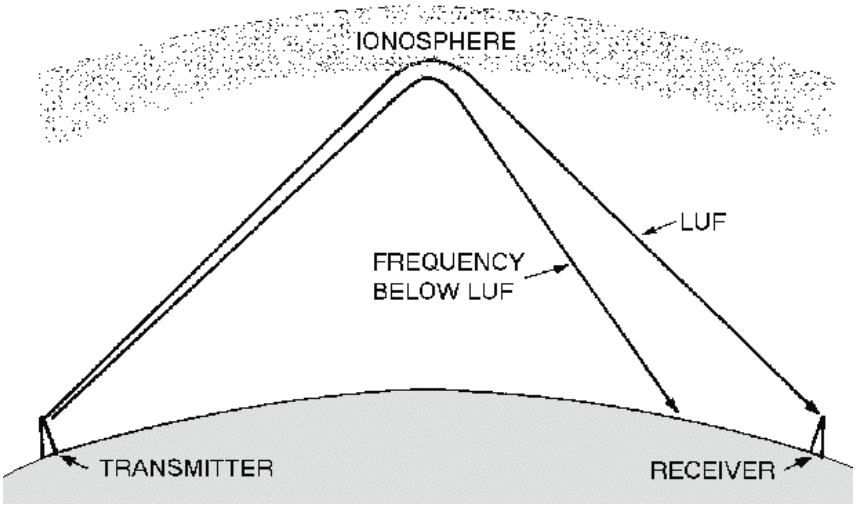


Some **TRANSMISSION LOSSES** that affect radio-wave propagation are ionospheric absorption, ground reflection, and free-space losses.

ELECTROMAGNETIC INTERFERENCE (emi), both natural and man-made, interfere with radio communications.

The **MAXIMUM USABLE FREQUENCY (muf)** is the highest frequency that can be used for communications between two locations at a given angle of incidence and time of day.

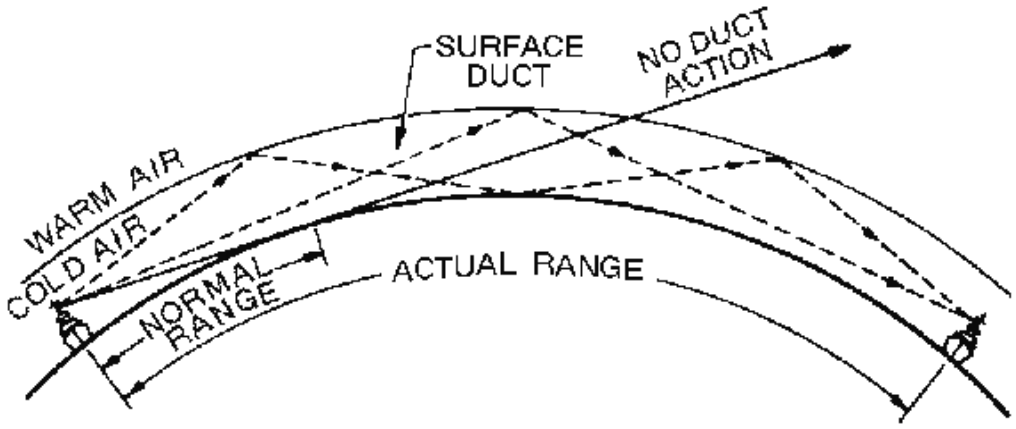
The **LOWEST USABLE FREQUENCY (luf)** is the lowest frequency that can be used for communications between two locations.



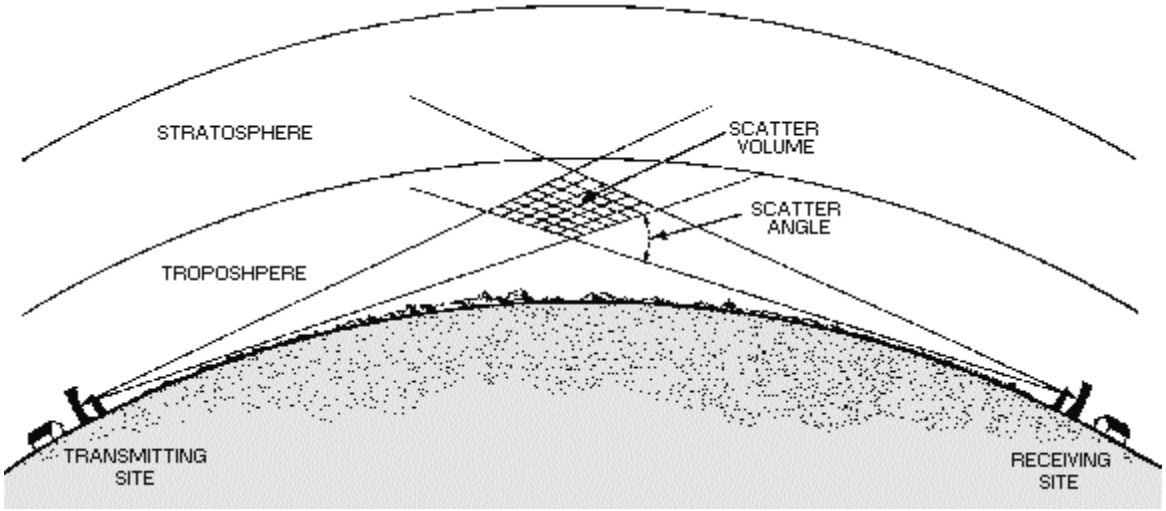
OPTIMUM WORKING FREQUENCY (fot) is the most practical operating frequency and the one that can be relied on to have the fewest problems.

PRECIPITATION ATTENUATION can be caused by rain, fog, snow, and hail; and can affect overall communications considerably.

TEMPERATURE INVERSION causes channels, or ducts, of cool air to form between layers of warm air, which can cause radio waves to travel far beyond the normal line-of-sight distances.



TROPOSPHERIC PROPAGATION uses the scattering principle to achieve beyond the line-of-sight radio communications within the troposphere.



ANSWERS TO QUESTIONS Q1. THROUGH Q48.

A1. Induction field and radiation field.

A2. Induction field.

A3. Radiation field.

A4. Fundamental frequency.

A5. Harmonic frequency or harmonics.

A6. 30 meters.

A7. 5 megahertz.

A8. Vertically polarized.

A9. Direction of wave propagation.

A10. Shifting in the phase relationships of the wave.

A11. Troposphere, stratosphere, and ionosphere.

A12. Stratosphere.

A13. Whether the component of the wave is travelling along the surface or over the surface of the earth.

A14. Radio horizon is about 1/3 farther.

A15. Sea water.

A16. (a) electrical properties of the terrain (b) frequency (c) polarization of the antenna

A17. High energy ultraviolet light waves from the sun.

A18. D, E, F_1, and F_2 layers.

A19. D layer is 30-55 miles, E layer 55-90 miles, and F layers are 90-240 miles.

A20. Thickness of ionized layer.

A21. Critical frequency.

A22. (a) density of ionization of the layer (b) frequency (c) angle at which it enters the layer

A23. A zone of silence between the ground wave and sky wave where there is no reception.

A24. Where ionization density is greatest.

A25. A term used to describe the multiple pattern a radio wave may follow.

A26. Selective fading.

A27. Natural and man-made interference.

A28. Natural.

A29. Man-made.

A30. (a) filtering and shielding of the transmitter (b) limiting bandwidth (c) cutting the antenna to the correct frequency

A31. (a) physical separation of the antenna (b) limiting bandwidth of the antenna (c) use of directional antennas

A32. Regular and irregular variations.

A33. Regular variations can be predicted but irregular variations are unpredictable.

A34. Daily, seasonal, 11-year, and 27-days variation.

A35. Sporadic E, sudden disturbances, and ionospheric storms.

A36. Muf is maximum usable frequency. Luf is lowest usable frequency. Fot is commonly known as optimum working frequency.

A37. Muf is highest around noon. Ultraviolet light waves from the sun are most intense.

A38. When luf is too low it is absorbed and is too weak for reception.

A39. Signal-to-noise ratio is low and the probability of multipath propagation is greater.

A40. Frequent signal fading and dropouts.

A41. Fot is the most practical operating frequency that can be relied on to avoid problems of multipath, absorbtion, and noise.

A42. They can cause attenuation by scattering.

A43. It can cause attenuation by absorbtion.

A44. It is a condition where layers of warm air are formed above layers of cool air.

A45. It can cause vhf and uhf transmission to be propagated far beyond normal line-of-sight distances.

A46. Troposphere.

A47. Vhf and above.

A48. Near the mid-point between the transmitting and receiving antennas, just above the radio horizon.

CHAPTER 3

PRINCIPLES OF TRANSMISSION LINES

LEARNING OBJECTIVES

Upon completion of this chapter, you will be able to:

1. State what a transmission line is and how transmission lines are used.
2. Explain the operating principles of transmission lines.
3. Describe the five types of transmission lines.
4. State the length of a transmission line.
5. Explain the theory of the transmission line.
6. Define the term LUMPED CONSTANTS in relation to a transmission line.
7. Define the term DISTRIBUTED CONSTANTS in relation to a transmission line.
8. Define LEAKAGE CURRENT.
9. Describe how the electromagnetic lines of force around a transmission line are affected by the distributed constants.
10. Define the term CHARACTERISTIC IMPEDANCE and explain how it affects the transfer of energy along a transmission line.
11. State how the energy transfer along a transmission line is affected by characteristic impedance and the infinite line.
12. Identify the cause of and describe the characteristics of reflections on a transmission line.
13. Define the term STANDING WAVES as applied to a transmission line.
14. Describe how standing waves are produced on a transmission line and identify the types of terminations.
15. Describe the types of standing-wave ratios.

INTRODUCTION TO TRANSMISSION LINES

A TRANSMISSION LINE is a device designed to guide electrical energy from one point to another. It is used, for example, to transfer the output rf energy of a transmitter to an antenna. This energy will not travel through normal electrical wire without great losses. Although the antenna can be connected directly to the transmitter, the antenna is usually located some distance away from the transmitter. On board ship,

the transmitter is located inside a radio room and its associated antenna is mounted on a mast. A transmission line is used to connect the transmitter and the antenna.

The transmission line has a single purpose for both the transmitter and the antenna. This purpose is to transfer the energy output of the transmitter to the antenna with the least possible power loss. How well this is done depends on the special physical and electrical characteristics (impedance and resistance) of the transmission line.

TERMINOLOGY

All transmission lines have two ends (see figure 3-1). The end of a two-wire transmission line connected to a source is ordinarily called the INPUT END or the GENERATOR END. Other names given to this end are TRANSMITTER END, SENDING END, and SOURCE. The other end of the line is called the OUTPUT END or RECEIVING END. Other names given to the output end are LOAD END and SINK.

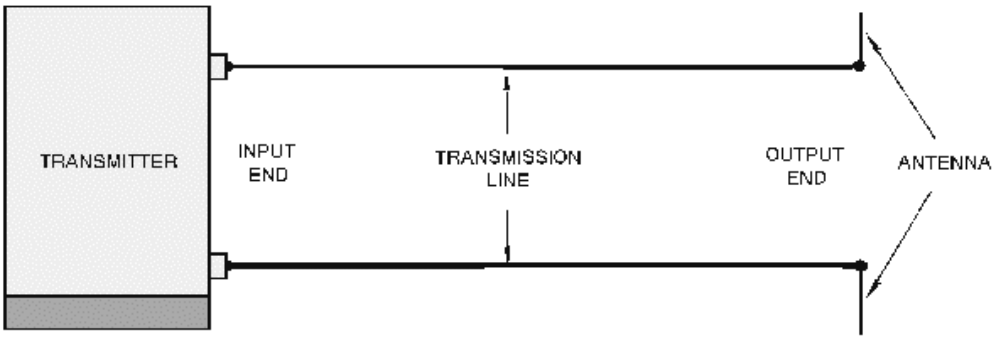


Figure 3-1.—Basic transmission line.

You can describe a transmission line in terms of its impedance. The ratio of voltage to current (E_{in}/I_{in}) at the input end is known as the INPUT IMPEDANCE (Z_{in}). This is the impedance presented to the transmitter by the transmission line and its load, the antenna. The ratio of voltage to current at the output (E_{out}/I_{out}) end is known as the OUTPUT IMPEDANCE (Z_{out}). This is the impedance presented to the load by the transmission line and its source. If an infinitely long transmission line could be used, the ratio of voltage to current at any point on that transmission line would be some particular value of impedance. This impedance is known as the CHARACTERISTIC IMPEDANCE.

Q1. What connecting link is used to transfer energy from a radio transmitter to its antenna located on the mast of a ship?

Q2. What term is used for the end of the transmission line that is connected to a transmitter?

Q3. What term is used for the end of the transmission line that is connected to an antenna?

TYPES OF TRANSMISSION MEDIUMS

The Navy uses many different types of TRANSMISSION MEDIUMS in its electronic applications. Each medium (line or wave guide) has a certain characteristic impedance value, current-carrying capacity, and physical shape and is designed to meet a particular requirement.

The five types of transmission mediums that we will discuss in this chapter include PARALLEL-LINE, TWISTED PAIR, SHIELDED PAIR, COAXIAL LINE, and WAVEGUIDES. The use of a particular line depends, among other things, on the applied frequency, the power-handling capabilities, and the type of installation.

NOTE: In the following paragraphs, we will mention LOSSES several times. We will discuss these losses more thoroughly under "LOSSES IN TRANSMISSION LINES."

Two-Wire Open Line

One type of parallel line is the TWO-WIRE OPEN LINE illustrated in figure 3-2. This line consists of two wires that are generally spaced from 2 to 6 inches apart by insulating spacers. This type of line is most often used for power lines, rural telephone lines, and telegraph lines. It is sometimes used as a transmission line between a transmitter and an antenna or between an antenna and a receiver. An advantage of this type of line is its simple construction. The principal disadvantages of this type of line are the high radiation losses and electrical noise pickup because of the lack of shielding. Radiation losses are produced by the changing fields created by the changing current in each conductor.

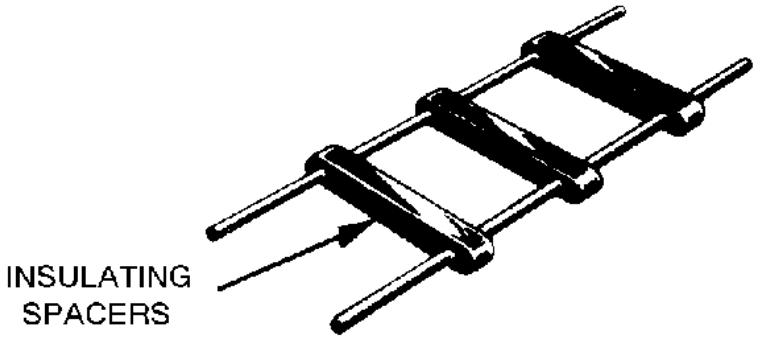

Figure 3-2.—Parallel two-wire line.

Another type of parallel line is the TWO-WIRE RIBBON (TWIN LEAD) illustrated in figure 3-3. This type of transmission line is commonly used to connect a television receiving antenna to a home television set. This line is essentially the same as the two-wire open line except that uniform spacing is assured by embedding the two wires in a low-loss dielectric, usually polyethylene. Since the wires are embedded in the thin ribbon of polyethylene, the dielectric space is partly air and partly polyethylene.

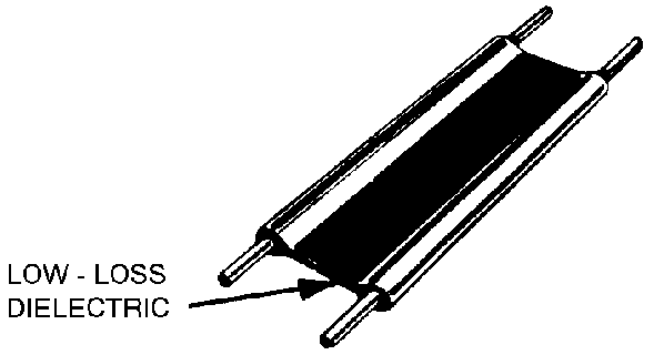

Figure 3-3.—Two-wire ribbon type line.

Twisted Pair

The TWISTED PAIR transmission line is illustrated in figure 3-4. As the name implies, the line consists of two insulated wires twisted together to form a flexible line without the use of spacers. It is not used for transmitting high frequency because of the high dielectric losses that occur in the rubber insulation. When the line is wet, the losses increase greatly.

Figure 3-4.—Twisted pair.

Shielded Pair

The SHIELDED PAIR, shown in figure 3-5, consists of parallel conductors separated from each other and surrounded by a solid dielectric. The conductors are contained within a braided copper tubing that acts as an electrical shield. The assembly is covered with a rubber or flexible composition coating that protects the line from moisture and mechanical damage. Outwardly, it looks much like the power cord of a washing machine or refrigerator.

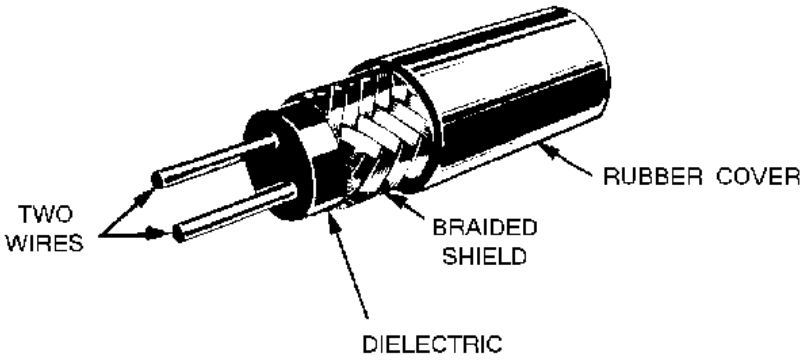

Figure 3-5.—Shielded pair.

The principal advantage of the shielded pair is that the conductors are balanced to ground; that is, the capacitance between the wires is uniform throughout the length of the line. This balance is due to the uniform spacing of the grounded shield that surrounds the wires along their entire length. The braided copper shield isolates the conductors from stray magnetic fields.

Coaxial Lines

There are two types of COAXIAL LINES, RIGID (AIR) COAXIAL LINE and FLEXIBLE (SOLID) COAXIAL LINE. The physical construction of both types is basically the same; that is, each contains two concentric conductors.

The rigid coaxial line consists of a central, insulated wire (inner conductor) mounted inside a tubular outer conductor. This line is shown in figure 3-6. In some applications, the inner conductor is also tubular. The inner conductor is insulated from the outer conductor by insulating spacers or beads at regular intervals. The spacers are made of Pyrex, polystyrene, or some other material that has good insulating characteristics and low dielectric losses at high frequencies.

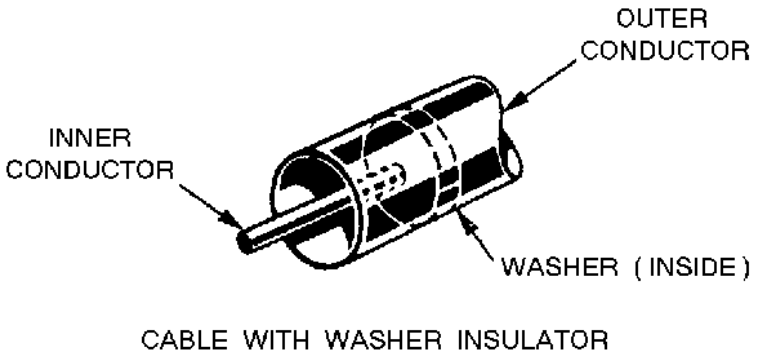

Figure 3-6.—Air coaxial line.

The chief advantage of the rigid line is its ability to minimize radiation losses. The electric and magnetic fields in a two-wire parallel line extend into space for relatively great distances and radiation losses occur. However, in a coaxial line no electric or magnetic fields extend outside of the outer conductor. The fields are confined to the space between the two conductors, resulting in a perfectly shielded coaxial line. Another advantage is that interference from other lines is reduced.

The rigid line has the following disadvantages: (1) it is expensive to construct; (2) it must be kept dry to prevent excessive leakage between the two conductors; and (3) although high-frequency losses are somewhat less than in previously mentioned lines, they are still excessive enough to limit the practical length of the line.

Leakage caused by the condensation of moisture is prevented in some rigid line applications by the use of an inert gas, such as nitrogen, helium, or argon. It is pumped into the dielectric space of the line at a pressure that can vary from 3 to 35 pounds per square inch. The inert gas is used to dry the line when it is first installed and pressure is maintained to ensure that no moisture enters the line.

Flexible coaxial lines (figure 3-7) are made with an inner conductor that consists of flexible wire insulated from the outer conductor by a solid, continuous insulating material. The outer conductor is made of metal braid, which gives the line flexibility. Early attempts at gaining flexibility involved using rubber insulators between the two conductors. However, the rubber insulators caused excessive losses at high frequencies.

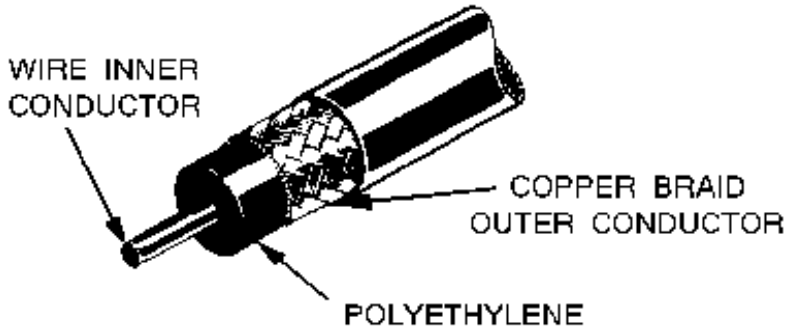

Figure 3-7.—Flexible coaxial line.

Because of the high-frequency losses associated with rubber insulators, polyethylene plastic was developed to replace rubber and eliminate these losses. Polyethylene plastic is a solid substance that remains flexible over a wide range of temperatures. It is unaffected by seawater, gasoline, oil, and most other liquids that may be found aboard ship. The use of polyethylene as an insulator results in greater high-frequency losses than the use of air as an insulator. However, these losses are still lower than the losses associated with most other solid dielectric materials.

Waveguides

The WAVEGUIDE is classified as a transmission line. However, the method by which it transmits energy down its length differs from the conventional methods. Waveguides are cylindrical, elliptical, or rectangular (cylindrical and rectangular shapes are shown in figure 3-8). The rectangular waveguide is used more frequently than the cylindrical waveguide.

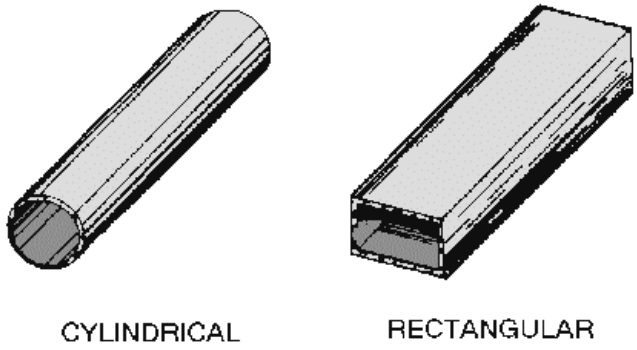

Figure 3-8.—Waveguides.

The term *waveguide* can be applied to all types of transmission lines in the sense that they are all used to guide energy from one point to another. However, usage has generally limited the term to mean a hollow metal tube or a dielectric transmission line. In this chapter, we use the term *waveguide* only to mean "hollow metal tube." It is interesting to note that the transmission of electromagnetic energy along a waveguide travels at a velocity somewhat slower than electromagnetic energy traveling through free space.

A waveguide may be classified according to its cross section (rectangular, elliptical, or circular), or according to the material used in its construction (metallic or dielectric). Dielectric waveguides are

seldom used because the dielectric losses for all known dielectric materials are too great to transfer the electric and magnetic fields efficiently.

The installation of a complete waveguide transmission system is somewhat more difficult than the installation of other types of transmission lines. The radius of bends in the waveguide must measure greater than two wavelengths at the operating frequency of the equipment to avoid excessive attenuation. The cross section must remain uniform around the bend. These requirements hamper installation in confined spaces. If the waveguide is dented, or if solder is permitted to run inside the joints, the attenuation of the line is greatly increased. Dents and obstructions in the waveguide also reduce its breakdown voltage, thus limiting the waveguide's power-handling capability because of possible arc over. Great care must be exercised during installation; one or two carelessly made joints can seriously inhibit the advantage of using the waveguide.

We will not consider the waveguide operation in this module, since waveguide theory is discussed in *NEETS*, Module 11, *Microwave Principles*.

Q4. List the five types of transmission lines in use today.

Q5. Name two of the three described uses of a two-wire open line.

Q6. What are the two primary disadvantages of a two-wire open line?

Q7. What type of transmission line is often used to connect a television set to its antenna?

Q8. What is the primary advantage of the shielded pair?

Q10. What is the chief advantage of the air coaxial line?

Q11. List the three disadvantages of the air coaxial line.

Q12. List the two common types of waveguides in use today.

LOSSES IN TRANSMISSION LINES

The discussion of transmission lines so far has not directly addressed LINE LOSSES; actually some line losses occur in all lines. Line losses may be any of three types—COPPER, DIELECTRIC, and RADIATION or INDUCTION LOSSES.

NOTE: Transmission lines are sometimes referred to as rf lines. In this text the terms are used interchangeably.

Copper Losses

One type of copper loss is I^2R LOSS. In rf lines the resistance of the conductors is never equal to zero. Whenever current flows through one of these conductors, some energy is dissipated in the form of heat. This heat loss is a POWER LOSS. With copper braid, which has a resistance higher than solid tubing, this power loss is higher.

Another type of copper loss is due to SKIN EFFECT. When dc flows through a conductor, the movement of electrons through the conductor's cross section is uniform. The situation is somewhat different when ac is applied. The expanding and collapsing fields about each electron encircle other electrons. This phenomenon, called SELF INDUCTION, retards the movement of the encircled electrons.

The flux density at the center is so great that electron movement at this point is reduced. As frequency is increased, the opposition to the flow of current in the center of the wire increases. Current in the center of the wire becomes smaller and most of the electron flow is on the wire surface. When the frequency applied is 100 megahertz or higher, the electron movement in the center is so small that the center of the wire could be removed without any noticeable effect on current. You should be able to see that the effective cross-sectional area decreases as the frequency increases. Since resistance is inversely proportional to the cross-sectional area, the resistance will increase as the frequency is increased. Also, since power loss increases as resistance increases, power losses increase with an increase in frequency because of skin effect.

Copper losses can be minimized and conductivity increased in an rf line by plating the line with silver. Since silver is a better conductor than copper, most of the current will flow through the silver layer. The tubing then serves primarily as a mechanical support.

Dielectric Losses

DIELECTRIC LOSSES result from the heating effect on the dielectric material between the conductors. Power from the source is used in heating the dielectric. The heat produced is dissipated into the surrounding medium. When there is no potential difference between two conductors, the atoms in the dielectric material between them are normal and the orbits of the electrons are circular. When there is a potential difference between two conductors, the orbits of the electrons change. The excessive negative charge on one conductor repels electrons on the dielectric toward the positive conductor and thus distorts the orbits of the electrons. A change in the path of electrons requires more energy, introducing a power loss.

The atomic structure of rubber is more difficult to distort than the structure of some other dielectric materials. The atoms of materials, such as polyethylene, distort easily. Therefore, polyethylene is often used as a dielectric because less power is consumed when its electron orbits are distorted.

Radiation and Induction Losses

RADIATION and INDUCTION LOSSES are similar in that both are caused by the fields surrounding the conductors. Induction losses occur when the electromagnetic field about a conductor cuts through any nearby metallic object and a current is induced in that object. As a result, power is dissipated in the object and is lost.

Radiation losses occur because some magnetic lines of force about a conductor do not return to the conductor when the cycle alternates. These lines of force are projected into space as radiation and this results in power losses. That is, power is supplied by the source, but is not available to the load.

Q13. What are the three types of line losses associated with transmission lines?

Q14. Losses caused by skin effect and the I^2R (power) loss are classified as what type of loss?

Q15. What types of losses cause the dielectric material between the conductors to be heated?

LENGTH OF A TRANSMISSION LINE

A transmission line is considered to be electrically short when its physical length is short compared to a quarter-wavelength ($1/4\lambda$) of the energy it is to carry.

NOTE: In this module, for ease of reading, the value of the wavelength will be spelled out in some cases, and in other cases, the numerical value will be used.

A transmission line is electrically long when its physical length is long compared to a quarter-wavelength of the energy it is to carry. You must understand that the terms "short" and "long" are relative ones. For example, a line that has a physical length of 3 meters (approximately 10 feet) is considered quite short electrically if it transmits a radio frequency of 30 kilohertz. On the other hand, the same transmission line is considered electrically long if it transmits a frequency of 30,000 megahertz.

To show the difference in physical and electrical lengths of the lines mentioned above, compute the wavelength of the two frequencies, taking the 30-kilohertz example first:

Given:

$$\lambda = \frac{v}{f}$$

Where:

λ = Wavelength
v = Velocity of rf in free space
f = Frequency of transmission
Hz = Cycles per second

$$\lambda = \frac{300 \times 10^6 \text{ meters/second}}{30 \times 10^3 \text{ cycles/second (Hz)}}$$

$\lambda = 10 \times 10^3$ meters/cycle
λ = 10,000 meters, or approxiamtely 6 miles for complete wavelength

Now, computing the wavelength for the line carrying 30,000 megahertz:

$$\lambda = \frac{v}{f}$$

$$\lambda = \frac{300 \times 10^6 \text{ meters/second}}{30{,}000 \times 10^6 \text{ cycles/second (Hz)}}$$

$$\lambda = \frac{1}{100} \text{ meter/cycle}$$

λ = .01 meter, or approximately .03 foot for a complete wavelength

Thus, you can see that a 3-meter line is electrically very short for a frequency of 30 kilohertz. Also, the 3-meter line is electrically very long for a frequency of 30,000 megahertz.

When power is applied to a very short transmission line, practically all of it reaches the load at the output end of the line. This very short transmission line is usually considered to have practically no electrical properties of its own, except for a small amount of resistance.

However, the picture changes considerably when a long line is used. Since most transmission lines are electrically long (because of the distance from transmitter to antenna), the properties of such lines must be considered. Frequently, the voltage necessary to drive a current through a long line is considerably greater than the amount that can be accounted for by the impedance of the load in series with the resistance of the line.

TRANSMISSION LINE THEORY

The electrical characteristics of a two-wire transmission line depend primarily on the construction of the line. The two-wire line acts like a long capacitor. The change of its capacitive reactance is noticeable as the frequency applied to it is changed. Since the long conductors have a magnetic field about them when electrical energy is being passed through them, they also exhibit the properties of inductance. The values of inductance and capacitance presented depend on the various physical factors that we discussed earlier. For example, the type of line used, the dielectric in the line, and the length of the line must be considered. The effects of the inductive and capacitive reactances of the line depend on the frequency applied. Since no dielectric is perfect, electrons manage to move from one conductor to the other through the dielectric. Each type of two-wire transmission line also has a conductance value. This conductance value represents the value of the current flow that may be expected through the insulation. If the line is uniform (all values equal at each unit length), then one small section of the line may represent several feet. This illustration of a two-wire transmission line will be used throughout the discussion of transmission lines; but, keep in mind that the principles presented apply to all transmission lines. We will explain the theories using LUMPED CONSTANTS and DISTRIBUTED CONSTANTS to further simplify these principles.

LUMPED CONSTANTS

A transmission line has the properties of inductance, capacitance, and resistance just as the more conventional circuits have. Usually, however, the constants in conventional circuits are lumped into a single device or component. For example, a coil of wire has the property of inductance. When a certain amount of inductance is needed in a circuit, a coil of the proper dimensions is inserted. The inductance of the circuit is lumped into the one component. Two metal plates separated by a small space, can be used to supply the required capacitance for a circuit. In such a case, most of the capacitance of the circuit is lumped into this one component. Similarly, a fixed resistor can be used to supply a certain value of circuit resistance as a lumped sum. Ideally, a transmission line would also have its constants of inductance, capacitance, and resistance lumped together, as shown in figure 3-9. Unfortunately, this is not the case. Transmission line constants are *distributed*, as described below.

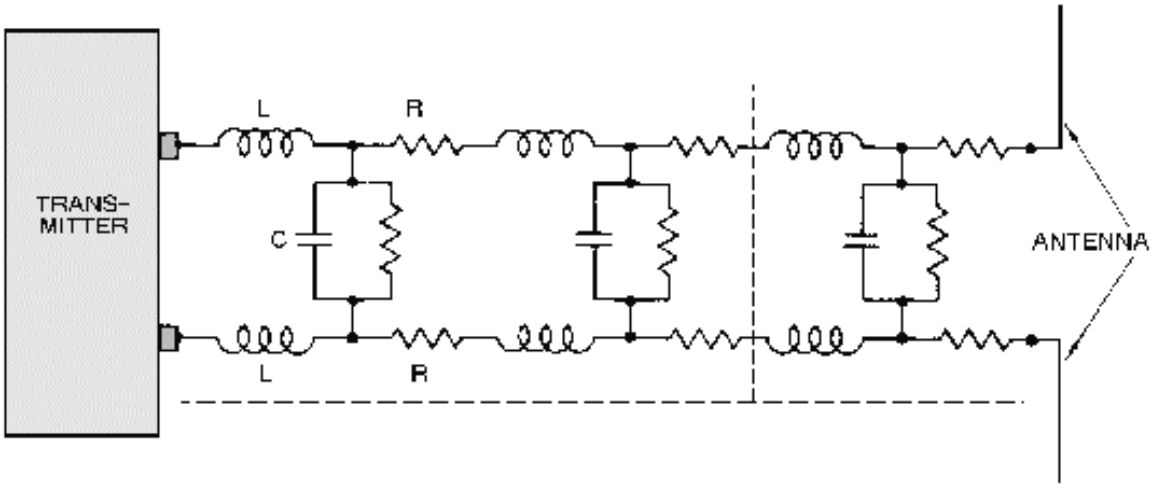

Figure 3-9.—Equivalent circuit of a two-wire transmission line.

DISTRIBUTED CONSTANTS

Transmission line constants, called *distributed constants*, are spread along the entire length of the transmission line and cannot be distinguished separately. The amount of inductance, capacitance, and resistance depends on the length of the line, the size of the conducting wires, the spacing between the wires, and the dielectric (air or insulating medium) between the wires. The following paragraphs will be useful to you as you study distributed constants on a transmission line.

Inductance of a Transmission Line

When current flows through a wire, magnetic lines of force are set up around the wire. As the current increases and decreases in amplitude, the field around the wire expands and collapses accordingly. The energy produced by the magnetic lines of force collapsing back into the wire tends to keep the current flowing in the same direction. This represents a certain amount of inductance, which is expressed in *microhenrys per unit length*. Figure 3-10 illustrates the inductance and magnetic fields of a transmission line.

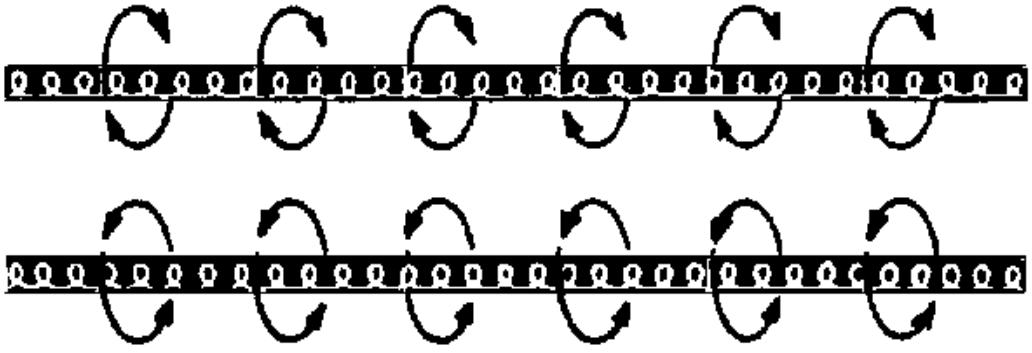

Figure 3-10.—Distributed inductance

Capacitance of a Transmission Line

Capacitance also exists between the transmission line wires, as illustrated in figure 3-11. Notice that the two parallel wires act as plates of a capacitor and that the air between them acts as a dielectric. The capacitance between the wires is usually expressed in *picofarads per unit length*. This electric field between the wires is similar to the field that exists between the two plates of a capacitor.

Figure 3-11.—Distributed capacitance.

Resistance of a Transmission Line

The transmission line shown in figure 3-12 has electrical resistance along its length. This resistance is usually expressed in *ohms per unit length* and is shown as existing continuously from one end of the line to the other.

Figure 3-12.—Distributed resistance.

Q16. What must the physical length of a transmission line be if it will be operated at 15,000,000 Hz? Use the formula:

$$\lambda = \frac{V}{f}$$

Q17. What are two of the three physical factors that determine the values of capacitance and inductance of a transmission line?

Q18. A transmission line is said to have distributed constants of inductance, capacitance, and resistance along the line. What units of measurement are used to express these constants?

Leakage Current

Since any dielectric, even air, is not a perfect insulator, a small current known as LEAKAGE CURRENT flows between the two wires. In effect, the insulator acts as a resistor, permitting current to pass between the two wires. Figure 3-13 shows this leakage path as resistors in parallel connected between the two lines. This property is called CONDUCTANCE (G) and is the opposite of resistance.

Conductance in transmission lines is expressed as the reciprocal of resistance and is usually given in *micromhos per unit length*.

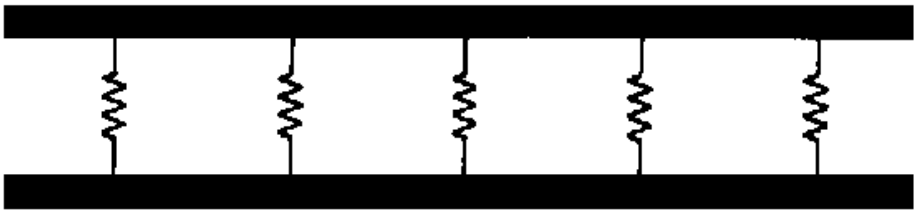

Figure 3-13.—Leakage in a transmission line.

ELECTROMAGNETIC FIELDS ABOUT A TRANSMISSION LINE

The distributed constants of resistance, inductance, and capacitance are basic properties common to all transmission lines and exist whether or not any current flow exists. As soon as current flow and voltage exist in a transmission line, another property becomes quite evident. This is the presence of an electromagnetic field, or lines of force, about the wires of the transmission line. The lines of force themselves are not visible; however, understanding the force that an electron experiences while in the field of these lines is very important to your understanding of energy transmission.

There are two kinds of fields; one is associated with voltage and the other with current. The field associated with voltage is called the ELECTRIC (E) FIELD. It exerts a force on any electric charge placed in it. The field associated with current is called a MAGNETIC (H) FIELD, because it tends to exert a force on any magnetic pole placed in it. Figure 3-14 illustrates the way in which the E fields and H fields tend to orient themselves between conductors of a typical two-wire transmission line. The illustration shows a cross section of the transmission lines. The E field is represented by solid lines and the H field by dotted lines. The arrows indicate the direction of the lines of force. Both fields normally exist together and are spoken of collectively as the electromagnetic field.

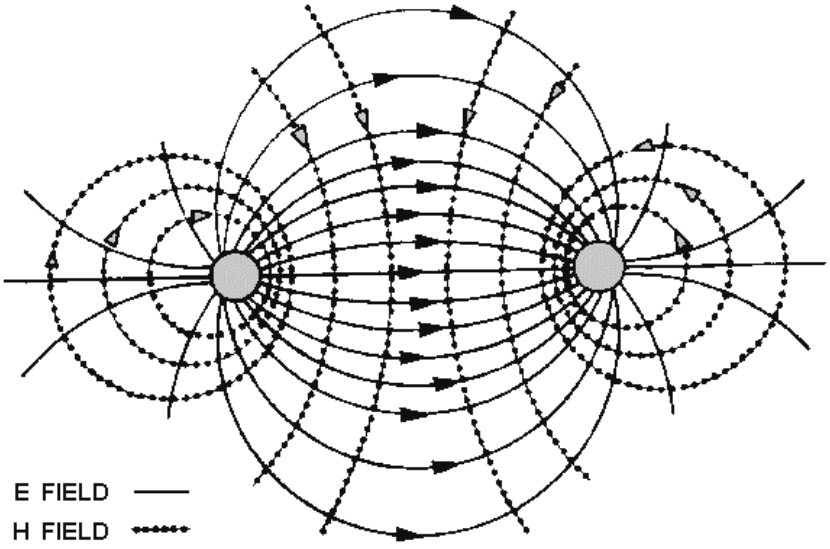

Figure 3-14.—Fields between conductors.

CHARACTERISTIC IMPEDANCE OF A TRANSMISSION LINE

You learned earlier that the maximum (and most efficient) transfer of electrical energy takes place when the source impedance is matched to the load impedance. This fact is very important in the study of transmission lines and antennas. If the characteristic impedance of the transmission line and the load impedance are equal, energy from the transmitter will travel down the transmission line to the antenna with no power loss caused by reflection.

Definition and Symbols

Every transmission line possesses a certain CHARACTERISTIC IMPEDANCE, usually designated as Z_0. Z_0 is the ratio of E to I at every point along the line. If a load equal to the characteristic impedance is placed at the output end of any length of line, the same impedance will appear at the input terminals of the line. The characteristic impedance is the only value of impedance for any given type and size of line that acts in this way. The characteristic impedance determines the amount of current that can flow when a given voltage is applied to an infinitely long line. Characteristic impedance is comparable to the resistance that determines the amount of current that flows in a dc circuit.

In a previous discussion, lumped and distributed constants were explained. Figure 3-15, view A, shows the properties of resistance, inductance, capacitance, and conductance combined in a short section of two-wire transmission line. The illustration shows the evenly distributed capacitance as a single lumped capacitor and the distributed conductance as a lumped leakage path. Lumped values may be used for transmission line calculations if the physical length of the line is very short compared to the wavelength of energy being transmitted. Figure 3-15, view B, shows all four properties lumped together and represented by their conventional symbols.

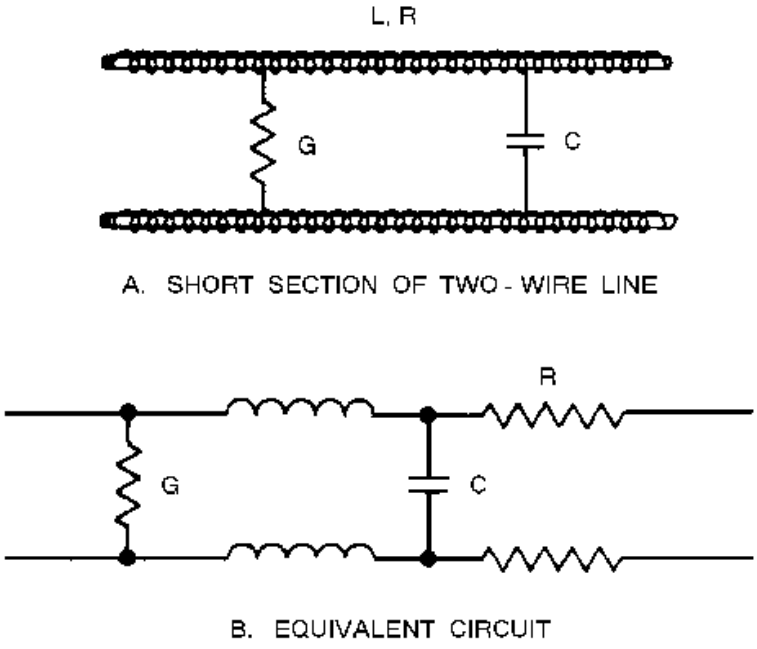

Figure 3-15.—Short section of two-wire transmission line and equivalent circuit.

Q19. Describe the leakage current in a transmission line and in what unit it is expressed.

Q20. All the power sent down a transmission line from a transmitter can be transferred to an antenna under what optimum conditions?

Q21. What symbol is used to designate the characteristic impedance of a line, and what two variables does it compare?

Characteristic Impedance and the Infinite Line

Several short sections, as shown in figure 3-15, can be combined to form a large transmission line, as shown in figure 3-16. Current will flow if voltage is applied across points K and L. In fact, any circuit, such as that represented in figure 3-16, view A, has a certain current flow for each value of applied voltage. The ratio of the voltage to the current is the impedance (Z).

Recall that:

$$Z = \frac{E}{I}$$

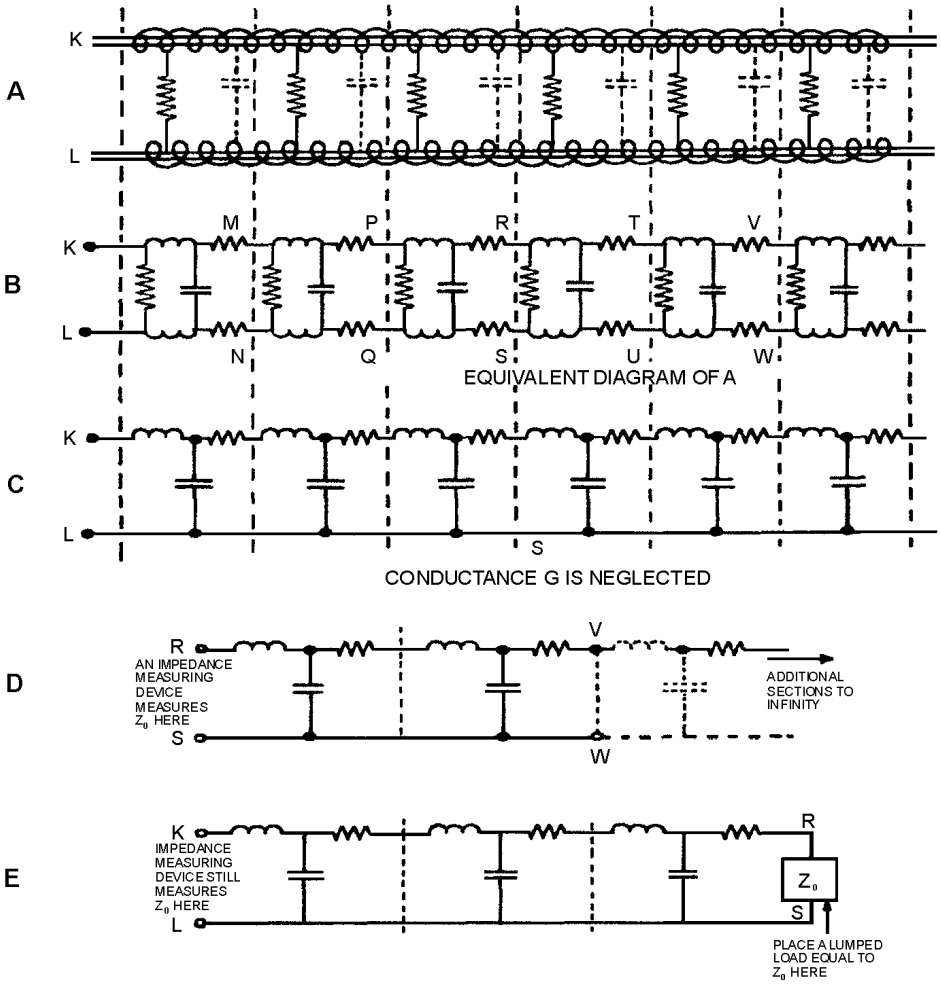

Figure 3-16.—Characteristic impedance.

The impedance presented to the input terminals of the transmission line is not merely the resistance of the wire in series with the impedance of the load. The effects of series inductance and shunt capacitance of the line itself may overshadow the resistance, and even the load, as far as the input terminals are concerned.

To find the input impedance of a transmission line, determine the impedance of a single section of line. The impedance between points K and L, in view B of figure 3-16, can be calculated by the use of series-parallel impedance formulas, provided the impedance across points M and N is known. But since this section is merely one small part of a longer line, another similar section is connected to points M and N. Again, the impedance across points K and L of the two sections can be calculated, provided the impedance of the third section is known. This process of adding one section to another can be repeated endlessly. The addition of each section produces an impedance across points K and L of a new and lower value. However, after many sections have been added, each successive added section has less and less effect on the impedance across points K and L. If sections are added to the line endlessly, the line is infinitely long, and a certain finite value of impedance across points K and L is finally reached.

In this discussion of transmission lines, the effect of conductance (G) is minor compared to that of inductance (L) and capacitance (C), and is frequently neglected. In figure 3-16, view C, G is omitted and the inductance and resistance of each line can be considered as one line.

Let us assume that the sections of view C continue to the right with an infinite number of sections. When an infinite number of sections extends to the right, the impedance appearing across K and L is Z_0. If the line is cut at R and S, an infinite number of sections still extends to the right since the line is endless in that direction. Therefore, the impedance now appearing across points R and S is also Z_0, as illustrated in view D. You can see that if only the first three sections are taken and a load impedance of Z_0 is connected across points R and S, the impedance across the input terminals K and L is still Z_0. The line continues to act as an infinite line. This is illustrated in view E.

Figure 3-17, view A, illustrates how the characteristic impedance of an infinite line can be calculated. Resistors are added in series parallel across terminals K and L in eight steps, and the resultant impedances are noted. In step 1 the impedance is infinite; in step 2 the impedance is 110 ohms. In step 3 the impedance becomes 62.1 ohms, a change of 47.9 ohms. In step 4 the impedance is 48.5 ohms, a change of only 13.6 ohms. The resultant changes in impedance from each additional increment become progressively smaller. Eventually, practically no change in impedance results from further additions to the line. The total impedance of the line at this point is said to be at its characteristic impedance; which, in this case, is 37 ohms. This means that an infinite line constructed as indicated in step 8 could be effectively replaced by a 37-ohm resistor. View B shows a 37-ohm resistor placed in the line at various points to replace the infinite line of step 8 in view A. There is no change in total impedance.

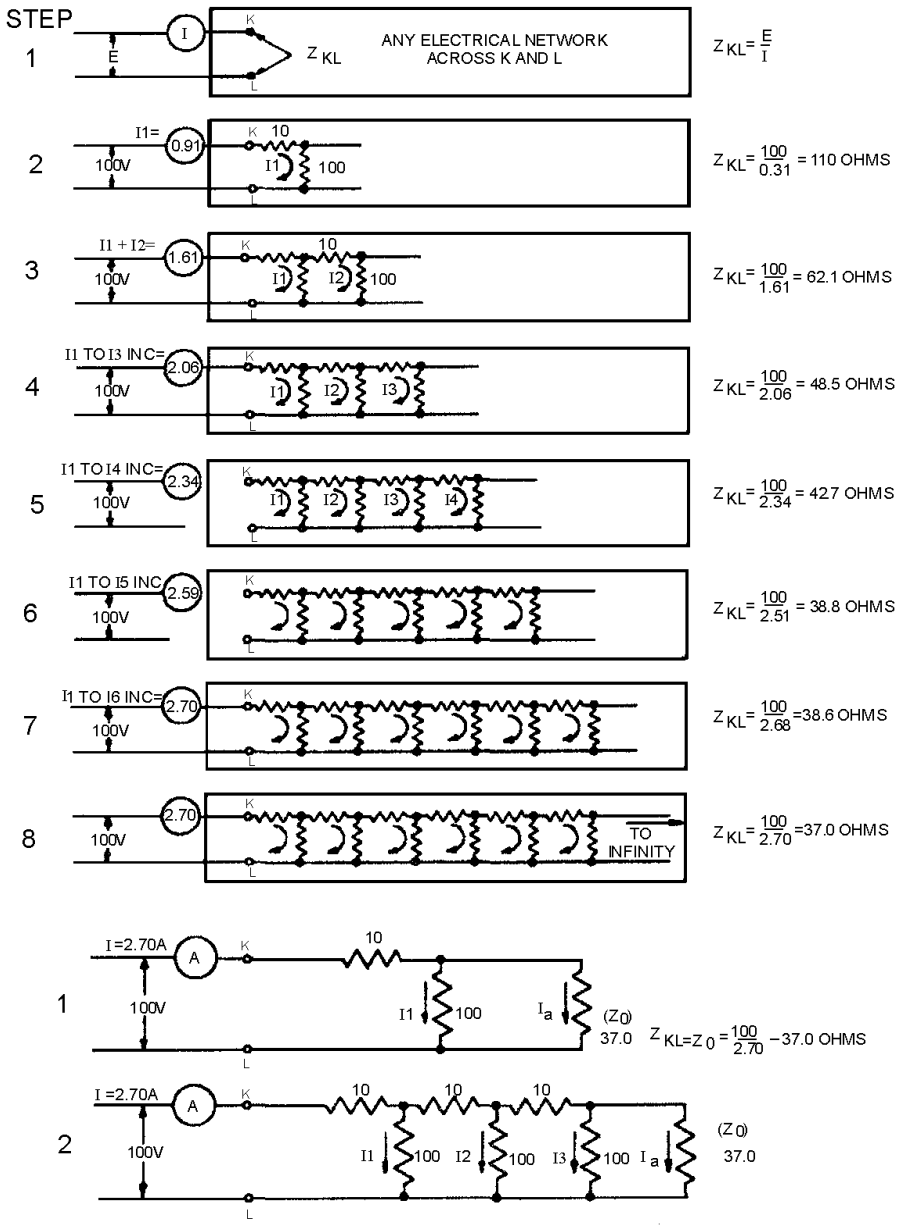

Figure 3-17.—Termination of a line.

In figure 3-17, resistors were used to show impedance characteristics for the sake of simplicity. Figuring the actual impedance of a line having reactance is very similar, with inductance taking the place of the series resistors and capacitance taking the place of the shunt resistors. The characteristic impedance of lines in actual use normally lies between 50 and 600 ohms.

When a transmission line is "short" compared to the length of the radio-frequency waves it carries, the opposition presented to the input terminals is determined primarily by the load impedance. A small amount of power is dissipated in overcoming the resistance of the line. However, when the line is "long" and the load is an incorrect impedance, the voltages necessary to drive a given amount of current through the line cannot be accounted for by considering just the impedance of the load in series with the

impedance of the line. The line has properties other than resistance that affect input impedance. These properties are inductance in series with the line, capacitance across the line, resistance leakage paths across the line, and certain radiation losses.

Q22. What is the range of the characteristic impedance of lines used in actual practice?

VOLTAGE CHANGE ALONG A TRANSMISSION LINE

Let us summarize what we have just discussed. In an electric circuit, energy is stored in electric and magnetic fields. These fields must be brought to the load to transmit that energy. At the load, energy contained in the fields is converted to the desired form of energy.

Transmission of Energy

When the load is connected directly to the source of energy, or when the transmission line is short, problems concerning current and voltage can be solved by applying Ohm's law. When the transmission line becomes long enough so the time difference between a change occurring at the generator and the change appearing at the load becomes appreciable, analysis of the transmission line becomes important.

Dc Applied to a Transmission Line

In figure 3-18, a battery is connected through a relatively long two-wire transmission line to a load at the far end of the line. At the instant the switch is closed, neither current nor voltage exists on the line. When the switch is closed, point A becomes a positive potential, and point B becomes negative. These points of difference in potential move down the line. However, as the initial points of potential leave points A and B, they are followed by new points of difference in potential which the battery adds at A and B. This is merely saying that the battery maintains a constant potential difference between points A and B. A short time after the switch is closed, the initial points of difference in potential have reached points A' and B'; the wire sections from points A to A' and points B to B' are at the same potential as A and B, respectively. The points of charge are represented by plus (+) and minus (-) signs along the wires. The directions of the currents in the wires are represented by the arrowheads on the line, and the direction of travel is indicated by an arrow below the line. Conventional lines of force represent the electric field that exists between the opposite kinds of charge on the wire sections from A to A' and B to B'. Crosses (tails of arrows) indicate the magnetic field created by the electric field moving down the line. The moving electric field and the accompanying magnetic field constitute an electromagnetic wave that is moving from the generator (battery) toward the load. This wave travels at approximately the speed of light in free space. The energy reaching the load is equal to that developed at the battery (assuming there are no losses in the transmission line). If the load absorbs all of the energy, the current and voltage will be evenly distributed along the line.

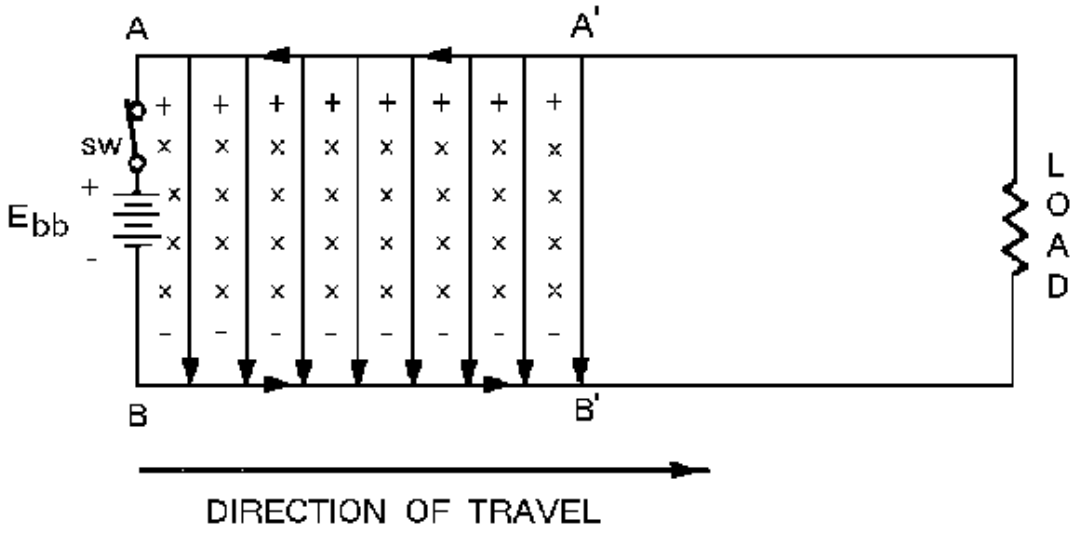

Figure 3-18.—Dc voltage applied to a line.

Ac Applied to a Transmission Line

When the battery of figure 3-18 is replaced by an ac generator (fig. 3-19), each successive instantaneous value of the generator voltage is propagated down the line at the speed of light. The action is similar to the wave created by the battery except that the applied voltage is sinusoidal instead of constant. Assume that the switch is closed at the moment the generator voltage is passing through zero and that the next half cycle makes point A positive. At the end of one cycle of generator voltage, the current and voltage distribution will be as shown in figure 3-19.

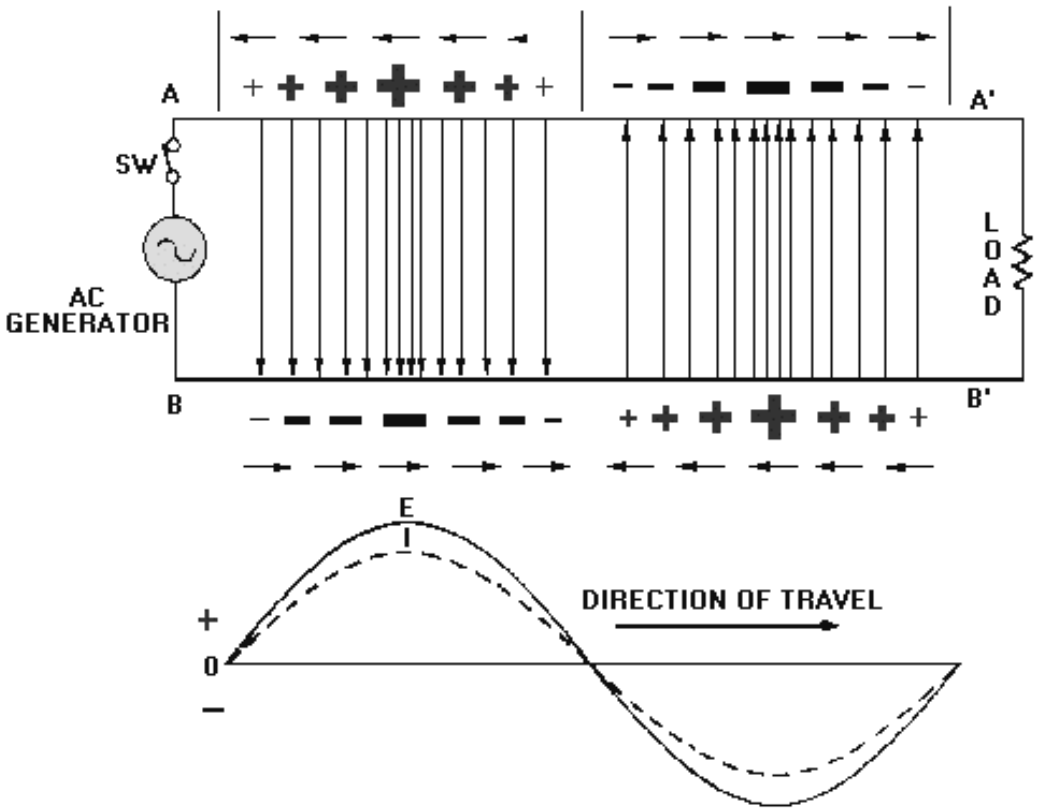

Figure 3-19.—Ac voltage applied to a line.

In this illustration the conventional lines of force represent the electric fields. For simplicity, the magnetic fields are not shown. Points of charge are indicated by plus (+) and minus (–) signs, the larger signs indicating points of higher amplitude of both voltage and current. Short arrows indicate direction of current (electron flow). The waveform drawn below the transmission line represents the voltage (E) and current (I) waves. The line is assumed to be infinite in length so there is no reflection. Thus, traveling sinusoidal voltage and current waves continually travel in phase from the generator toward the load, or far end of the line. Waves traveling from the generator to the load are called INCIDENT WAVES. Waves traveling from the load back to the generator are called REFLECTED WAVES and will be explained in later paragraphs.

Dc Applied to an Infinite Line

Figure 3-20 shows a battery connected to a circuit that is the equivalent of a transmission line. In this line the series resistance and shunt conductance are not shown. In the following discussion the line will be considered to have no losses.

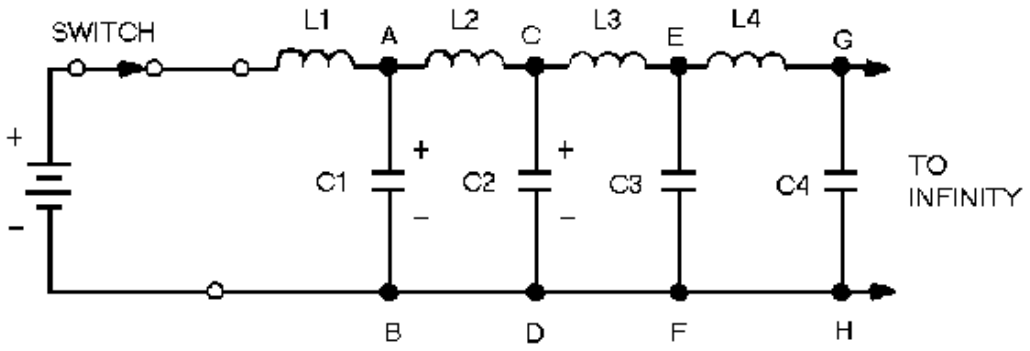

Figure 3-20.—Dc applied to an equivalent transmission line.

As the switch is closed, the battery voltage is applied to the input terminals of the line. Now, C1 has no charge and appears, effectively, as a short circuit across points A and B. The full battery voltage appears across inductor L1. Inductor L1 opposes the change of current (0 now) and limits the rate of charge of C1.

Capacitor C2 cannot begin to charge until after C1 has charged. No current can flow beyond points A and B until C1 has acquired some charge. As the voltage across C1 increases, current through L2 and C2 charges C2. This action continues down the line and charges each capacitor, in turn, to the battery voltage. Thus a voltage wave is traveling along the line. Beyond the wavefront, the line is uncharged. Since the line is infinitely long, there will always be more capacitors to be charged, and current will not stop flowing. Thus current will flow indefinitely in the line.

Notice that current flows to charge the capacitors along the line. The flow of current is not advanced along the line until a voltage is developed across each preceding capacitor. In this manner voltage and current move down the line together in phase.

Ac Applied to an Infinite Line

An rf line displays similar characteristics when an ac voltage is applied to its sending end or input terminals. In figure 3-21, view A, an ac voltage is applied to the line represented by the circuit shown.

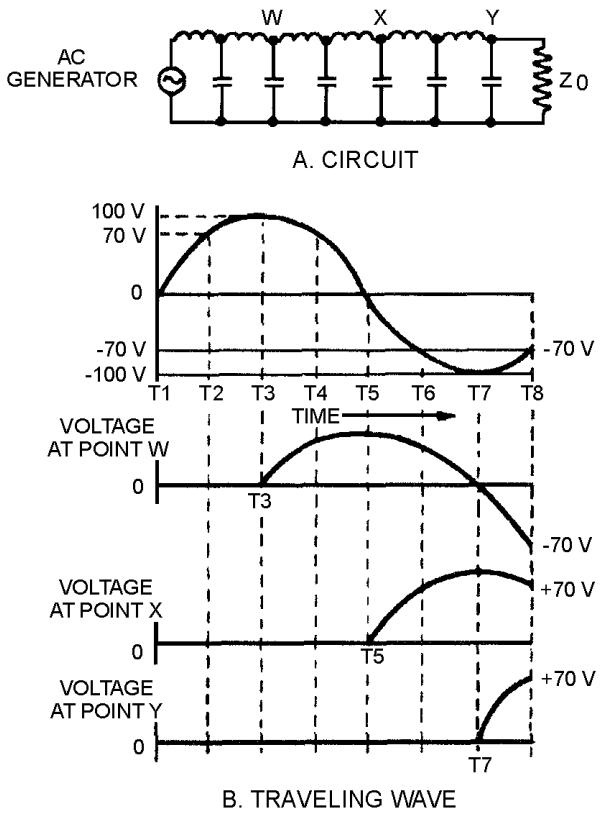

Figure 3-21.—Ac applied to an equivalent transmission line.

In view B the generator voltage starts from zero (T1) and produces the voltage shown. As soon as a small voltage change is produced, it starts its journey down the line while the generator continues to produce new voltages along a sine curve. At T2 the generator voltage is 70 volts. The voltages still move along the line until, at T3, the first small change arrives at point W, and the voltage at that point starts increasing. At T5, the same voltage arrives at point X on the line. Finally, at T7, the first small change arrives at the receiving end of the line. Meanwhile, all the changes in the sine wave produced by the generator pass each point in turn. The amount of time required for the changes to travel the length of the line is the same as that required for a dc voltage to travel the same distance.

At T7, the voltage at the various points on the line is as follows:

At the generator:	-100 V
At point W:	0 V
At point X:	+100 V
At point Y:	0 V

If these voltages are plotted along the length of the line, the resulting curve is like the one shown in figure 3-22, view A. Note that such a curve of instantaneous voltages resembles a sine wave. The changes in voltage that occur between T7 and T8 are as follows:

At the generator:	Rise from	-100 V to -70 V
At point W:	Drop from	0 V to -70 V
At point X:	Drop from	+100 V to +70 V
At point Y:	Rise from	0 V to + 70 V

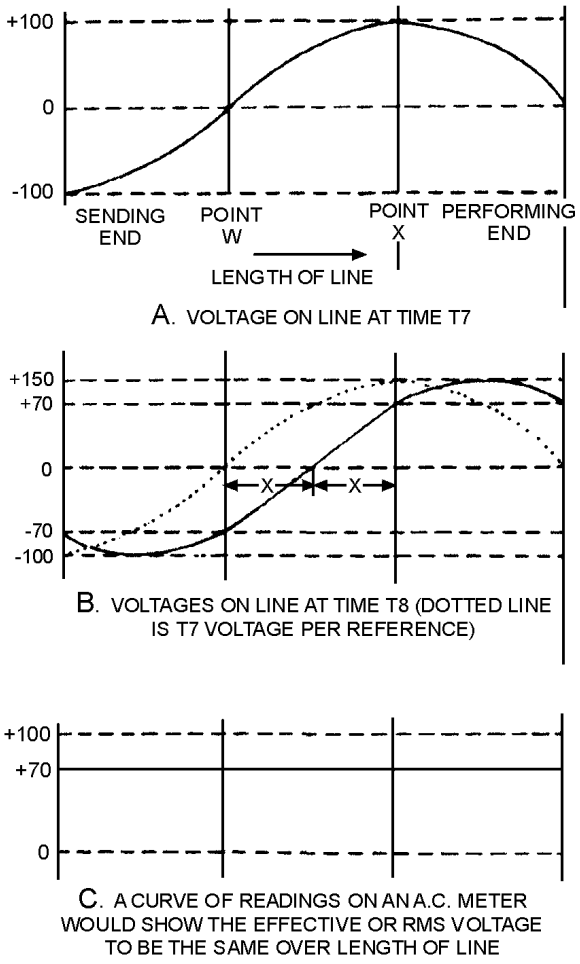

Figure 3-22.—Instantaneous voltages along a transmission line.

A plot of these new voltages produces the solid curve shown in figure 3-22, view B. For reference, the curve from T7 is drawn as a dotted line. The solid curve has exactly the same shape as the dotted curve, but has moved to the right by the distance X. Another plot at T9 would show a new curve similar to the one at T8, but moved to the right by the distance Y.

By analyzing the points along the graph just discussed, you should be able to see that the actions associated with voltage changes along an rf line are as follows:

1. All instantaneous voltages of the sine wave produced by the generator travel down the line in the order they are produced.

2. At any point, a sine wave can be obtained if all the instantaneous voltages passing the point are plotted. An oscilloscope can be used to plot these values of instantaneous voltages against time.

3. The instantaneous voltages (oscilloscope displays) are the same in all cases except that a phase difference exists in the displays seen at different points along the line. The phase changes continually with respect to the generator until the change is 360 degrees over a certain length of line.

4. All parts of a sine wave pass every point along the line. A plot of the readings of an ac meter (which reads the effective value of the voltage over a given time) taken at different points along the line shows that the voltage is constant at all points. This is shown in view C of figure 3-22.

5. Since the line is terminated with a resistance equal to Z_0, the energy arriving at the end of the line is absorbed by the resistance.

VELOCITY OF WAVE PROPAGATION

If a voltage is initially applied to the sending end of a line, that same voltage will appear later some distance from the sending end. This is true regardless of any change in voltage, whether the change is a jump from zero to some value or a drop from some value to zero. The voltage change will be conducted down the line at a constant rate.

Recall that the inductance of a line delays the charging of the line capacitance. The velocity of propagation is therefore related to the values of L and C. If the inductance and capacitance of the rf line are known, the time required for any waveform to travel the length of the line can be determined. To see how this works, observe the following relationship:

$$Q = IT$$

This formula shows that the total charge or quantity is equal to the current multiplied by the time the current flows. Also:

$$Q = CE$$

This formula shows that the total charge on a capacitor is equal to the capacitance multiplied by the voltage across the capacitor.

If the switch in figure 3-23 is closed for a given time, the quantity (Q) of electricity leaving the battery can be computed by using the equation Q = IT. The electricity leaves the battery and goes into the line, where a charge is built up on the capacitors. The amount of this charge is computed by using the equation Q = CE.

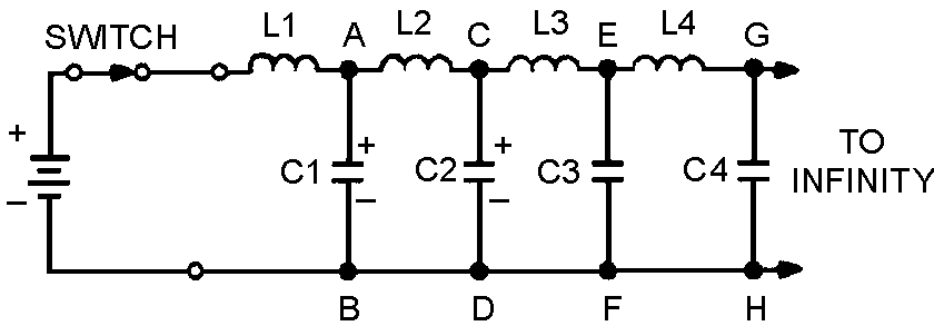

Figure 3-23.—Dc applied to an equivalent transmission line.

Since none of the charge is lost, the total charge leaving the battery during T is equal to the total charge on the line. Therefore:

$$Q = IT = CE$$

As each capacitor accumulates a charge equal to CE, the voltage across each inductor must change. As C1 in figure 3-23 charges to a voltage of E, point A rises to a potential of E volts while point B is still at zero volts. This makes E appear across L2. As C2 charges, point B rises to a potential of E volts as did point A. At this time, point B is at E volts and point C rises. Thus, we have a continuing action of voltage moving down the infinite line.

In an inductor, these circuit components are related, as shown in the formula

$$E = L\left(\frac{\Delta I}{\Delta T}\right).$$

This shows that the voltage across the inductor is directly proportional to inductance and the change in current, but inversely proportional to a change in time. Since current and time start from zero, the change in time (ΔT) and the change in current (ΔI) are equal to the final time (T) and final current (I). For this case the equation becomes:

$$ET = LI$$

If voltage E is applied for time (T) across the inductor (L), the final current (I) will flow. The following equations show how the three terms (T, L, and C) are related:

$$IT = CE$$
$$ET = LI$$

For convenience, you can find T in terms of L and C in the following manner. Multiply the left and right member of each equation as follows:

$$(IT)(ET) = (CE)(LI)$$

Then: $EIT^2 = LCEI$

Dividing by (EI): $T^2 = LC$

and $T = \sqrt{LC}$

This final equation is used for finding the time required for a voltage change to travel a unit length, since L and C are given in terms of unit length. The velocity of the waves may be found by:

$$V = \frac{D}{T} \text{ or } V = \frac{D}{\sqrt{LC}}$$

Where: D is the physical length of a unit

This is the rate at which the wave travels over a unit length. The units of L and C are henrys and farads, respectively. T is in seconds per unit length and V is in unit lengths per second.

DETERMINING CHARACTERISTIC IMPEDANCE

As previously discussed, an infinite transmission line exhibits a definite input impedance. This impedance is the CHARACTERISTIC IMPEDANCE and is independent of line length. The exact value of this impedance is the ratio of the input voltage to the input current. If the line is infinite or is terminated in a resistance equal to the characteristic impedance, voltage and current waves traveling the line are in phase. To determine the characteristic impedance or voltage-to-current ratio, use the following procedure:

Divide the equation:

$ET = LI$ by $IT = CE$

$$\frac{ET}{IT} = \frac{LI}{CE}$$

Multiply by $\frac{E}{I}$:

$$\frac{E^2T}{I^2T} = \frac{LIE}{CEI}$$

Simplify:

$$\frac{E^2}{I^2} = \frac{L}{C}$$

Take the square root:

$$\frac{E}{I} = \sqrt{\frac{L}{C}} = Z_0 \text{(characteristic impedance)}$$

Example:

A problem using this equation will illustrate how to determine the characteristics of a transmission line. Assume that the line shown in figure 3-23 is 1000 feet long. A 100-foot (approximately 30.5 meter) section is measured to determine L and C. The section is found to have an inductance of 0.25 millihenries and a capacitance of 1000 picofarads. Find the characteristic impedance of the line and the velocity of the wave on the line.

The characteristic impedance is:

$$Z_0 = \sqrt{LC}$$

$$Z_0 = \sqrt{\frac{0.25 \times 10^{-3}}{1000 \times 10^{-12}}}$$

$$Z_0 = \sqrt{0.25 \times 10^{6}}$$

$$Z_0 = 0.5 \times 10^{3}$$

$$Z_0 = 500\Omega$$

If any other unit length had been considered, the values of L and C would be different, but their ratio would remain the same as would the characteristic impedance.

The formula for T is:

$$T = \sqrt{LC}$$

$$T = \sqrt{0.25 \times 10^{-3} \times 1000 \times 10^{-12}}$$

$$T = \sqrt{.025 \times 10^{-12}}$$

$$T = 0.5 \times 10^{-6} \text{ second}$$

$$T = 0.5 \text{ microsecond}$$

The formula for the velocity of a wave is:

$$V = \frac{D}{T}$$

$$V = \frac{100 \text{ feet}}{0.5 \times 10^{-6} \text{ second}}$$

$$V = 200 \times 10^{6} \text{ feet/second}$$

$$V = 200{,}000{,}000 \text{ feet/second}$$

REFLECTIONS ON A TRANSMISSION LINE

Transmission line characteristics are based on an infinite line. A line cannot always be terminated in its characteristic impedance since it is sometimes operated as an OPEN-ENDED line and other times as a SHORT-CIRCUIT at the receiving end. If the line is open-ended, it has a terminating impedance that is infinitely large. If a line is not terminated in characteristic impedance, it is said to be finite.

When a line is not terminated in Z_0, the incident energy is not absorbed but is returned along the only path available—the transmission line. Thus, the behavior of a finite line may be quite different from that of the infinite line.

REFLECTION OF DC VOLTAGE FROM AN OPEN CIRCUIT

The equivalent circuit of an open-ended transmission line is shown in figure 3-24, view A. Again, losses are to be considered as negligible, and L is lumped in one branch. Assume that (1) the battery in this circuit has an internal impedance equal to the characteristic impedance of the transmission line ($Z_i = Z_0$); (2) the capacitors in the line are not charged before the battery is connected; and (3) since the line is open-ended, the terminating impedance is infinitely large.

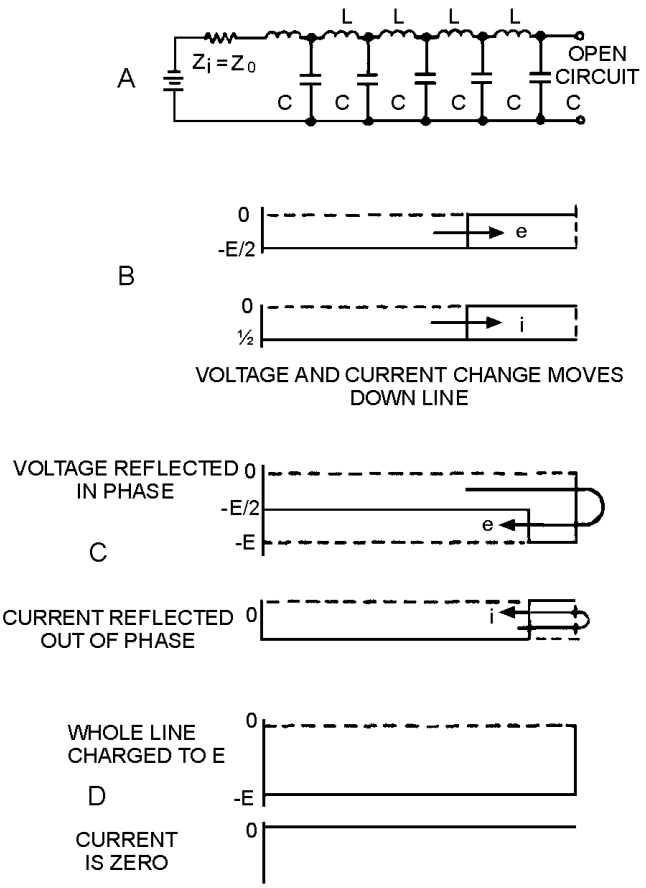

Figure 3-24.—Reflection from an open-ended line.

When the battery is connected to the sending end as shown, a negative voltage moves down the line. This voltage charges each capacitor, in turn, through the preceding inductor. Since Z_i equals Z_0, one-half the applied voltage will appear across the internal battery impedance, Z_i, and one-half across the impedance of the line, Z_0. Each capacitor is then charged to E/2 (view B). When the last capacitor in the line is charged, there is no voltage across the last inductor and current flow through the last inductor stops. With no current flow to maintain it, the magnetic field in the last inductor collapses and forces current to continue to flow in the same direction into the last capacitor. Because the direction of current has not changed, the capacitor charges in the same direction, thereby increasing the charge in the capacitor. Since the energy in the magnetic field equals the energy in the capacitor, the energy transfer to the capacitor doubles the voltage across the capacitor. The last capacitor is now charged to E volts and the current in the last inductor drops to zero.

At this point, the same process takes place with the next to the last inductor and capacitor. When the magnetic field about the inductor collapses, current continues to flow into the next to the last capacitor, charging it to E volts. This action continues backward down the line until the first capacitor has been fully charged to the applied voltage. This change of voltage, moving backward down the line, can be thought of in the following manner. The voltage, arriving at the end of the line, finds no place to go and returns to the sending end with the same polarity (view C). Such action is called REFLECTION.

When a reflection of voltage occurs on an open-ended line, the polarity is unchanged. The voltage change moves back to the source, charging each capacitor in turn until the first capacitor is charged to the

source voltage and the action stops (view D). As each capacitor is charged, current in each inductor drops to zero, effectively reflecting the current with the opposite polarity (view C). Reflected current of opposite polarity cancels the original current at each point, and the current drops to zero at that point. When the last capacitor is charged, the current from the source stops flowing (view D).

Important facts to remember in the reflection of dc voltages in open-ended lines are:

- Voltage is reflected from an open end without change in polarity, amplitude, or shape.
- Current is reflected from an open end with opposite polarity and without change in amplitude or shape.

REFLECTION OF DC VOLTAGE FROM A SHORT CIRCUIT

A SHORT-CIRCUITED line affects voltage change differently from the way an open-circuited line affects it. The voltage across a perfect short circuit must be zero; therefore, no power can be absorbed in the short, and the energy is reflected toward the generator.

The initial circuit is shown in figure 3-25, view A. The initial voltage and current waves (view B) are the same as those given for an infinite line. In a short-circuited line the voltage change arrives at the last inductor in the same manner as the waves on an open-ended line. In this case, however, there is no capacitor to charge. The current through the final inductor produces a voltage with the polarity shown in view C. When the field collapses, the inductor acts as a battery and forces current through the capacitor in the opposite direction, causing it to discharge (view D). Since the amount of energy stored in the magnetic field is the same as that in the capacitor, the capacitor discharges to zero.

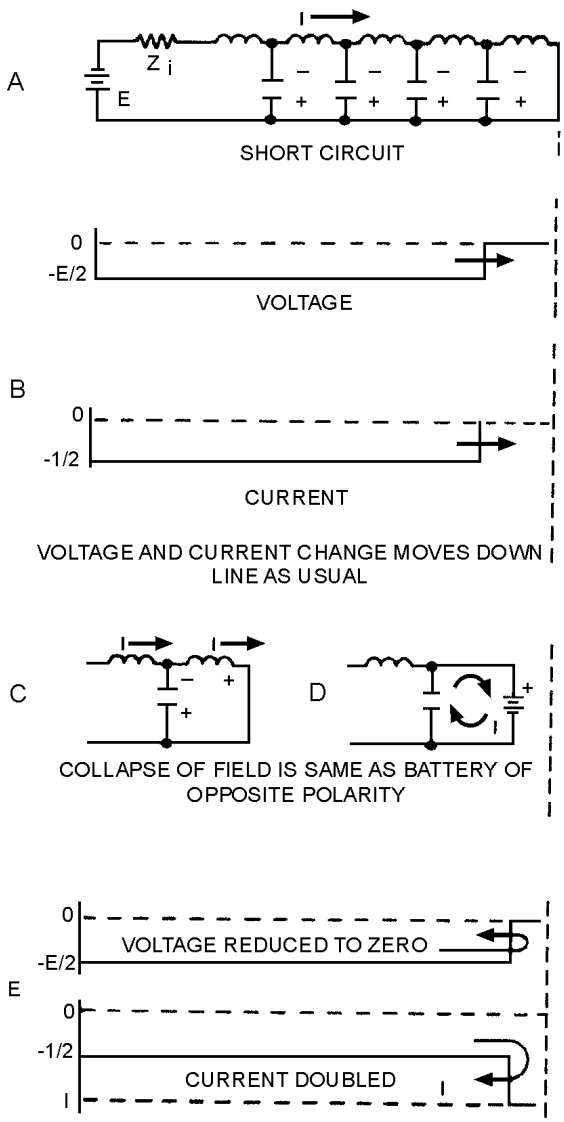

Figure 3-25.—Reflection from a short-circuited line.

Now there is no voltage to maintain the current through the next to the last inductor. Therefore, this inductor discharges the next to the last capacitor.

As each capacitor is discharged to zero, the next inductor effectively becomes a new source of voltage. The amplitude of each of these voltages is equal to E/2, but the polarity is the opposite of the battery at the input end of the line. The collapsing field around each inductor, in turn, produces a voltage that forces the current to continue flowing in the same direction, adding to the current from the source to make it 2I. This action continues until all the capacitors are discharged (view E).

Reflected waves from a short-circuited transmission line are characterized as follows:

- The reflected voltage has the opposite polarity but the same amplitude as the incident wave.
- The reflected current has the same polarity and the same amplitude as the incident current.

REFLECTION OF AC VOLTAGE FROM AN OPEN CIRCUIT

In most cases where rf lines are used, the voltages applied to the sending end are ac voltages. The action at the receiving end of the line is exactly the same for ac as for dc. In the open-ended line, shown in figure 3-26, view A, the generated ac voltage is distributed along the line, shown in view B. This voltage is distributed in such a way that as each instantaneous voltage arrives at the end, it is reflected with the same polarity and amplitude. When ac is used, this reflection is in phase. Each of the reflected voltages travels back along the line until it reaches the generator. If the generator impedance is the same as the line impedance, energy arriving at the generator is absorbed and not reflected again. Now two voltages are on the line.

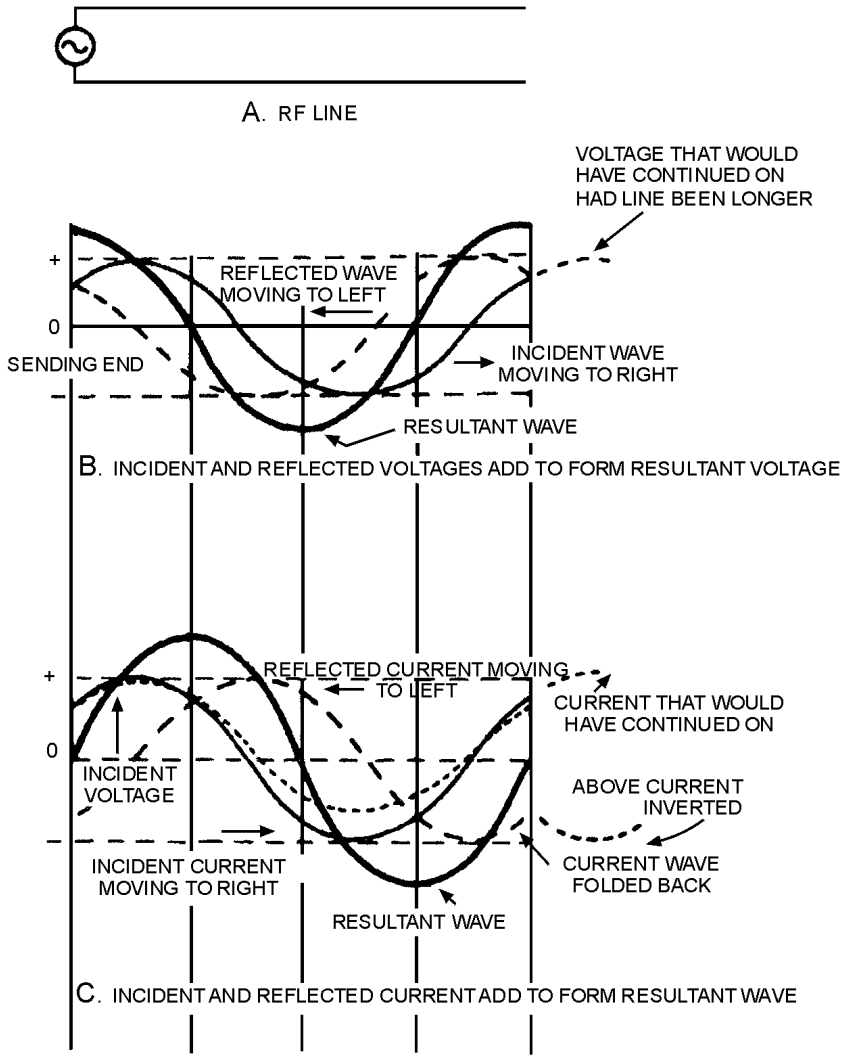

Figure 3-26.—Formation of standing waves.

View B shows how two waves of the same frequency and amplitude moving in opposite directions on the same conductor will combine to form a resultant wave. The small solid line is moving steadily from left to right and is the INCIDENT WAVE (from the source). The broken-line waveform is moving from right to left and is the REFLECTED WAVE. The resultant waveform, the heavy line, is found by algebraically adding instantaneous values of the two waveforms. The resultant waveform has an

instantaneous peak amplitude that is equal to the sum of the peak amplitudes of the incident and reflected waves. Since most indicating instruments are unable to separate these voltages, they show the vector sum. An oscilloscope is usually used to study the instantaneous voltages on rf lines.

Since two waves of voltage are moving on the line, you need to know how to distinguish between the two. The voltages moving toward the receiving end are called INCIDENT VOLTAGES, and the whole waveshape is called the INCIDENT WAVE. The wave moving back to the sending end after reflection is called the REFLECTED WAVE. The resultant voltage curve (view B of figure 3-26) shows that the voltage is maximum at the end of the line, a condition that occurs across an open circuit.

Another step in investigating the open-circuited rf line is to see how the current waves act. The incident current wave is the solid line in figure 3-26, view C. The voltage is represented by the dotted line. The current is in phase with the voltage while traveling toward the receiving end. At the end of the line, the current is reflected in the opposite polarity; that is, it is shifted 180 degrees in phase, but its amplitude remains the same. The reflected wave of current is shown by dashed lines in view C. The heavy-line curve represents the sum of the two instantaneous currents and is the resultant wave. Notice that current is zero at the end of the line. This is reasonable, since there can be no current flow through an open circuit.

Views B and C of figure 3-26 show the voltage and current distribution along a transmission line at a point about 1/8 after a maximum voltage or current reaches the end of the line. Since the instantaneous values are continuously changing during the generation of a complete cycle, a large number of these pictures are required to show the many different relationships.

Figure 3-27 shows the incident and reflected waveshapes at several different times. The diagrams in the left column of figure 3-27 (representing *voltage*) show the incident wave and its reflection without change in polarity. In figure 3-27, waveform (1), the incident wave and the reflected wave are added algebraically to produce the resultant wave indicated by the heavy line. In waveform (2), a zero point preceding the negative-going cycle of the incident wave is at the end of the line. The reflected wave and incident wave are 180 degrees out of phase at all points. (The reflected wave is the positive cycle that just preceded the negative cycle now approaching the end of the line.) The resultant of the incident and reflected waves is zero at all points along the line. In waveform (3), the waves have moved $1/8\lambda$ along the line; the incident wave has moved 45 degrees to the right, and the reflected wave has moved 45 degrees to the left. The resultant voltage, shown by the heavy line, has a maximum negative at the end of the line and a maximum positive $1/2\lambda$ from the end of the line.

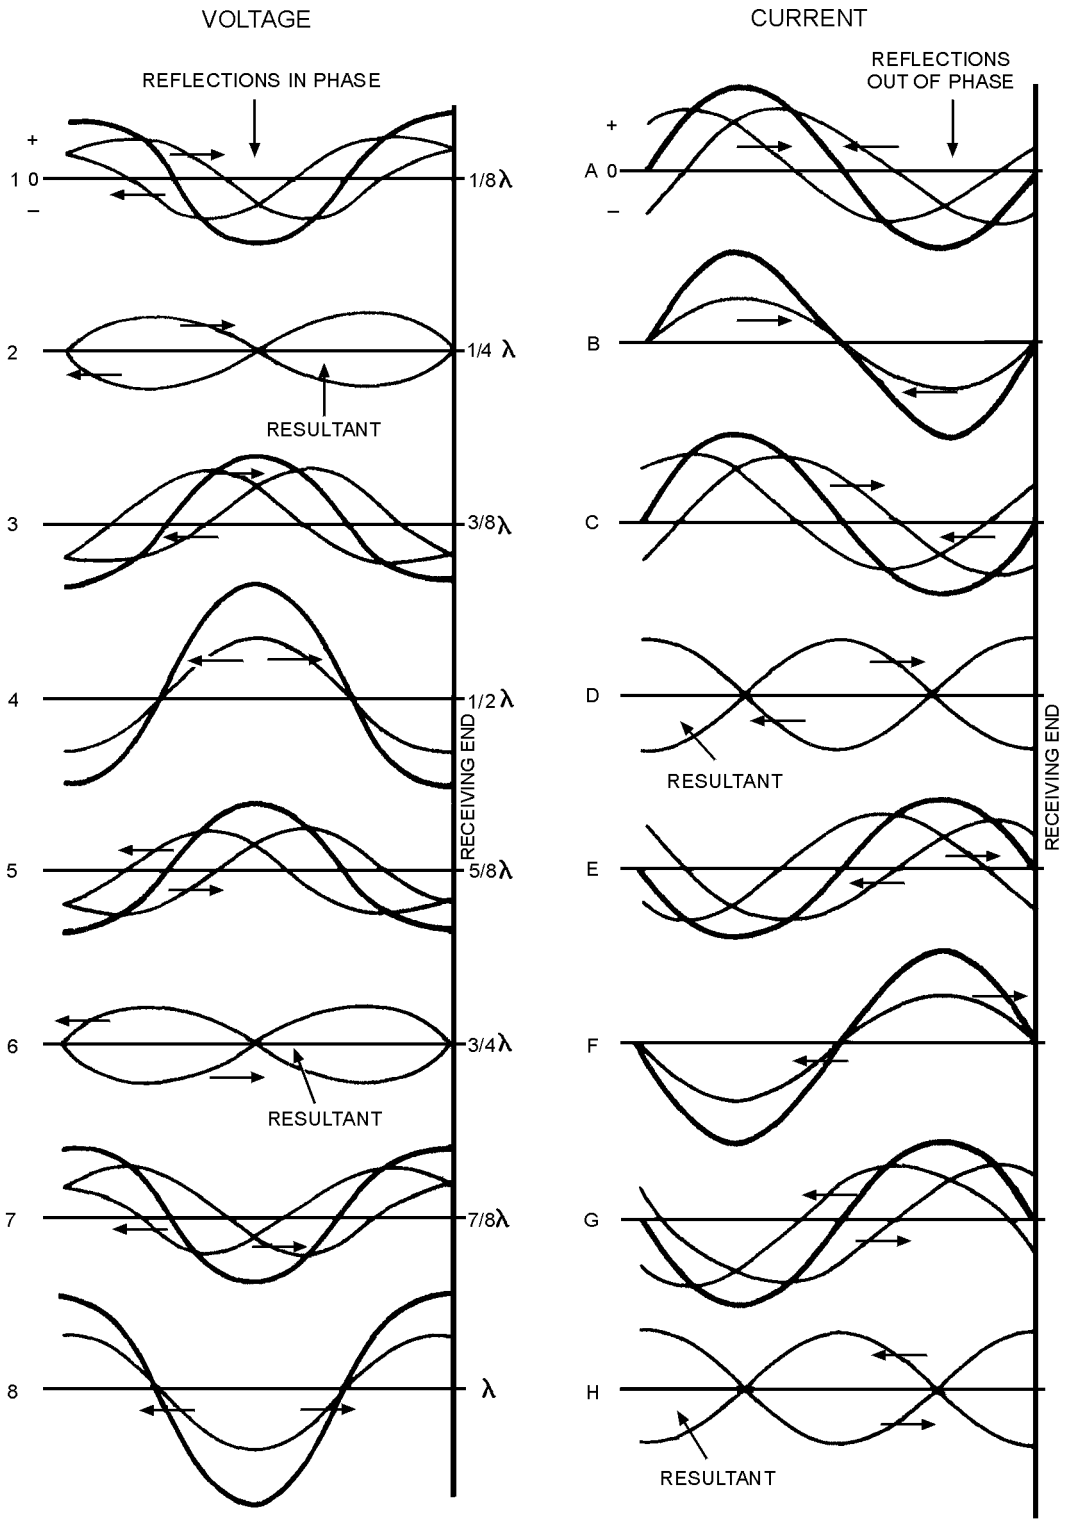

Figure 3-27.—Instantaneous values of incident and reflected waves on an open-ended line.

In waveform (4), the incident wave is at a maximum negative value at the end of the line. The wave has moved another 45 degrees to the right from the wave in the preceding illustration. The reflected wave has also moved 45 degrees, but to the left. The reflected wave is in phase with the incident wave. The resultant of these two waves, shown by the dark line, again has a negative maximum at the end of the line and a positive maximum 1/2λ from the end of the line. Notice that these maxima have a greater amplitude than those in waveform (3).

In waveform (5), the incident wave has moved another 45 degrees to the right and the reflected wave 45 degrees to the left. The resultant again is maximum negative at the end and positive maximum 1/2λ from the end. The maxima are lower than those in waveform (4). In waveform (6), the incident and reflected wave have moved another 1/8λ. The two waves again are 180 degrees out of phase, giving a resultant wave with no amplitude. The incident and reflected waves continue moving in opposite directions, adding to produce the resultant waveshapes shown in waveforms (7) and (8). Notice that the maximum voltage in each resultant wave is at the end and 1/2λ from the end.

Study each part of figure 3-27 carefully and you will get a clear picture of how the resultant waveforms of voltage are produced. You will also see that the resultant voltage wave on an open-ended line is always zero at 1/4λ and 3/4λ from the end of the transmission line. Since the zero and maximum points are always in the same place, the resultant of the incident and the reflected wave is called a STANDING WAVE of voltage.

The right-hand column in figure 3-27 shows the *current* waveshapes on the open-ended line. Since the current is reflected out of phase at an open end, the resultant waveshapes differ from those for voltage. The two out-of-phase components always cancel at the end of the transmission line, so the resultant is always zero at that point. If you check all the resultant waveshapes shown in the right-hand column of figure 3-27, you will see that a zero point always occurs at the end and at a point 1/2λ from the end. Maximum voltages occur 1/4λ and 3/4λ from the end.

When an ac meter is used to measure the voltages and currents along a line, the polarity is not indicated. If you plot all the current and voltage readings along the length of the line, you will get curves like the ones shown in figure 3-28. Notice that all are positive. These curves are the conventional method of showing current and voltage standing waves on rf lines.

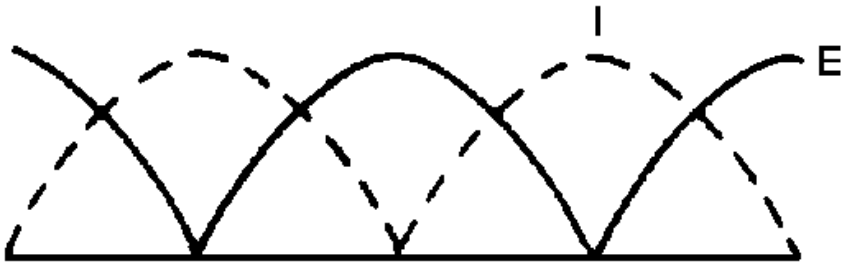

Figure 3-28.—Conventional picture of standing waves.

When an rf line is terminated in a short circuit, reflection is complete, but the effect on voltage and current differs from that in an open-ended line. Voltage is reflected in opposite phase, while current is reflected in phase. Again refer to the series of pictures shown in figure 3-27. However, this time the left column represents *current*, since it shows reflection in phase; and the right column of pictures now represents the *voltage* changes on the shorted line, since it shows reflection out of phase.

The composite diagram in figure 3-29 shows all resultant curves on a full-wavelength section of line over a complete cycle. Notice that the amplitude of the voltage varies between zero and maximum in both directions at the center and at both ends as well but, one-fourth of the distance from each end the voltage is always zero. The resultant waveshape is referred to as a standing wave of voltage. Standing waves, then, are caused by reflections, which occur only when the line is not terminated in its characteristic impedance.

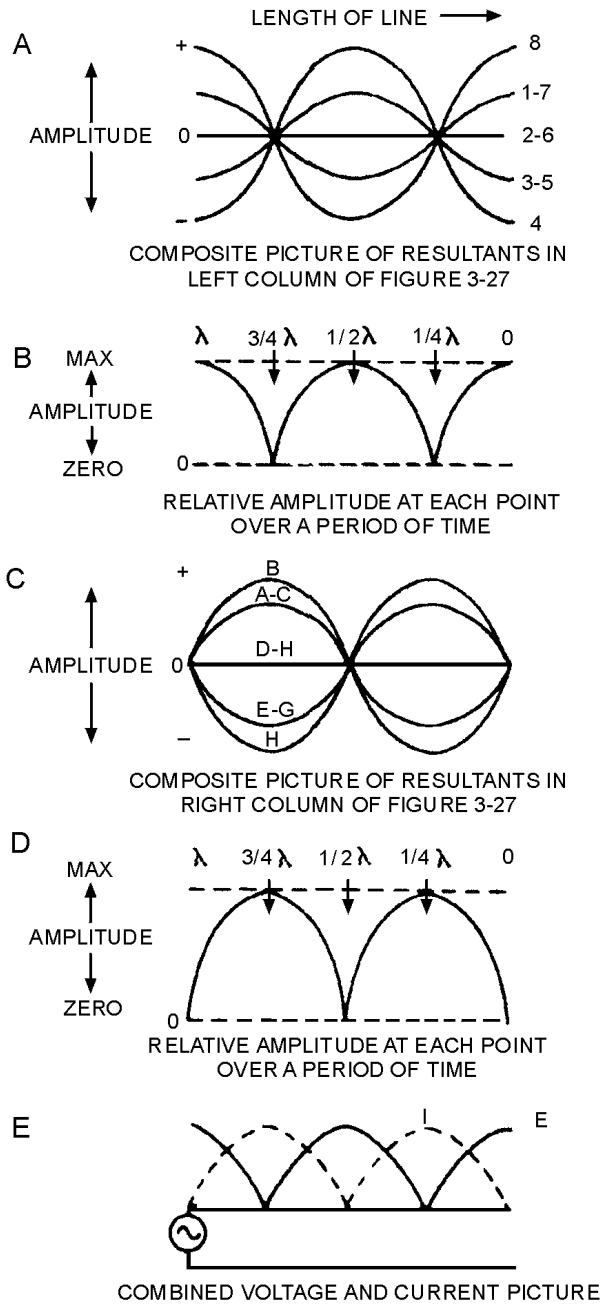

Figure 3-29.—Composite results of instantaneous waves.

The voltage at the center and the ends varies at a sinusoidal rate between the limits shown. At the one-fourth the three-fourths points, the voltage is always zero. A continuous series of diagrams such as these is difficult to see with conventional test equipment, which reads the effective or average voltage over several cycles. The curve of amplitude over the length of line for several cycles is shown in figure 3-29, view B. A meter will read zero at the points shown and will show a maximum voltage at the center, no matter how many cycles pass.

As shown in view D, the amplitude varies along the length of the line. In this case it is zero at the end and center but maximum at the one-fourth and three-fourths points. The entire diagram of the open-ended line conditions is shown in view E. The standing waves of voltage and current appear together. Observe that one is maximum when the other is minimum. The current and voltage standing waves are one-quarter cycle, or 90 degrees, out of phase with one another.

REFLECTION OF AC VOLTAGE FROM A SHORT CIRCUIT

Reflection is complete when an rf line is terminated in a short circuit, but the effect on voltage and current differs from the effect obtained in an open-ended line. Voltage is reflected in opposite phase, while current is reflected in phase. Again look at the series of diagrams in figure 3-27. The left column represents current, and the right column shows voltage changes on the shorted line. The standard representation of standing waves on a shorted line is shown in figure 3-30; the voltage is a solid line, and the current is a dashed line. The voltage is zero at the end and center (1/2λ) and maximum at the 1/4λ and 3/4λ points, while the current is maximum at the end and center and minimum at the 1/4λ and 3/4λ points.

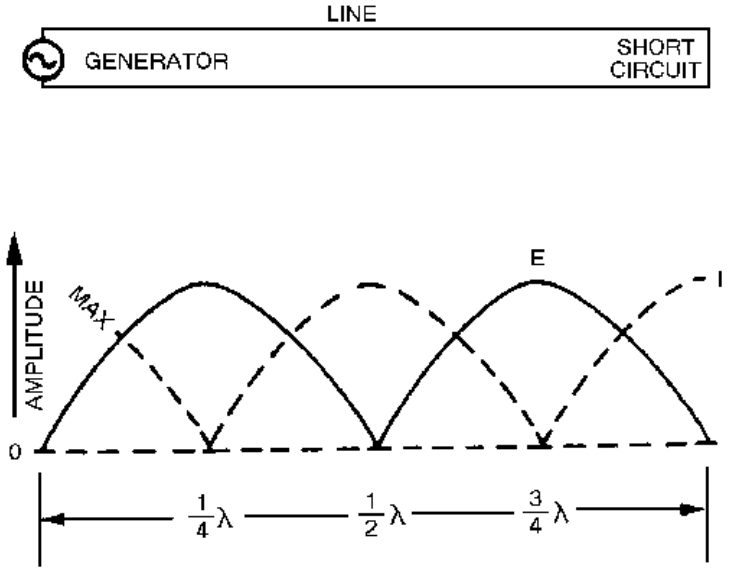

Figure 3-30.—Standing waves on a shorted line.

As we discussed voltage and current waves on transmission lines, we pointed out several differences between open and shorted lines. Basic differences also appear in the standing-wave patterns for open and shorted lines. You can see these differences by comparing figure 3-29, view E, and figure 3-30. Notice that the current and voltage standing waves are shifted 90 degrees with respect to the termination. At the open end of a line, voltage is maximum (zero if there are no losses in the line). At a short circuit, current is maximum and voltage is minimum.

Q23. Two types of waves are formed on a transmission line. What names are given to these waves?

Q24. In figure 3-27, which waveforms on the left have a resultant wave of zero, and what is indicated by these waves?

Q25. On an open-ended transmission line, the voltage is always zero at what distance from each end of the line?

TERMINATING A TRANSMISSION LINE

A transmission line is either NONRESONANT or RESONANT. First, let us define the terms nonresonant lines and resonant lines. A nonresonant line is a line that has no standing waves of current and voltage. A resonant line is a line that has standing waves of current and voltage.

Nonresonant Lines

A nonresonant line is either infinitely long or terminated in its characteristic impedance. Since no reflections occur, all the energy traveling down the line is absorbed by the load which terminates the line. Since no standing waves are present, this type of line is sometimes spoken of as a FLAT line. In addition, because the load impedance of such a line is equal to Z_0, no special tuning devices are required to effect a maximum power transfer; hence, the line is also called an UNTUNED line.

Resonant Lines

A resonant line has a finite length and is not terminated in its characteristic impedance. Therefore reflections of energy do occur. The load impedance is different from the Z_0 of the line; therefore, the input impedance may not be purely resistive but may have reactive components. Tuning devices are used to eliminate the reactance and to bring about maximum power transfer from the source to the line. Therefore, a resonant line is sometimes called a TUNED line. The line also may be used for a resonant or tuned circuit.

A resonant line is sometimes said to be resonant at an applied frequency. This means that at one frequency the line acts as a resonant circuit. It may act either as a high-resistive circuit (parallel resonant) or as a low-resistive circuit (series resonant). The line may be made to act in this manner by either open- or short-circuiting it at the output end and cutting it to some multiple of a quarter-wavelength.

At the points of voltage maxima and minima on a short-circuited or open-circuited line, the line impedance is resistive. On a short-circuited line, each point at an odd number of quarter-wavelengths from the receiving end has a high impedance (figure 3-31, view A). If the frequency of the applied voltage to the line is varied, this impedance decreases as the effective length of the line changes. This variation is exactly the same as the change in the impedance of a parallel-resonant circuit when the applied frequency is varied.

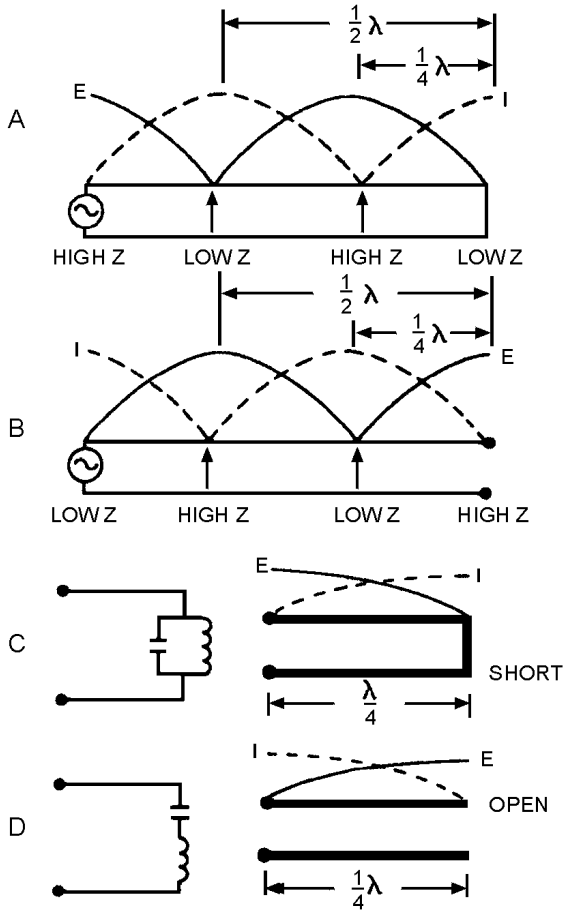

Figure 3-31.—Sending-end impedance of various lengths and terminations.

At all even numbered quarter-wavelength points from the short circuit, the impedance is extremely low. When the frequency of the voltage applied to the line is varied, the impedance at these points increases just as the impedance of a series-resonant circuit varies when the frequency applied to it is changed. The same is true for an open-ended line (figure 3-31, view B) except that the points of high and low impedance are reversed.

At this point let us review some of the characteristics of resonant circuits so we can see how resonant line sections may be used in place of LC circuits.

A PARALLEL-RESONANT circuit has the following characteristics:

- At resonance the impedance appears as a very high resistance. A loss-free circuit has infinite impedance (an open circuit). Other than at resonance, the impedance decreases rapidly.

- If the circuit is resonant at a point above the generator frequency (the generator frequency is too low), more current flows through the coil than through the capacitor. This happens because X_L decreases with a decrease in frequency but X_C increases.

A SERIES-RESONANT circuit has these characteristics:

- At resonance the impedance appears as a very low resistance. A loss-free circuit has zero impedance (a short circuit). Other than at resonance the impedance increases rapidly.

- If the circuit is resonant at a point above the generator frequency (the generator frequency is too low), then X_C is larger than X_L and the circuit acts capacitively.

- If the circuit is resonant at a point below the generator frequency (the generator frequency is too high), then X_L is larger than X_C and the circuit acts inductively.

Since the impedance a generator sees at the quarter-wave point in a shorted line is that of a parallel-resonant circuit, a shorted quarter-wave- length of line may be used as a parallel-resonant circuit (figure 3-31, view C). An open quarter-wavelength of line may be used as a series-resonant circuit (view D). The Q of such a resonant line is much greater than can be obtained with lumped capacitance and inductance.

Impedance for Various Lengths of Open Lines

In figure 3-32, the impedance (Z) the generator sees for various lengths of line is shown at the top. The curves above the letters of various heights show the relative value of the impedances presented to the generator for the various line lengths. The circuit symbols indicate the equivalent electrical circuits for the transmission lines at each particular length. The standing waves of voltage and current are shown on each length of line.

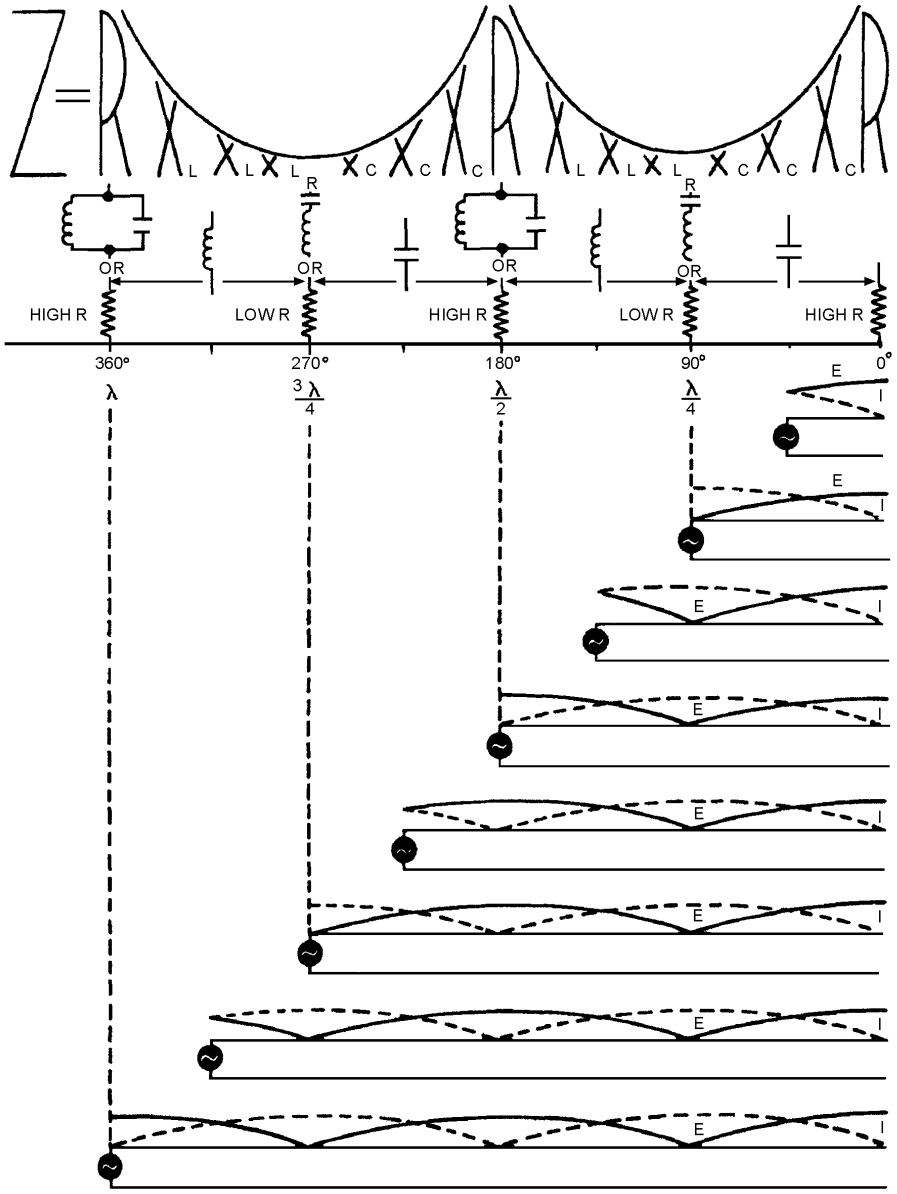

Figure 3-32.—Voltage, current, and impedance on open line.

At all odd quarter-wave points (1/4λ, 3/4λ, etc.), the voltage is minimum, the current is maximum, and the impedance is minimum. Thus, at all odd quarter-wave points, the open-ended transmission line acts as a series-resonant circuit. The impedance is equivalent to a very low resistance, prevented from being zero only by small circuit losses.

At all even quarter-wave points (1/2λ, 1λ, 3/2λ, etc.), the voltage is maximum, the current is minimum, and the impedance is maximum. Comparison of the line with an LC resonant circuit shows that at an even number of quarter-wavelengths, an open line acts as a parallel-resonant circuit. The impedance is therefore an extremely high resistance.

In addition, resonant open lines may also act as nearly pure capacitances or inductances. The illustration shows that an open line less than a quarter-wavelength long acts as a capacitance. Also, it acts

as an inductance from 1/4 to 1/2 wavelength, as a capacitance from 1/2 to 3/4 wavelength, and as an inductance from 3/4 to 1 wavelength, etc. A number of open transmission lines, with their equivalent circuits, are shown in the illustration.

Impedance of Various Lengths of Shorted Lines

Follow figure 3-33 as we study the shorted line. At the odd quarter-wavelength points, the voltage is high, the current is low, and the impedance is high. Since these conditions are similar to those found in a parallel-resonant circuit, the shorted transmission line acts as a parallel-resonant circuit at these lengths.

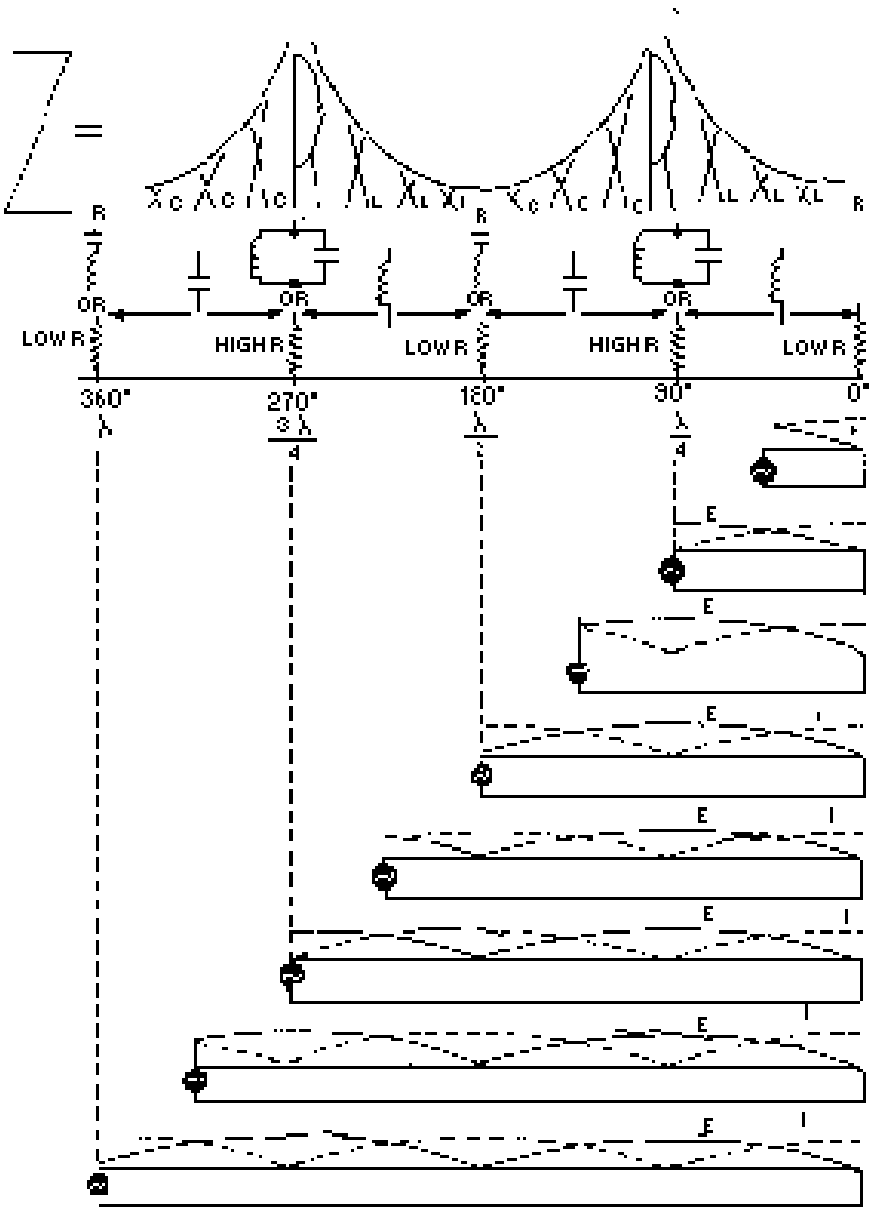

Figure 3-33.—Voltage, current, and impedance on shorted line.

At the even quarter-wave points voltage is minimum, current is maximum, and impedance is minimum. Since these characteristics are similar to those of a series-resonant LC circuit, a shorted transmission line whose length is an even number of quarter-wavelengths acts as a series-resonant circuit.

Resonant shorted lines, like open-end lines, also may act as pure capacitances or inductances. The illustration shows that a shorted line less than 1/4 wavelength long acts as an inductance. A shorted line with a length of from 1/4 to 1/2 wavelength acts as a capacitance. From 1/2 to 3/4 wavelength, the line acts as an inductance; and from 3/4 to 1 wavelength, it acts as a capacitance, and so on. The equivalent circuits of shorted lines of various lengths are shown in the illustration. Thus, properly chosen line segments may be used as parallel-resonant, series-resonant, inductive, or capacitive circuits.

STANDING WAVES ON A TRANSMISSION LINE

There is a large variety of terminations for rf lines. Each type of termination has a characteristic effect on the standing waves on the line. From the nature of the standing waves, you can determine the type of termination that produces the waves.

TERMINATION IN Z_0

Termination in Z_0 (characteristic impedance) will cause a constant reading on an ac meter when it is moved along the length of the line. As illustrated in figure 3-34, view A, the curve, provided there are no losses in the line, will be a straight line. If there are losses in the line, the amplitude of the voltage and current will diminish as they move down the line (view B). The losses are due to dc resistance in the line itself.

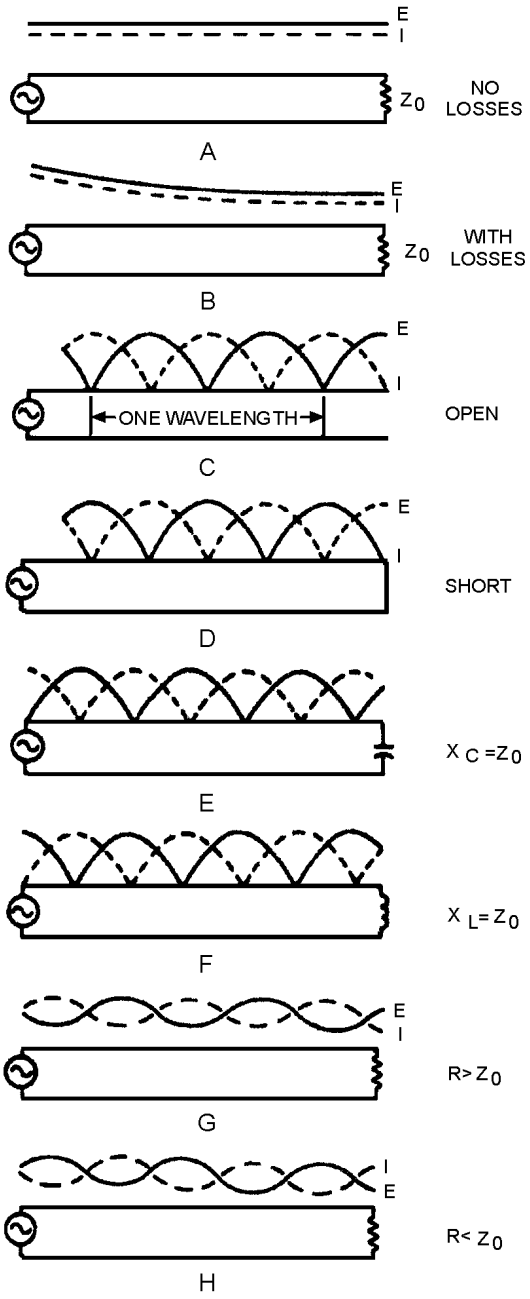

Figure 3-34.—Effects of various terminations on standing waves.

TERMINATION IN AN OPEN CIRCUIT

In an open-circuited rf line (figure 3-34, view C), the voltage is maximum at the end, but the current is minimum. The distance between two adjacent zero current points is 1/2λ, and the distance between alternate zero current points is 1λ. The voltage is zero at a distance of 1/4λ from the end of the line. This is true at any frequency. A voltage peak occurs at the end of the line, at 1/2λ from the end, and at each 1/2λ thereafter.

TERMINATION IN A SHORT CIRCUIT

On the line terminated in a short circuit, shown in figure 3-34, view D, the voltage is zero at the end and maximum at 1/4λ from the end. The current is maximum at the end, zero at 1/4λ from the end, and alternately maximum and zero every 1/4λ thereafter.

TERMINATION IN CAPACITANCE

When a line is terminated in capacitance, the capacitor does not absorb energy, but returns all of the energy to the circuit. This means there is 100 percent reflection. The current and voltage relationships are somewhat more involved than in previous types of termination. For this explanation, assume that the capacitive reactance is equal to the Z_0 of the line. Current and voltage are in phase when they arrive at the end of the line, but in flowing through the capacitor and the characteristic impedance (Z_0) connected in series, they shift in phase relationship. Current and voltage arrive in phase and leave out of phase. This results in the standing-wave configuration shown in figure 3-34, view E. The standing wave of voltage is minimum at a distance of exactly 1/8λ from the end. If the capacitive reactance is greater than Z_0 (smaller capacitance), the termination looks more like an open circuit; the voltage minimum moves away from the end. If the capacitive reactance is smaller than Z_0, the minimum moves toward the end.

TERMINATION IN INDUCTANCE

When the line is terminated in an inductance, both the current and voltage shift in phase as they arrive at the end of the line. When X_L is equal to Z_0, the resulting standing waves are as shown in figure 3-34, view F. The current minimum is located 1/8λ from the end of the line. When the inductive reactance is increased, the standing waves appear closer to the end. When the inductive reactance is decreased, the standing waves move away from the end of the line.

TERMINATION IN A RESISTANCE NOT EQUAL TO THE CHARACTERISTIC IMPEDANCE (Z_0)

Whenever the termination is not equal to Z_0, reflections occur on the line. For example, if the terminating element contains resistance, it absorbs some energy, but if the resistive element does not equal the Z_0 of the line, some of the energy is reflected. The amount of voltage reflected may be found by using the equation:

$$E_R = E_i\left(\frac{R_L - Z_0}{R_L + Z_0}\right)$$

Where:

E_R = the reflected voltage

E_i = the incident voltage

R_R = the terminating resistance

Z_0= the characteristic impedance of the line

If you try different values of R_L in the preceding equation, you will find that the reflected voltage is equal to the incident voltage only when R_L equals 0 or is infinitely large. When R_L equals Z_0, no reflected voltage occurs. When R_L is greater than Z_0, E_R is positive, but less than E_i. As R_L increases and

approaches an infinite value, E_R increases and approaches E_i in value. When R_L is smaller than Z_0, E_R has a negative value. This means that the reflected voltage is of opposite polarity to the incident wave at the termination of the line. As R_L approaches zero, E_R approaches E_i in value. The smaller the value of E_R, the smaller is the peak amplitude of the standing waves and the higher are the minimum values.

TERMINATION IN A RESISTANCE GREATER THAN Z_0

When R_L is greater than Z_0, the end of the line is somewhat like an open circuit; that is, standing waves appear on the line. The voltage maximum appears at the end of the line and also at half-wave intervals back from the end. The current is minimum (not zero) at the end of the line and maximum at the odd quarter-wave points. Since part of the power in the incident wave is consumed by the load resistance, the minimum voltage and current are less than for the standing waves on an open-ended line. Figure 3-34, view G, illustrates the standing waves for this condition.

TERMINATION IN A RESISTANCE LESS THAN Z_0

When R_L is less than Z_0, the termination appears as a short circuit. The standing waves are shown in figure 3-34, view H. Notice that the line terminates in a current LOOP (peak) and a voltage NODE (minimum). The values of the maximum and minimum voltage and current approach those for a shorted line as the value of R_L approaches zero.

A line does not have to be any particular length to produce standing waves; however, it cannot be an infinite line. Voltage and current must be reflected to produce standing waves. For reflection to occur, a line must not be terminated in its characteristic impedance. Reflection occurs on lines terminated in opens, shorts, capacitances, and inductances, because no energy is absorbed by the load. If the line is terminated in a resistance not equal to the characteristic impedance of the line, some energy will be absorbed and the rest will be reflected.

The voltage and current relationships for open-ended and shorted lines are opposite to each other, as shown in figure 3-34, views C and D. The points of maximum and minimum voltage and current are determined from the output end of the line, because reflection always begins at that end.

Q26. A nonresonant line is a line that has no standing waves of current and voltage on it and is considered to be flat. Why is this true?

Q27. On an open line, the voltage and impedance are maximum at what points on the line?

STANDING-WAVE RATIO

The measurement of standing waves on a transmission line yields information about equipment operating conditions. Maximum power is absorbed by the load when $Z_L = Z_0$. If a line has no standing waves, the termination for that line is correct and maximum power transfer takes place.

You have probably noticed that the variation of standing waves shows how near the rf line is to being terminated in Z_0. A wide variation in voltage along the length means a termination far from Z_0. A small variation means termination near Z_0. Therefore, the ratio of the maximum to the minimum is a measure of the perfection of the termination of a line. This ratio is called the STANDING-WAVE RATIO (swr) and is always expressed in whole numbers. For example, a ratio of 1:1 describes a line terminated in its characteristic impedance (Z_0).

Voltage Standing-Wave Ratio

The ratio of maximum voltage to minimum voltage on a line is called the VOLTAGE STANDING-WAVE RATIO (vswr). Therefore:

$$\text{vswr} = \frac{E_{max}}{E_{min}}$$

The vertical lines in the formula indicate that the enclosed quantities are absolute and that the two values are taken without regard to polarity. Depending on the nature of the standing waves, the numerical value of vswr ranges from a value of 1 ($Z_L = Z_0$, no standing waves) to an infinite value for theoretically complete reflection. Since there is always a small loss on a line, the minimum voltage is never zero and the vswr is always some finite value. However, if the vswr is to be a useful quantity, the power losses along the line must be small in comparison to the transmitted power.

Power Standing-Wave Ratio

The square of the voltage standing-wave ratio is called the POWER STANDING-WAVE RATIO (pswr). Therefore:

$$\text{pswr} = \frac{P_{max}}{P_{min}}$$

This ratio is useful because the instruments used to detect standing waves react to the square of the voltage. Since power is proportional to the square of the voltage, the ratio of the square of the maximum and minimum voltages is called the power standing-wave ratio. In a sense, the name is misleading because the power along a transmission line does not vary.

Current Standing-Wave Ratio

The ratio of maximum to minimum current along a transmission line is called CURRENT STANDING-WAVE RATIO (iswr). Therefore:

$$\text{iswr} = \frac{I_{max}}{I_{min}}$$

This ratio is the same as that for voltages. It can be used where measurements are made with loops that sample the magnetic field along a line. It gives the same results as vswr measurements.

Q28. At what point on an open-circuited rf line do voltage peaks occur?

Q29. What is the square of the voltage standing-wave ratio called?

Q30. What does vswr measure?

SUMMARY

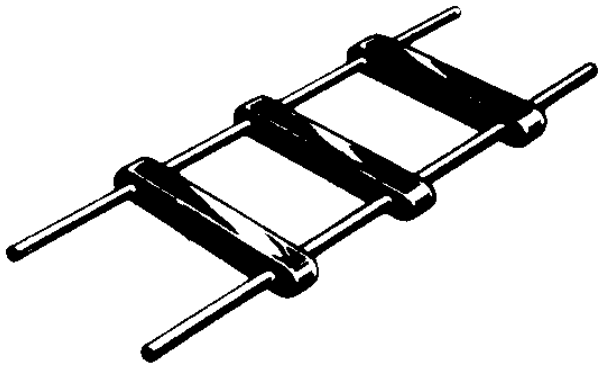
This chapter has presented information on the characteristics of transmission lines. The information that follows summarizes the important points of this chapter.

TRANSMISSION LINES are devices for guiding electrical energy from one point to another.

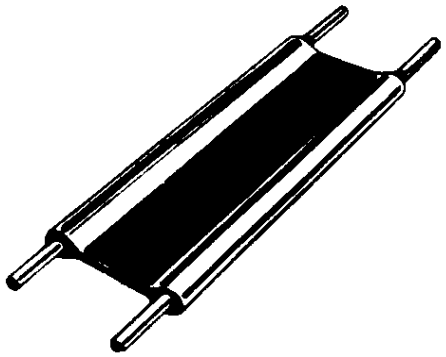
INPUT IMPEDANCE is the ratio of voltage to current at the input end of a transmission line.

OUTPUT IMPEDANCE is the ratio of voltage to current at the output end of the line.

TWO-WIRE OPEN LINES are parallel lines and have uses such as power lines, rural telephone lines, and telegraph lines. This type of line has high radiation losses and is subject to noise pickup.

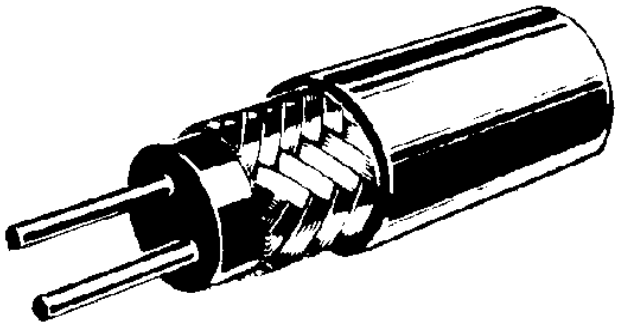


TWIN LEAD has parallel lines and is most often used to connect televisions to their antennas.

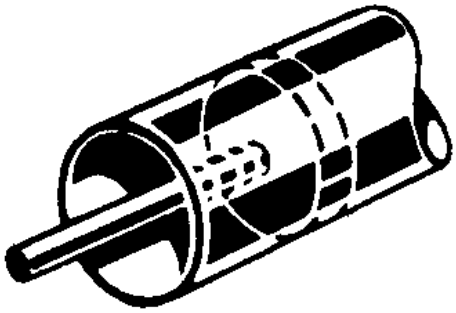


A **TWISTED PAIR** consists of two insulated wires twisted together. This line has high insulation loss.

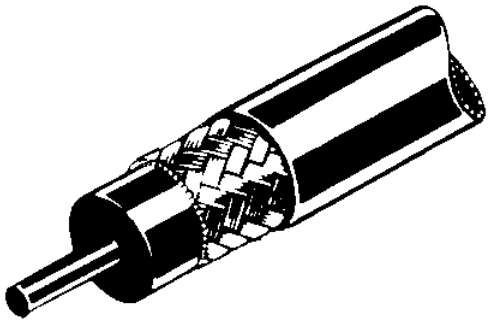
A **SHIELDED PAIR** has parallel conductors separated by a solid dielectric and surrounded by copper braided tubing. The conductors are balanced to ground.



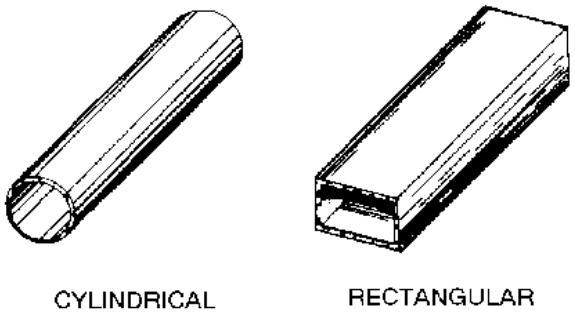
RIGID COAXIAL LINE contains two concentric conductors insulated from each other by spacers. Some rigid coaxial lines are pressurized with an inert gas to prevent moisture from entering. High-frequency losses are less than with other lines.



FLEXIBLE COAXIAL LINES consist of a flexible inner conductor and a concentric outer conductor of metal braid. The two are separated by a continuous insulating material.



WAVEGUIDES are hollow metal tubes used to transfer energy from one point to another. The energy travels slower in a waveguide than in free space.



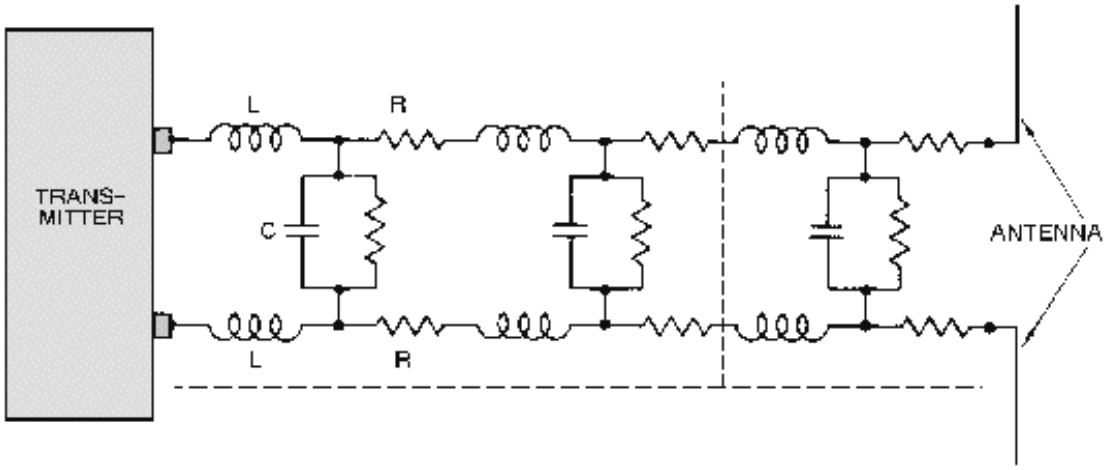
COPPER LOSSES can result from power (I^2R) loss, in the form of heat, or skin effect. These losses decrease the conductivity of a line.

DIELECTRIC LOSSES are caused by the heating of the dielectric material between conductors, taking power from the source.

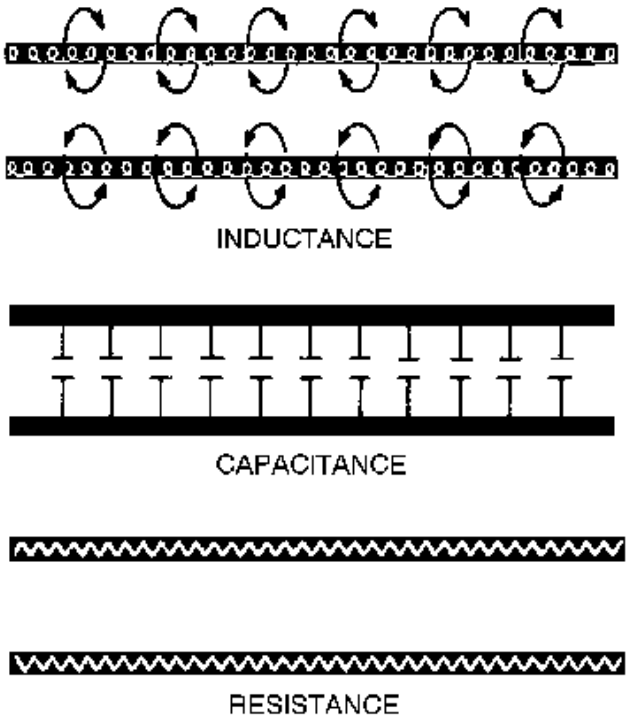
RADIATION and **INDUCTION LOSSES** are caused by part of the electromagnetic fields of a conductor being dissipated into space or nearby objects.

A transmission line is either electrically **LONG** or **SHORT** if its physical length is not equal to $1/4\lambda$ for the frequency it is to carry.

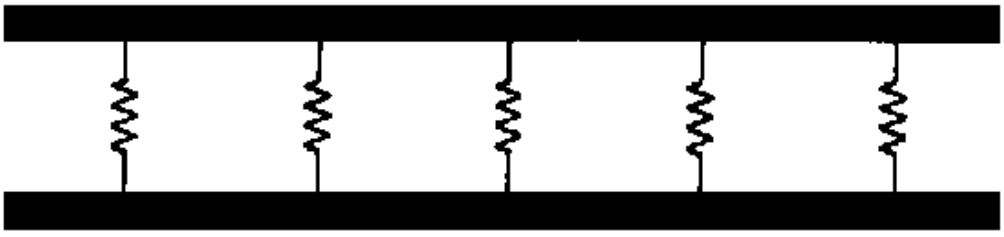
LUMPED CONSTANTS are theoretical properties (inductance, resistance, and capacitance) of a transmission line that are lumped into a single component.



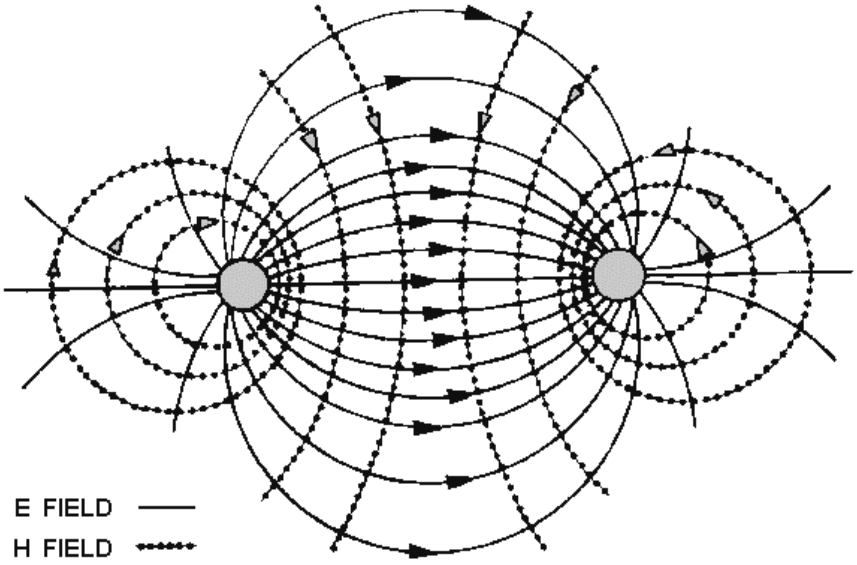
DISTRIBUTED CONSTANTS are constants of inductance, capacitance and resistance that are distributed along the transmission line.



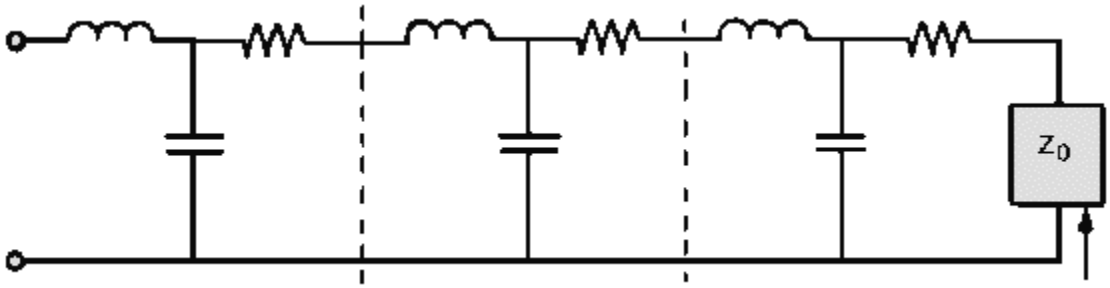
LEAKAGE CURRENT flows between the wires of a transmission line through the dielectric. The dielectric acts as a resistor.



An **ELECTROMAGNETIC FIELD** exists along transmission line when current flows through it.



CHARACTERISTIC IMPEDANCE, Z_0, is the ratio of E to I at every point along the line. For maximum transfer of electrical power, the characteristic impedance and load impedance must be matched.



The **VELOCITY** at which a wave travels over a given length of transmission line can be found by using the formula:

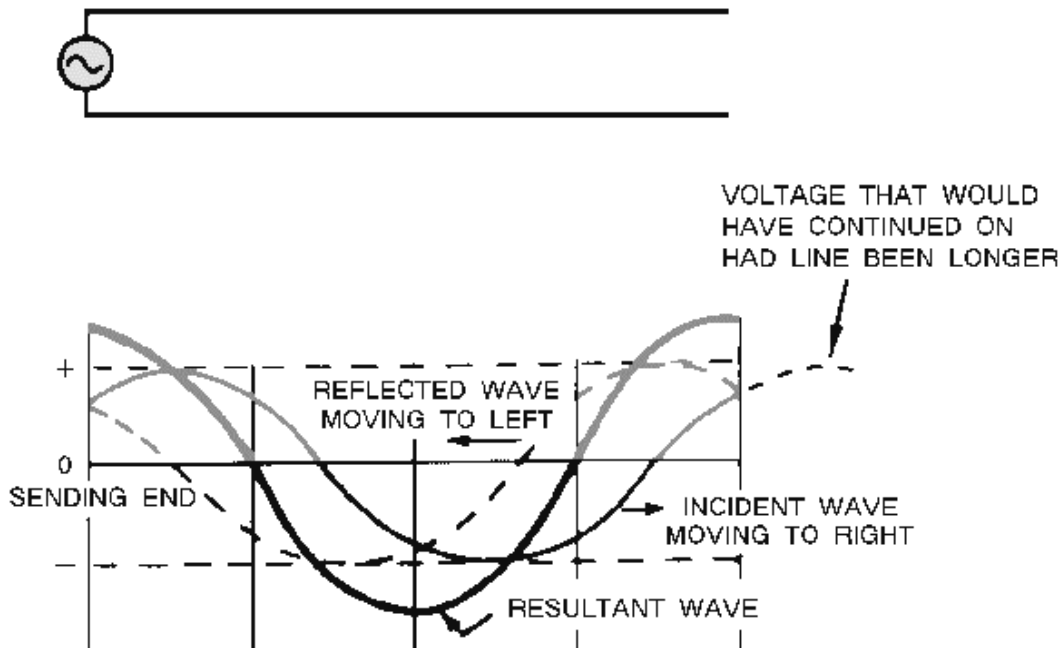
$$V = \frac{D}{\sqrt{LC}}$$

A transmission line that is not terminated in its characteristic impedance is said to be **FINITE**.

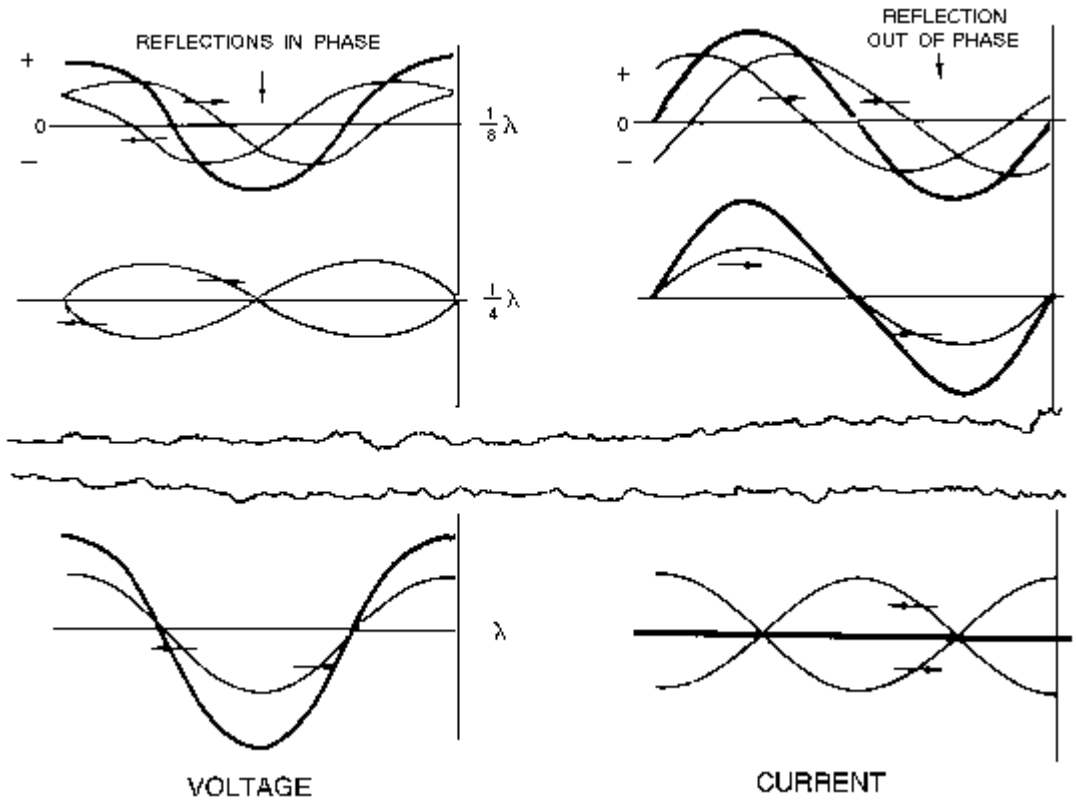
When dc is applied to an **OPEN-ENDED** line, the voltage is reflected back from the open end without any change in polarity, amplitude, or shape. Current is reflected back with the same amplitude and shape but with opposite polarity.

When dc is applied to a **SHORT-CIRCUITED** line, the current is reflected back with the same amplitude, and polarity. The voltage is reflected back with the same amplitude but with opposite polarity.

When ac is applied to an **OPEN-END** line, voltage is always reflected back in phase with the incident wave and current is reflected back out of phase.



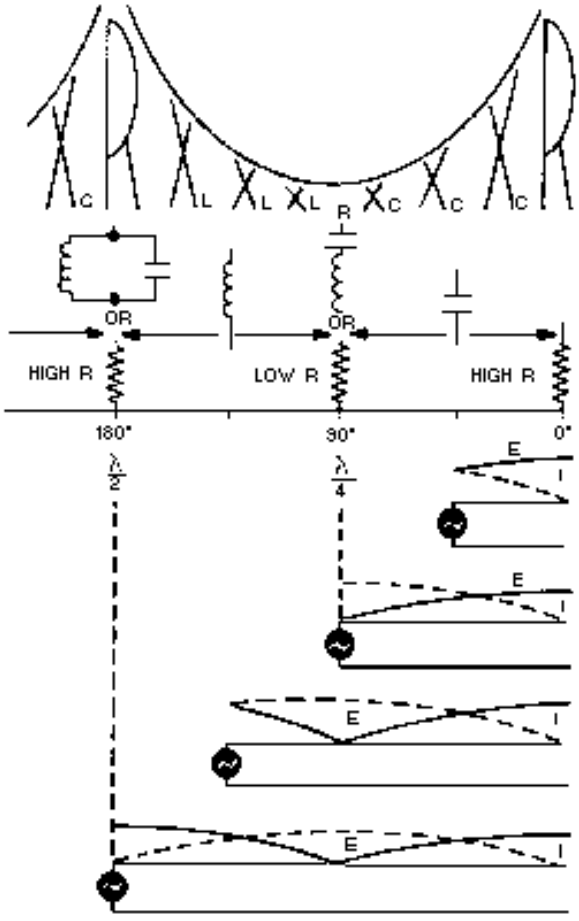
When ac is applied to a **SHORT-CIRCUITED** line, voltage is reflected in opposite phase, while current is reflected in phase.



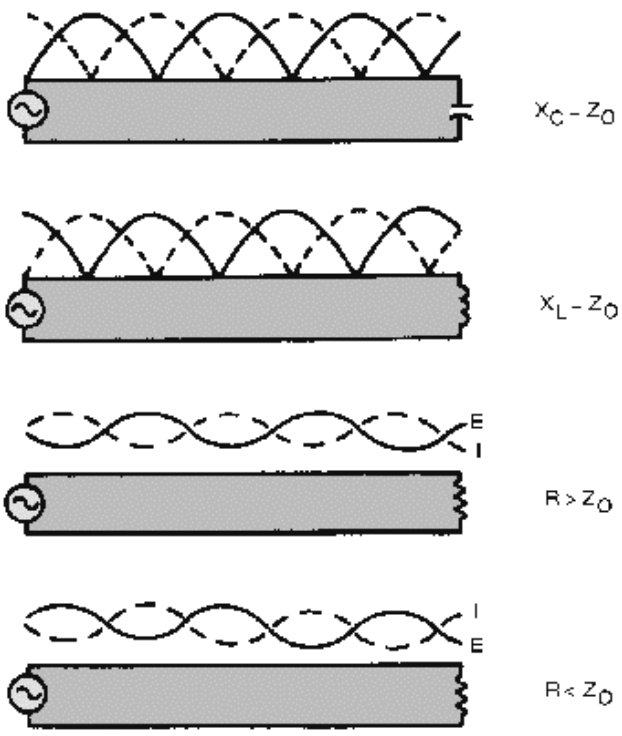
A **NONRESONANT** line has **NO STANDING WAVES** of current and voltage and is either infinitely long or terminated in its characteristic impedance.

A **RESONANT** line has **STANDING WAVES** of current and voltage and is of finite length and is NOT terminated in its characteristic impedance.

On an open-ended resonant line, and at all odd 1/4λ points, the voltage is minimum, the current is maximum, and the impedance is minimum. At all even 1/4λ points, the voltage is maximum, the current is minimum and the impedance is maximum.



There are a variety of **TERMINATIONS** for rf lines. Each termination has an effect on the standing waves on the line.



A transmission line can be terminated in its characteristic impedance as an open- or short-circuit, or in capacitance or inductance.

Whenever the termination on a transmission line is NOT EQUAL TO Z_0, there are reflections on the line. The amount of voltage reflected may be found by using the equation:

$$E_R = E_i\left(\frac{R_L - Z_0}{R_L + Z_0}\right)$$

When the termination on a transmission line EQUALS Z_0, there is NO reflected voltage.

The measurement of standing waves on a transmission line yields information about operating conditions. If there are NO standing waves, the termination for that line is correct and maximum power transfer takes place.

The **STANDING WAVE RATIO** is the measurement of maximum voltage (current) to minimum voltage (current) on a transmission line and measures the perfection of the termination of the line. A ratio of 1:1 describes a line terminated in its characteristic impedance.

ANSWERS TO QUESTIONS Q1. THROUGH Q30.

A1. Transmission line.

A2. Input end, generator end, transmitter end, sending end, and source.

A3. Output end, receiving end, load end and sink.

A4. Parallel two-wire, twisted pair, shielded pair, coaxial line and waveguide.

A5. Power lines, rural telephone lines, and telegraph lines.

A6. High radiation losses and noise pickup.

A7. Twin lead.

A8. The conductors are balanced to ground.

A9. Air coaxial (rigid) and solid coaxial (flexible).

A10. The ability to minimize radiation losses.

A11. Expensive to construct, must be kept dry, and high frequency losses limit the practical length of the line.

A12. Cylindrical and rectangular.

A13. Copper, dielectric, and radiation.

A14. Copper losses.

A15. Dielectric losses.

A16. λ = 20 meters.

A17. (1) Type of line used, (2) dielectric in the line, and (3) length of line.

A18. Inductance is expressed in microhenrys per unit length, capacitance is expressed in picofarads per unit length, and resistance is expressed in ohms per unit length.

A19. The small amount of current that flows through the dielectric between two wires of a transmission line and is expressed in micromhos per unit length.

A20. When the characteristic impedance of the transmission line and the load impedance are equal.

A21. Z_0 and it is the ratio of E to I at every point along the line.

A22. Between 50 and 600 ohms.

A23. Incident waves from generator to load. Reflected waves from load back to generator.

A24. 2 and 6 have zero resultant wave and they indicate that the incident and reflected waves are 180 degrees out of phase at all parts.

A25. One-fourth the distance from each end of the line.

A26. The load impedance of such a line is equal to Z_0.

A27. Even quarter-wave points (1/2λ, 1λ, 3/2λ, etc.).

A28. At 1/2 wavelength from the end and at every 1/2 wavelength along the line.

A29. Power standing-wave ratio (pswr).

A30. The existence of voltage variations on a line.

CHAPTER 4

ANTENNAS

LEARNING OBJECTIVES

Upon completion of this chapter you will be able to:

1. State the basic principles of antenna radiation and list the parts of an antenna.
2. Explain current and voltage distribution on an antenna.
3. Describe how electromagnetic energy is radiated from an antenna.
4. Explain polarization, gain, and radiation resistance characteristics of an antenna.
5. Describe the theory of operation of half- wave and quarter-wave antennas.
6. List the various array antennas.
7. Describe the directional array antennas presented and explain the basic operation of each.
8. Identify various special antennas presented, such as long-wire, V, rhombic, turnstile, ground-plane, and corner-reflector; describe the operation of each.
9. List safety precautions when working aloft and around antennas.

INTRODUCTION

If you had been around in the early days of electronics, you would have considered an ANTENNA (AERIAL) to be little more than a piece of wire strung between two trees or upright poles. In those days, technicians assumed that longer antennas automatically provided better reception than shorter antennas. They also believed that a mysterious MEDIUM filled all space, and that an antenna used this medium to send and receive its energy. These two assumptions have since been discarded. Modern antennas have evolved to the point that highly directional, specially designed antennas are used to relay worldwide communications in space through the use of satellites and Earth station antennas (fig. 4-1). Present transmission theories are based on the assumption that space itself is the only medium necessary to propagate (transmit) radio energy.

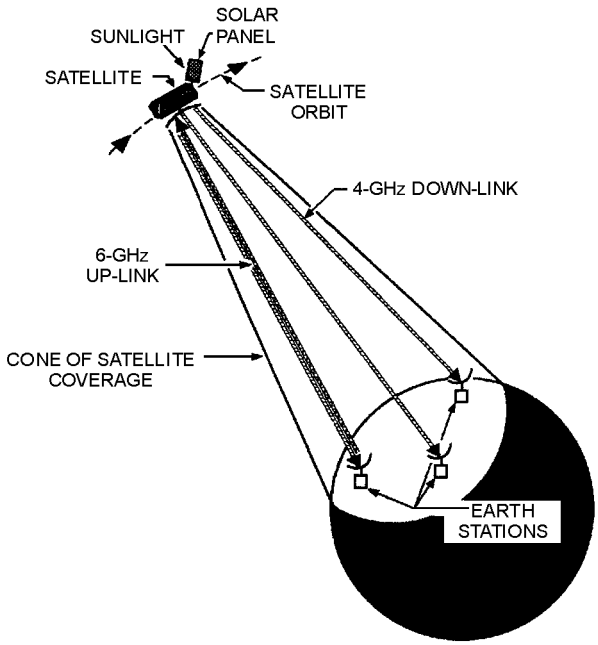


Figure 4-1.—Satellite/earth station communications system.

A tremendous amount of knowledge and information has been gained about the design of antennas and radio-wave propagation. Still, many old-time technicians will tell you that when it comes to designing the length of an antenna, the best procedure is to perform all calculations and try out the antenna. If it doesn't work right, use a cut-and-try method until it does. Fortunately, enough information has been collected over the last few decades that it is now possible to predict the behavior of antennas. This chapter will discuss and explain the basic design and operation of antennas.

PRINCIPLES OF ANTENNA RADIATION

After an rf signal has been generated in a transmitter, some means must be used to radiate this signal through space to a receiver. The device that does this job is the antenna. The transmitter signal energy is sent into space by a TRANSMITTING ANTENNA; the rf signal is then picked up from space by a RECEIVING ANTENNA.

The rf energy is transmitted into space in the form of an electromagnetic field. As the traveling electromagnetic field arrives at the receiving antenna, a voltage is induced into the antenna (a conductor). The rf voltages induced into the receiving antenna are then passed into the receiver and converted back into the transmitted rf information.

The design of the antenna system is very important in a transmitting station. The antenna must be able to radiate efficiently so the power supplied by the transmitter is not wasted. An efficient transmitting antenna must have exact dimensions. The dimensions are determined by the transmitting frequencies. The dimensions of the receiving antenna are not critical for relatively low radio frequencies. However, as the frequency of the signal being received increases, the design and installation of the receiving antenna become more critical. An example of this is a television receiving antenna. If you raise it a few more inches from the ground or give a slight turn in direction, you can change a snowy blur into a clear picture.

The conventional antenna is a conductor, or system of conductors, that radiates or intercepts electromagnetic wave energy. An ideal antenna has a definite length and a uniform diameter, and is completely isolated in space. However, this ideal antenna is not realistic. Many factors make the design of an antenna for a communications system a more complex problem than you would expect. These factors include the height of the radiator above the earth, the conductivity of the earth below it, and the shape and dimensions of the antenna. All of these factors affect the radiated-field pattern of the antenna in space. Another problem in antenna design is that the radiation pattern of the antenna must be directed between certain angles in a horizontal or vertical plane, or both.

Most practical transmitting antennas are divided into two basic classifications, HERTZ (half-wave) ANTENNAS and MARCONI (quarter-wave) ANTENNAS. Hertz antennas are generally installed some distance above the ground and are positioned to radiate either vertically or horizontally. Marconi antennas operate with one end grounded and are mounted perpendicular to the Earth or to a surface acting as a ground. Hertz antennas are generally used for frequencies above 2 megahertz. Marconi antennas are used for frequencies below 2 megahertz and may be used at higher frequencies in certain applications.

A complete antenna system consists of three parts: (1) The COUPLING DEVICE, (2) the FEEDER, and (3) the ANTENNA, as shown in figure 4-2. The coupling device (coupling coil) connects the transmitter to the feeder. The feeder is a transmission line that carries energy to the antenna. The antenna radiates this energy into space.

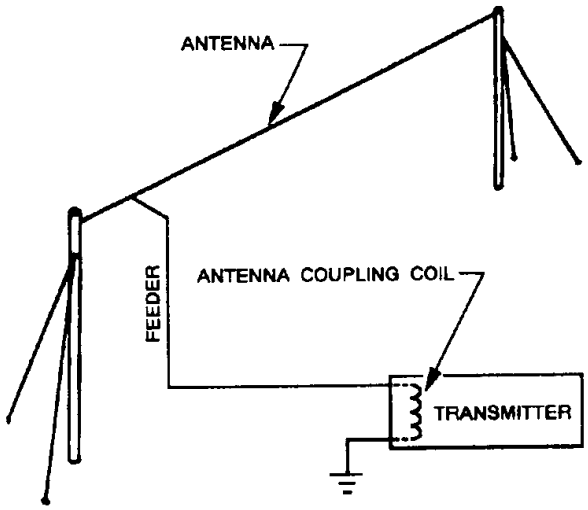

Figure 4-2.—Typical antenna system.

The factors that determine the type, size, and shape of the antenna are (1) the frequency of operation of the transmitter, (2) the amount of power to be radiated, and (3) the general direction of the receiving set. Typical antennas are shown in figure 4-3.

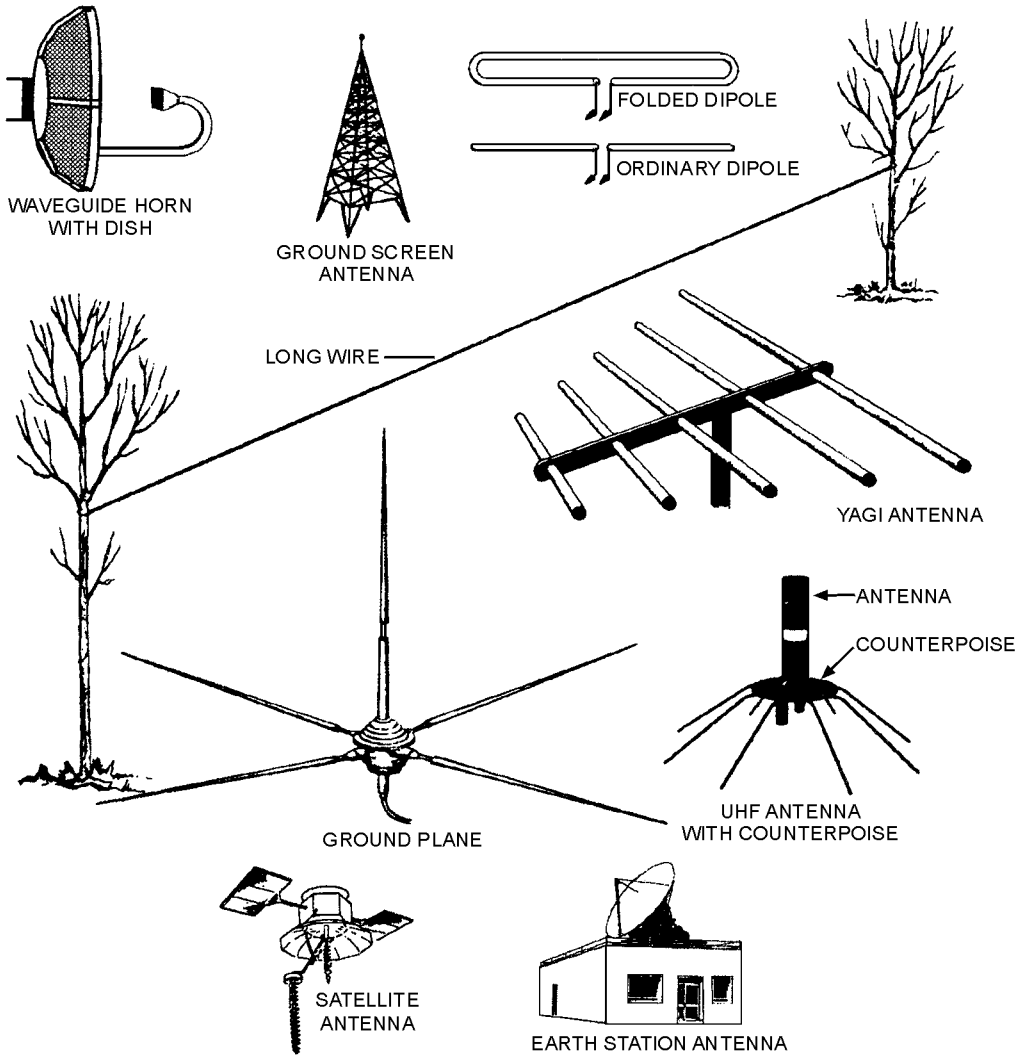

Figure 4-3.—Typical antennas.

CURRENT AND VOLTAGE DISTRIBUTION ON AN ANTENNA

A current flowing in a wire whose length is properly related to the rf produces an electro magnetic field. This field is radiated from the wire and is set free in space. We will discuss how these waves are set free later in this chapter. Remember, the principles of radiation of electromagnetic energy are based on two laws:

1. A MOVING ELECTRIC FIELD CREATES A MAGNETIC (H) FIELD.

2. A MOVING MAGNETIC FIELD CREATES AN ELECTRIC (E) FIELD.

In space, these two fields will be in phase and perpendicular to each other at any given time. Although a conductor is usually considered present when a moving electric or magnetic field is mentioned, the laws that govern these fields say nothing about a conductor. Therefore, these laws hold true whether a conductor is present or not.

Figure 4-4 shows the current and voltage distribution on a half-wave (Hertz) antenna. In view A, a piece of wire is cut in half and attached to the terminals of a high-frequency ac generator. The frequency of the generator is set so that each half of the wire is 1/4 wavelength of the output. The result is a common type of antenna known as a DIPOLE.

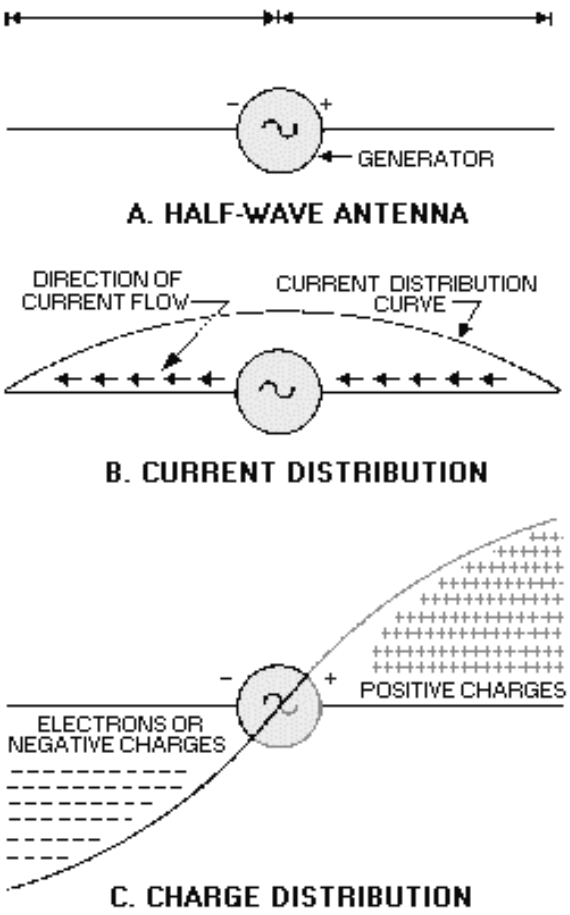

Figure 4-4.—Current and voltage distribution on an antenna.

At a given time the right side of the generator is positive and the left side negative. Remember that like charges repel. Because of this, electrons will flow away from the negative terminal as far as possible, but will be attracted to the positive terminal. View B shows the direction and distribution of electron flow. The distribution curve shows that most current flows in the center and none flows at the ends. The current distribution over the antenna will always be the same no matter how much or how little current is flowing. However, current at any given point on the antenna will vary directly with the amount of voltage developed by the generator.

One-quarter cycle after electrons have begun to flow, the generator will develop its maximum voltage and the current will decrease to 0. At that time the condition shown in view C will exist. No current will be flowing, but a maximum number of electrons will be at the left end of the line and a minimum number at the right end. The charge distribution view C along the wire will vary as the voltage of the generator varies. Therefore, you may draw the following conclusions:

1. A current flows in the antenna with an amplitude that varies with the generator voltage.

2. A sinusoidal distribution of charge exists on the antenna. Every 1/2 cycle, the charges reverse polarity.

3. The sinusoidal variation in charge magnitude lags the sinusoidal variation in current by 1/4 cycle.

Q1. What are the two basic classifications of antennas?

Q2. What are the three parts of a complete antenna system?

Q3. What three factors determine the type, size, and shape of an antenna?

RADIATION OF ELECTROMAGNETIC ENERGY

The electromagnetic radiation from an antenna is made up of two components, the E field and the H field. We discussed these fields in chapters 1 and 2. The two fields occur 90 degrees out of phase with each other. These fields add and produce a single electromagnetic field. The total energy in the radiated wave remains constant in space except for some absorption of energy by the Earth. However, as the wave advances, the energy spreads out over a greater area and, at any given point, decreases as the distance increases.

Various factors in the antenna circuit affect the radiation of these waves. In figure 4-5, for example, if an alternating current is applied at the A end of the length of wire from A to B, the wave will travel along the wire until it reaches the B end. Since the B end is free, an open circuit exists and the wave cannot travel farther. This is a point of high impedance. The wave bounces back (reflects) from this point of high impedance and travels toward the starting point, where it is again reflected. The energy of the wave would be gradually dissipated by the resistance of the wire of this back-and-forth motion (oscillation); however, each time it reaches the starting point, the wave is reinforced by an amount sufficient to replace the energy lost. This results in continuous oscillations of energy along the wire and a high voltage at the A end of the wire. These oscillations are applied to the antenna at a rate equal to the frequency of the rf voltage.

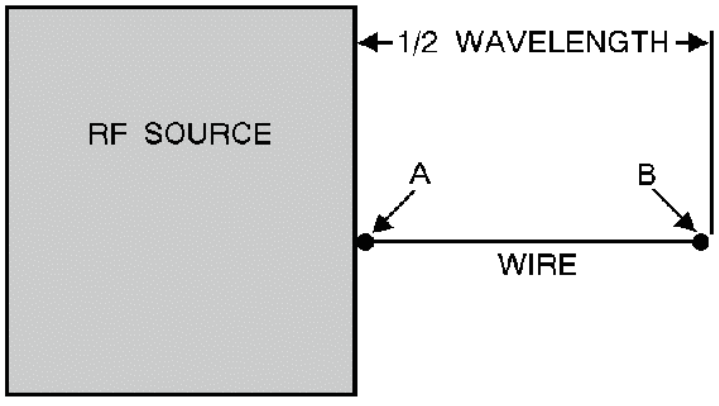

Figure 4-5.—Antenna and rf source.

These impulses must be properly timed to sustain oscillations in the antenna. The rate at which the waves travel along the wire is constant at approximately 300,000,000 meters per second. The length of

the antenna must be such that a wave will travel from one end to the other and back again during the period of 1 cycle of the rf voltage. Remember, the distance a wave travels during the period of 1 cycle is known as the wavelength and is found by dividing the rate of travel by the frequency.

Look at the current and voltage (charge) distribution on the antenna in figure 4-6. A maximum movement of electrons is in the center of the antenna at all times; therefore, the center of the antenna is at a low impedance. This condition is called a STANDING WAVE of current. The points of high current and high voltage are known as current and voltage LOOPS. The points of minimum current and minimum voltage are known as current and voltage NODES. View A shows a current loop and current nodes. View B shows voltage loops and a voltage node. View C shows the resultant voltage and current loops and nodes. The presence of standing waves describes the condition of resonance in an antenna. At resonance the waves travel back and forth in the antenna reinforcing each other and the electromagnetic waves are transmitted into space at maximum radiation. When the antenna is not at resonance, the waves tend to cancel each other and lose energy in the form of heat.

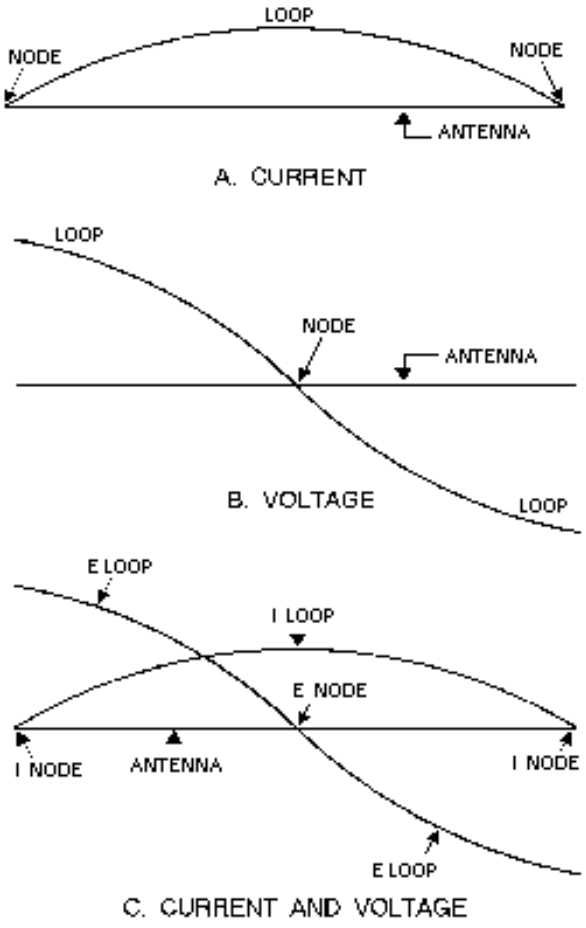

Figure 4-6.—Standing waves of voltage and current on an antenna.

Q4. If a wave travels exactly the length of an antenna from one end to the other and back during the period of 1 cycle, what is the length of the antenna?

Q5. What is the term used to identify the points of high current and high voltage on an antenna?

Q6. What is the term used to identify the points of minimum current and minimum voltage on an antenna?

ANTENNA CHARACTERISTICS

You can define an antenna as a conductor or group of conductors used either for radiating electromagnetic energy into space or for collecting it from space. Electrical energy from the transmitter is converted into electromagnetic energy by the antenna and radiated into space. On the receiving end, electromagnetic energy is converted into electrical energy by the antenna and is fed into the receiver.

Fortunately, separate antennas seldom are required for both transmitting and receiving rf energy. Any antenna can transfer energy from space to its input receiver with the same efficiency that it transfers energy from the transmitter into space. Of course, this is assuming that the same frequency is used in both cases. This property of interchangeability of the same antenna for transmitting and receiving is known as antenna RECIPROCITY. Antenna reciprocity is possible because antenna characteristics are essentially the same for sending and receiving electromagnetic energy.

RECIPROCITY OF ANTENNAS

In general, the various properties of an antenna apply equally, regardless of whether you use the antenna for transmitting or receiving. The more efficient a certain antenna is for transmitting, the more efficient it will be for receiving on the same frequency. Likewise, the directive properties of a given antenna also will be the same whether it is used for transmitting or receiving.

Assume, for example, that a certain antenna used with a transmitter radiates a maximum amount of energy at right angles to the axis of the antenna, as shown in figure 4-7, view A. Note the minimum amount of radiation along the axis of the antenna. Now, if this same antenna were used as a receiving antenna, as shown in view B, it would receive best in the same directions in which it produced maximum radiation; that is, at right angles to the axis of the antenna.

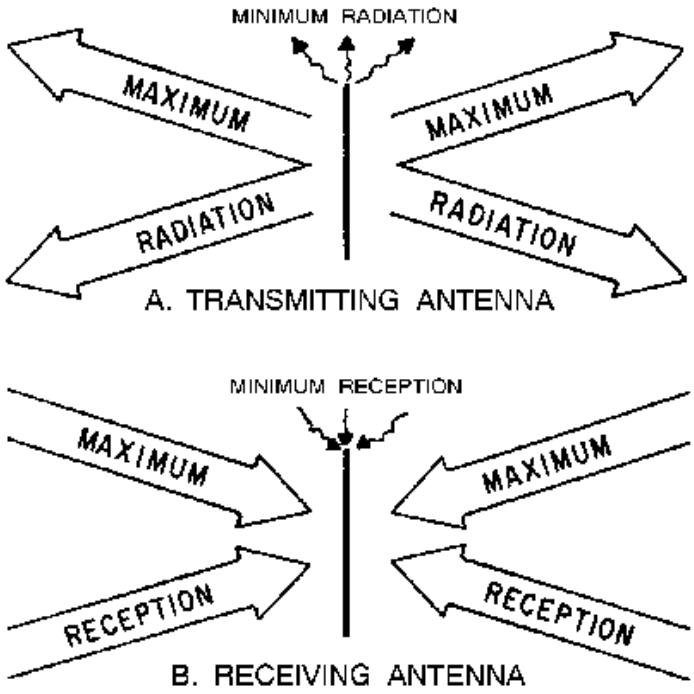

Figure 4-7.—Reciprocity of antennas.

ANTENNA GAIN

Another characteristic of a given antenna that remains the same whether the antenna is used for transmitting or receiving is GAIN. Some antennas are highly directional that is, more energy is propagated in certain directions than in others. The ratio between the amount of energy propagated in these directions compared to the energy that would be propagated if the antenna were not directional is known as its gain. When a transmitting antenna with a certain gain is used as a receiving antenna, it will also have the same gain for receiving.

POLARIZATION

Let's review polarization briefly. In chapter 2 you learned that the radiation field is composed of electric and magnetic lines of force. These lines of force are always at right angles to each other. Their intensities rise and fall together, reaching their maximums 90 degrees apart. The electric field determines the direction of polarization of the wave. In a vertically polarized wave, the electric lines of force lie in a vertical direction. In a horizontally polarized wave, the electric lines of force lie in a horizontal direction. Circular polarization has the electric lines of force rotating through 360 degrees with every cycle of rf energy.

The electric field was chosen as the reference field because the intensity of the wave is usually measured in terms of the electric field intensity (volts, millivolts, or microvolts per meter). When a single-wire antenna is used to extract energy from a passing radio wave, maximum pickup will result when the antenna is oriented in the same direction as the electric field. Thus a vertical antenna is used for the efficient reception of vertically polarized waves, and a horizontal antenna is used for the reception of horizontally polarized waves. In some cases the orientation of the electric field does not remain constant.

Instead, the field rotates as the wave travels through space. Under these conditions both horizontal and vertical components of the field exist and the wave is said to have an elliptical polarization.

Q7. The various properties of a transmitting antenna can apply equally to the same antenna when it is used as a receiving antenna. What term is used for this property?

Q8. The direction of what field is used to designate the polarization of a wave?

Q9. If a wave's electric lines of force rotate through 360 degrees with every cycle of rf energy, what is the polarization of this wave?

Polarization Requirements for Various Frequencies

Ground-wave transmission is widely used at medium and low frequencies. Horizontal polarization cannot be used at these frequencies because the electric lines of force are parallel to and touch the earth. Since the earth acts as a fairly good conductor at low frequencies, it would short out the horizontal electric lines of force and prevent the radio wave from traveling very far. Vertical electric lines of force, on the other hand, are bothered very little by the earth. Therefore vertical polarization is used for ground-wave transmission, allowing the radio wave to travel a considerable distance along the ground surface with minimum attenuation.

Sky-wave transmission is used at high frequencies. Either horizontal or vertical polarization can be used with sky-wave transmission because the sky wave arrives at the receiving antenna elliptically polarized. This is the result of the wave traveling obliquely through the Earth's magnetic field and striking the ionosphere. The radio wave is given a twisting motion as it strikes the ionosphere. Its orientation continues to change because of the unstable nature of the ionosphere. The relative amplitudes and phase differences between the horizontal and vertical components of the received wave also change. Therefore, the transmitting and receiving antennas can be mounted either horizontally or vertically.

Although either horizontally or vertically polarized antennas can be used for high frequencies, horizontally polarized antennas have certain advantages and are therefore preferred. One advantage is that vertically polarized interference signals, such as those produced by automobile ignition systems and electrical appliances, are minimized by horizontal polarization. Also, less absorption of radiated energy by buildings or wiring occurs when these antennas are used. Another advantage is that support structures for these antennas are of more convenient size than those for vertically polarized antennas.

For frequencies in the vhf or uhf range, either horizontal or vertical polarization is satisfactory. These radio waves travel directly from the transmitting antenna to the receiving antenna without entering the ionosphere. The original polarization produced at the transmitting antenna is maintained throughout the entire travel of the wave to the receiver. Therefore, if a horizontally polarized antenna is used for transmitting, a horizontally polarized antenna must be used for receiving. The requirements would be the same for a vertical transmitting and receiving antenna system.

For satellite communications, parallel frequencies can be used without interference by using polarized radiation. The system setup is shown in figure 4-8. One pair of satellite antennas is vertically polarized and another pair is horizontally polarized. Either vertically or horizontally polarized transmissions are received by the respective antenna and retransmitted in the same polarization. For example, transmissions may be made in the 3.7 to 3.74 GHz range on the vertical polarization path and in the 3.72 to 3.76 GHz range on the horizontal polarization path without adjacent frequency (co-channel) interference.

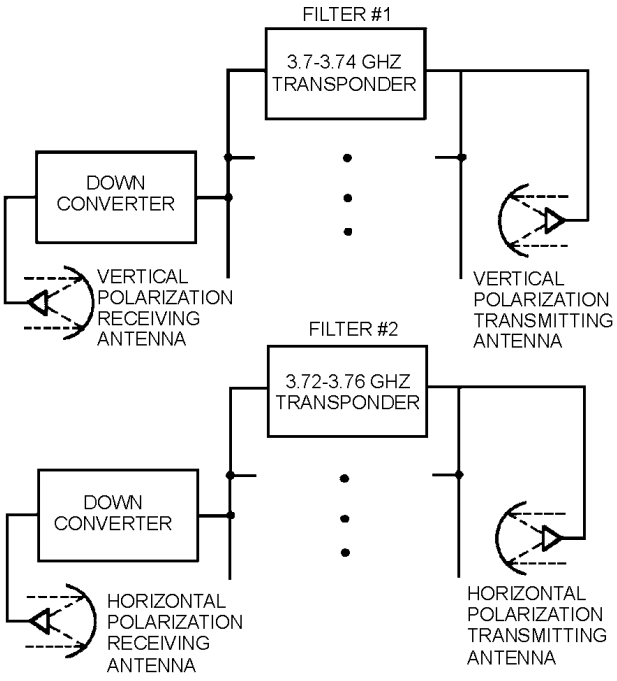

Figure 4-8.—Satellite transmissions using polarized radiation.

Advantages of Vertical Polarization

Simple vertical antennas can be used to provide OMNIDIRECTIONAL (all directions) communication. This is an advantage when communications must take place from a moving vehicle.

In some overland communications, such as in vehicular installations, antenna heights are limited to 3 meters (10 feet) or less. In such instances vertical polarization results in a stronger receiver signal than does horizontal polarization at frequencies up to about 50 megahertz. From approximately 50 to 100 megahertz, vertical polarization results in a slightly stronger signal than does horizontal polarization with antennas at the same height. Above 100 megahertz, the difference in signal strength is negligible.

For transmission over bodies of water, vertical polarization is much better than horizontal polarization for antennas at the lower heights. As the frequency increases, the minimum antenna height decreases. At 30 megahertz, vertical polarization is better for antenna heights below about 91 meters (300 feet); at 85 megahertz, antenna heights below 15 meters (50 feet); and still lower heights at the high frequencies. Therefore, at ordinary antenna mast heights of 12 meters (40 feet), vertical polarization is advantageous for frequencies less than about 100 megahertz.

Radiation is somewhat less affected by reflections from aircraft flying over the transmission path when vertical polarization is used instead of horizontal polarization. With horizontal polarization, such reflections cause variations in received signal strength. This factor is important in locations where aircraft traffic is heavy.

When vertical polarization is used, less interference is produced or picked up because of strong vhf and uhf broadcast transmissions (television and fm). This is because vhf and uhf transmissions use horizontal polarization. This factor is important when an antenna must be located in an urban area having several television and fm broadcast stations.

Advantages of Horizontal Polarization

A simple horizontal antenna is bi-directional. This characteristic is useful when you desire to minimize interference from certain directions. Horizontal antennas are less likely to pick up man-made interference, which ordinarily is vertically polarized.

When antennas are located near dense forests or among buildings, horizontally polarized waves suffer lower losses than vertically polarized waves, especially above 100 megahertz. Small changes in antenna locations do not cause large variations in the field intensity of horizontally polarized waves. When vertical polarization is used, a change of only a few meters in the antenna location may have a considerable effect on the received signal strength. This is the result of interference patterns that produce standing waves in space when spurious reflections from trees or buildings occur.

When simple antennas are used, the transmission line, which is usually vertical, is less affected by a horizontally mounted antenna. When the antenna is mounted at right angles to the transmission line and horizontal polarization is used, the line is kept out of the direct field of the antenna. As a result, the radiation pattern and electrical characteristics of the antenna are practically unaffected by the presence of the vertical transmission line.

Q10. What type of polarization should be used at medium and low frequencies?

Q11. What is an advantage of using horizontal polarization at high frequencies?

Q12. What type of polarization should be used if an antenna is mounted on a moving vehicle at frequencies below 50 megahertz?

RADIATION RESISTANCE

Radiated energy is the useful part of the transmitter's signal. However, it represents as much of a loss to the antenna as the energy lost in heating the antenna wire. In either case, the dissipated power is equal to I^2R. In the case of heat losses, the R is real resistance. In the case of radiation, R is an assumed resistance; if this resistance were actually present, it would dissipate the same amount of power that the antenna takes to radiate the energy. This assumed resistance is referred to as the RADIATION RESISTANCE.

Radiation resistance varies at different points on the antenna. This resistance is always measured at a current loop. For the antenna in free space, that is, entirely removed from any objects that might affect its operation, the radiation resistance is 73 ohms. A practical antenna located over a ground plane may have any value of radiation resistance from 0 to approximately 100 ohms. The exact value of radiation resistance depends on the height of the antenna above the ground. For most half-wave wire antennas, the radiation resistance is about 65 ohms. It will usually vary between 55 and 600 ohms for antennas constructed of rod or tubing. The actual value of radiation resistance, so long as it is 50 ohms or more, has little effect on the radiation efficiency of the antenna. This is because the ohmic resistance is about 1 ohm for conductors of large diameter. The ohmic resistance does not become important until the radiation resistance drops to a value less than 10 ohms. This may be the case when several antennas are coupled together.

RADIATION TYPES AND PATTERNS

The energy radiated from an antenna forms a field having a definite RADIATION PATTERN. A radiation pattern is a plot of the radiated energy from an antenna. This energy is measured at various angles at a constant distance from the antenna. The shape of this pattern depends on the type of antenna

used. In this section, we will introduce the basic types of radiation (isotropic and anisotropic) and their radiation patterns.

Isotropic Radiation

Some antenna sources radiate energy equally in all directions. Radiation of this type is known as ISOTROPIC RADIATION. We all know the Sun radiates energy in all directions. The energy radiated from the Sun measured at any fixed distance and from any angle will be approximately the same. Assume that a measuring device is moved around the Sun and stopped at the points indicated in figure 4-9 to make a measurement of the amount of radiation. At any point around the circle, the distance from the measuring device to the Sun is the same. The measured radiation will also be the same. The Sun is therefore considered an isotropic radiator.

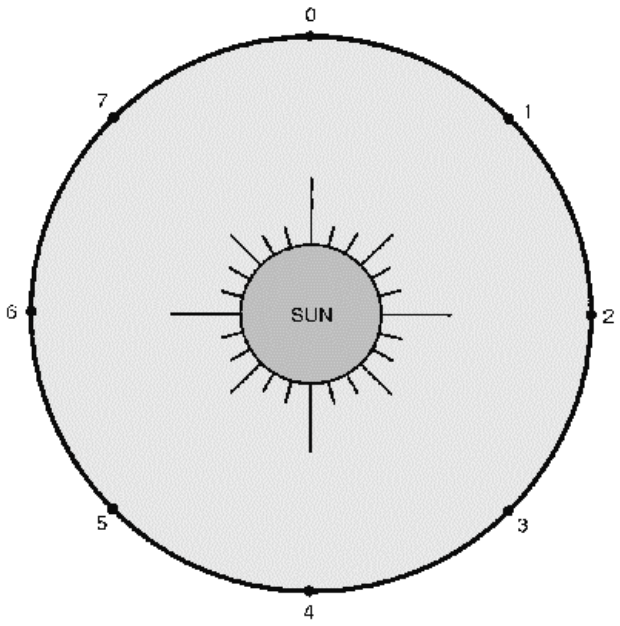

Figure 4-9.—Isotropic radiator.

To plot this pattern, we will assume that the radiation is measured on a scale of 0 to 10 units and that the measured amount of radiation is 7 units at all points. We will then plot our measurements on two different types of graphs, rectangular- and polar-coordinate graphs. The RECTANGULAR-COORDINATE GRAPH of the measured radiation, shown in view A of figure 4-10, is a straight line plotted against positions along the circle. View B shows the POLAR-COORDINATE GRAPH for the same isotropic source.

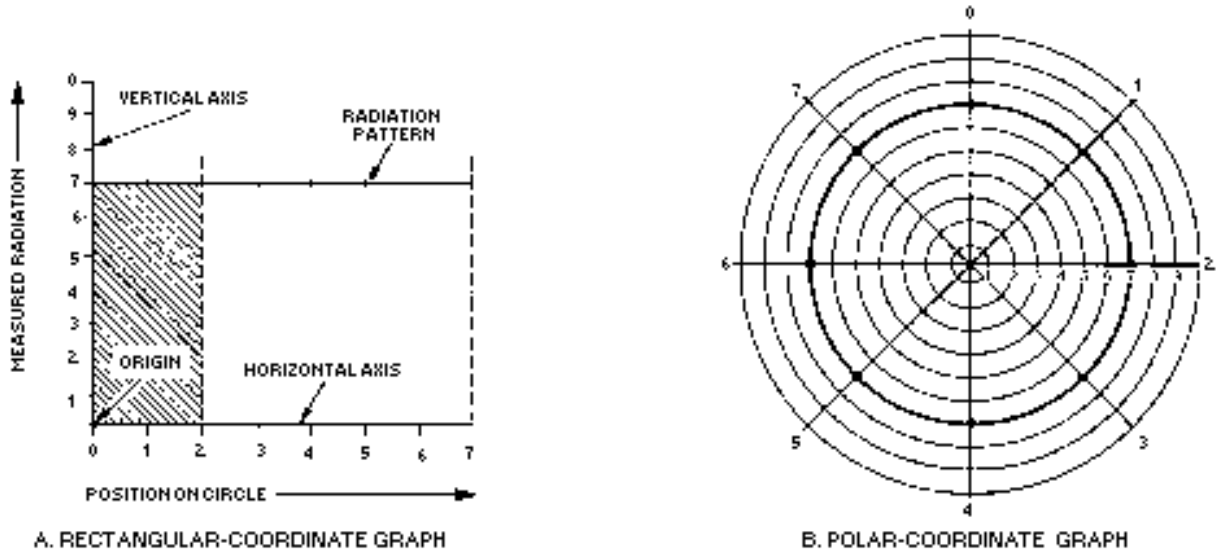

Figure 4-10.—Comparison of rectangular- and polar-coordinate graphs for an isotropic source.

In the rectangular-coordinate graph, points are located by projection from a pair of stationary, perpendicular axes. In the polar-coordinate graph, points are located by projection along a rotating axis (radius) to an intersection with one of several concentric, equally-spaced circles. The horizontal axis on the rectangular-coordinate graph corresponds to the circles on the polar-coordinate graph. The vertical axis on the rectangular-coordinate graph corresponds to the rotating axis (radius) on the polar-coordinate graph.

Rectangular-Coordinate Pattern

Look at view A of figure 4-10. The numbered positions around the circle are laid out on the HORIZONTAL AXIS of the graph from 0 to 7 units. The measured radiation is laid out on the VERTICAL AXIS of the graph from 0 to 10 units. The units on both axes are chosen so the pattern occupies a convenient part of the graph.

The horizontal and vertical axes are at a right angle to each other. The point where the axes cross each other is known as the ORIGIN. In this case, the origin is 0 on both axes. Now, assume that a radiation value of 7 units view B is measured at position 2. From position 2 on the horizontal axis, a dotted line is projected upwards that runs parallel to the vertical axis. From position 7 on the vertical axis, a line is projected to the right that runs parallel to the horizontal axis. The point where the two lines cross (INTERCEPT) represents a value of 7 radiation units at position 2. This is the only point on the graph that can represent this value.

As you can see from the figure, the lines used to plot the point form a rectangle. For this reason, this type of plot is called a *rectangular-coordinate graph*. A new rectangle is formed for each different point plotted. In this example, the points plotted lie in a straight line extending from 7 units on the vertical scale to the projection of position 7 on the horizontal scale. This is the characteristic pattern in rectangular coordinates of an isotropic source of radiation.

Polar-Coordinate Pattern

The polar-coordinate graph has proved to be of great use in studying radiation patterns. Compare views A and B of figure 4-10. Note the great difference in the shape of the radiation pattern when it is

transferred from the rectangular-coordinate graph in view A to the polar-coordinate graph in view B. The scale of radiation values used in both graphs is identical, and the measurements taken are both the same. However, the shape of the pattern is drastically different.

Look at view B of figure 4-10 and assume that the center of the concentric circles is the Sun. Assume that a radius is drawn from the Sun (center of the circle) to position 0 of the circle. When you move to position 1, the radius moves to position 1; when you move to position 2, the radius also moves to position 2, and so on.

The positions where a measurement was taken are marked as 0 through 7 on the graph. Note how the position of the radius indicates the actual direction from the source at which the measurement was taken. This is a distinct advantage over the rectangular-coordinate graph in which the position is indicated along a straight-line axis and has no physical relation to the actual direction of measurement. Now that we have a way to indicate the *direction* of measurement, we must devise a way to indicate the *magnitude* of the radiation.

Notice that the rotating axis is always drawn from the center of the graph to some position on the edge of the graph. As the axis moves toward the edge of the graph, it passes through a set of equally-spaced, concentric circles. In this example view B, they are numbered successively from 1 to 10 from the center out. These circles are used to indicate the magnitude of the radiation.

The advantages of the polar-coordinate graph are immediately evident. The source, which is at the center of the observation circles, is also at the center of the graph. By looking at a polar-coordinate plot of a radiation pattern, you can immediately see the direction and strength of radiation put out by the source. Therefore, the polar-coordinate graph is more useful than the rectangular-coordinate graph in plotting radiation patterns.

Anisotropic Radiation

Most radiators emit (radiate) stronger radiation in one direction than in another. A radiator such as this is referred to as ANISOTROPIC. An example of an anisotropic radiator is an ordinary flashlight. The beam of the flashlight lights only a portion of the space surrounding it. If a circle is drawn with the flashlight as the center, as shown in view B of figure 4-11, the radiated light can be measured at different positions around the circle. Again, as with the isotropic radiator, all positions are the same distance from the center, but at different angles. However, in this illustration the radiated light is measured at 16 different positions on the circle.

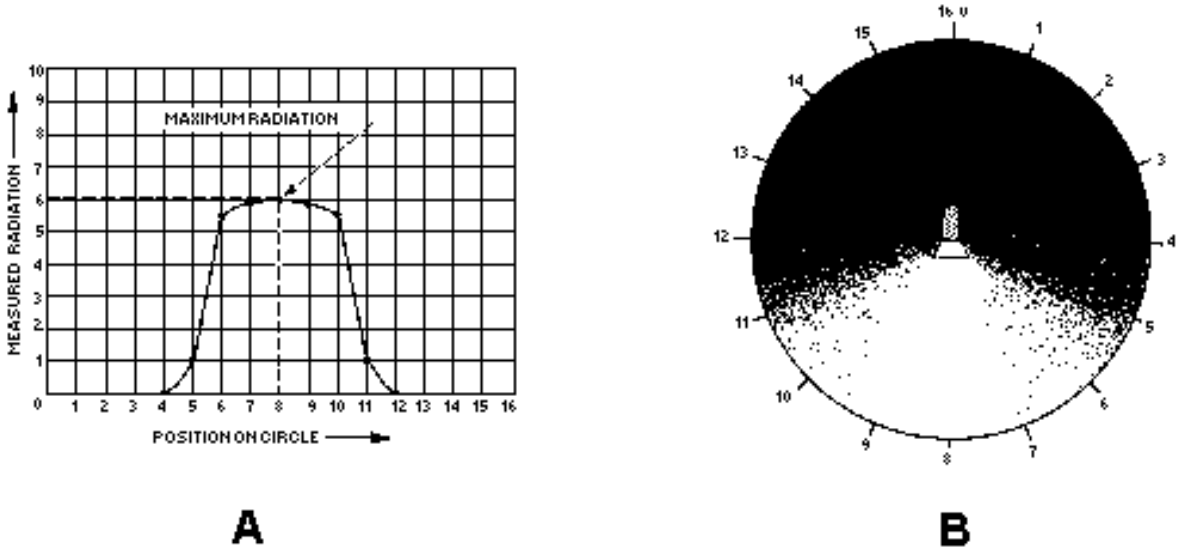

Figure 4-11.—Anisotropic radiator.

Directly behind the flashlight (position 0) the radiation measured is minimum. Accordingly, a 0 value is assigned to this position in the rectangular-coordinate graph (fig. 4-11, view A). This radiation remains at minimum until position 4 is reached. Between positions 4 and 6, the measuring device enters the flashlight beam. You can see this transition from darkness to brightness easily in view B. Radiation is fairly constant between positions 6 and 10. Maximum brightness occurs at position 8, which is directly in the path of the flashlight beam. From positions 10 to 12, the measuring device leaves the flashlight beam and the radiation measurement falls off sharply. At position 13 the radiation is again at 0 and stays at this value back to position 0.

Radiation from a light source and radiation from an antenna are both forms of electromagnetic waves. Therefore, the measurement of radiation of an antenna follows the same basic procedure as that just described for the Sun and the flashlight. Before proceeding further with the study of antenna patterns, you should be sure you understand the methods used to graph the measured radiation (magnitude of the radiation). Study the rectangular- and polar-coordinate systems of plotting presented in the following section.

Q13. What is the radiation resistance of a half-wave antenna in free space?

Q14. A radiating source that radiates energy stronger in one direction than another is known as what type of radiator?

Q15. A radiating source that radiates energy equally in all directions is known as what type of radiator?

Q16. A flashlight is an example of what type of radiator?

In figure 4-11, view A, the radiation pattern of the flashlight is graphed in rectangular coordinates. The illustration of the flashlight beam in view B clearly indicates the shape of the flashlight beam. This is not evident in the radiation pattern plotted on the rectangular-coordinate graph. Now look at figure 4-12. The radiation pattern shown in this figure looks very much like the actual flashlight beam. The pattern in figure 4-12 is plotted using the same values as those of figure 4-11, view A, but is drawn using polar coordinates.

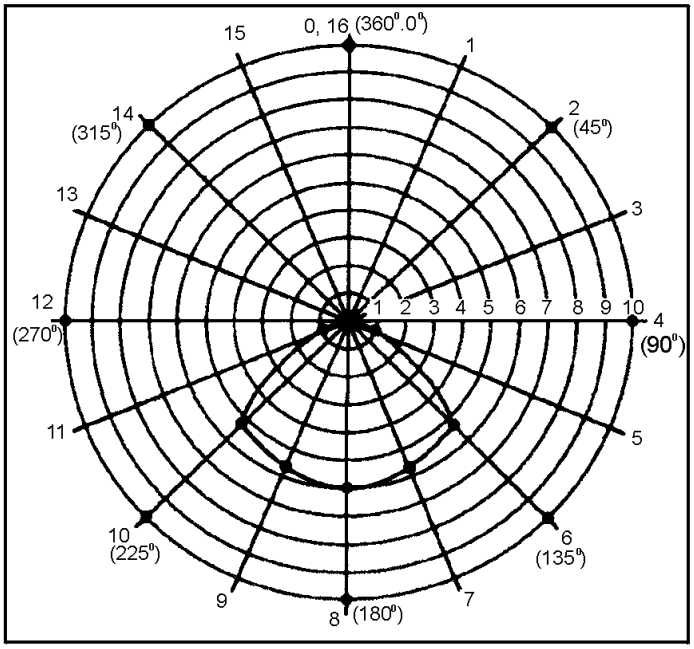

Figure 4-12.—Polar-coordinate graph for anisotropic radiator.

The positions marked off on the two polar-coordinate graphs in figures 4-10 and 4-12 were selected and numbered arbitrarily. However, a standard method allows the positions around a source to be marked off so that one radiation pattern can easily be compared with another. This method is based on the fact that a circle has a radius of 360 degrees. The radius extending vertically from the center (position 0 in figure 4-10) is designated 0 degrees. At position 4 the radius is at a right angle to the 0-degree radius. Accordingly, the radius at position 4 is marked 90 degrees, position 8 is 180 degrees, position 12 is 270 degrees, and position 16 is 360 degrees. The various radii drawn on the graph are all marked according to the angle each radius makes with the reference radius at 0 degrees.

The radiation pattern in figure 4-12 is obtained by using the same procedure that was used for (figure 4-10, view B). The radiation measured at positions 1, 2, 3, and 4 is 0. Position 5 measures approximately 1 unit. This is marked on the graph and the rotating radius moves to position 6. At this position a reading of 5.5 units is taken. As before, this point is marked on the graph. The procedure is repeated around the circle and a reading is obtained from positions 6 through 11. At position 12 no radiation is indicated, and this continues on to position 16.

The polar-coordinate graph now shows a definite area enclosed by the radiation pattern. This pattern indicates the general direction of radiation from the source. The enclosed area is called a LOBE. Outside of this area, minimum radiation is emitted in any direction. For example, at position 2 the radiation is 0. Such a point is called a NULL. In real situations, some radiation is usually transmitted in all directions. Therefore, a null is used to indicate directions of minimum radiation. The pattern of figure 4-12 shows one lobe and one continuous null.

ANTENNA LOADING

You will sometimes want to use one antenna system for transmitting and receiving on several different frequencies. Since the antenna must always be in resonance with the applied frequency, you may need to either physically or electrically lengthen or shorten the antenna.

Except for trailing-wire antennas used in aircraft installations (which may be lengthened or shortened), physically lengthening the antenna is not very practical. But you can achieve the same result by changing the electrical length of the antenna. To change the electrical length, you can insert either an inductor or a capacitor in series with the antenna. This is shown in figure 4-13, views A and B. Changing the electrical length by this method is known as LUMPED-IMPEDANCE TUNING, or LOADING. The electrical length of any antenna wire can be increased or decreased by loading. If the antenna is too short for the wavelength being used, it is resonant at a higher frequency than that at which it is being excited. Therefore, it offers a capacitive reactance at the excitation frequency. This capacitive reactance can be compensated for by introducing a lumped-inductive reactance, as shown in view A. Similarly, if the antenna is too long for the transmitting frequency, it offers an inductive reactance. Inductive reactance can be compensated for by introducing a lumped-capacitive reactance, as shown in view B. An antenna without loading is represented in view C.

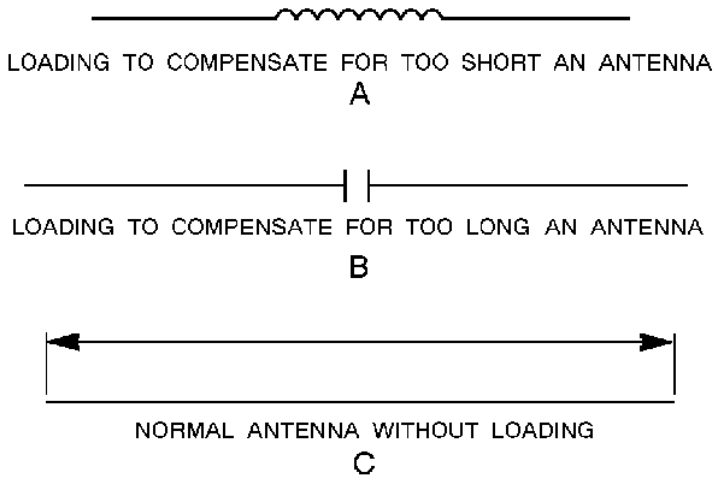

Figure 4-13.—Electrically equal antenna.

BASIC ANTENNAS

Before you look at the various types of antennas, consider the relationship between the wavelength at which the antenna is being operated and the actual length of the antenna. An antenna does not necessarily radiate or receive more energy when it is made longer. Specific dimensions must be used for efficient antenna operation.

Nearly all antennas have been developed from two basic types, the Hertz and the Marconi. The basic Hertz antenna is 1/2 wavelength long at the operating frequency and is insulated from ground. It is often called a DIPOLE or a DOUBLET. The basic Marconi antenna is 1/4 wavelength long and is either grounded at one end or connected to a network of wires called a COUNTERPOISE. The ground or counterpoise provides the equivalent of an additional 1/4 wavelength, which is required for the antenna to resonate.

HALF-WAVE ANTENNAS

A half-wave antenna (referred to as a dipole, Hertz, or doublet) consists of two lengths of wire rod, or tubing, each 1/4 wavelength long at a certain frequency. It is the basic unit from which many complex antennas are constructed. The half-wave antenna operates independently of ground; therefore, it may be installed far above the surface of the Earth or other absorbing bodies. For a dipole, the current is

maximum at the center and minimum at the ends. Voltage is minimum at the center and maximum at the ends, as was shown in figure 4-6.

Radiation Patterns

In the following discussion, the term DIPOLE is used to mean the basic half-wave antenna. The term DOUBLET is used to indicate an antenna that is very short compared with the wavelength of the operating frequency. Physically, it has the same shape as the dipole.

RADIATION PATTERN OF A DOUBLET.—The doublet is the simplest form of a practical antenna. Its radiation pattern can be plotted like the radiation pattern of the flashlight (fig. 4-12). Figure 4-14 shows the development of vertical and horizontal patterns for a doublet. This in NOT a picture of the radiation, but three-dimensional views of the pattern itself. In three views the pattern resembles a doughnut. From the dimensions in these views, two types of polar-coordinate patterns can be drawn, horizontal and vertical. The HORIZONTAL PATTERN view A is derived from the solid pattern view C by slicing it horizontally. This produces view B, which is converted to the polar coordinates seen in view A. The horizontal pattern illustrates that the radiation is constant in any direction along the horizontal plane.

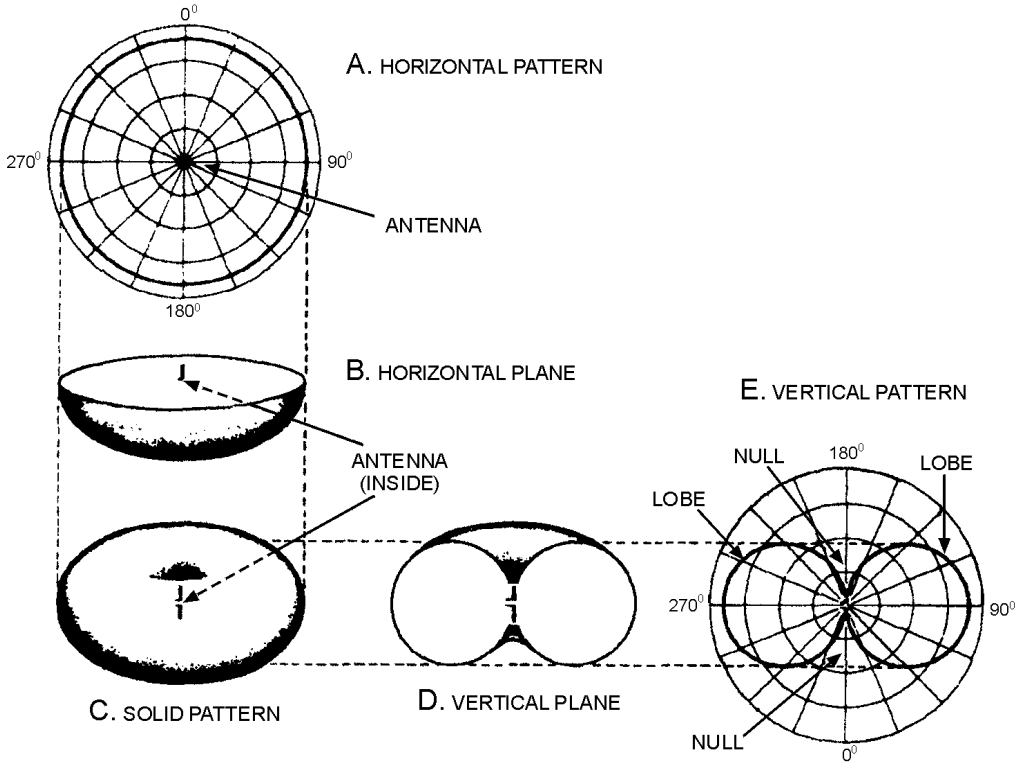

Figure 4-14.—Development of vertical and horizontal patterns.

A VERTICAL PATTERN view E is obtained from the drawing of the vertical plane view D of the radiation pattern view C. The radiation pattern view C is sliced in half along a vertical plane through the antenna. This produces the vertical plane pattern in view D. Note how the vertical plane in view D of the radiation pattern differs from the horizontal plane in view B. The vertical pattern view E exhibits two lobes and two nulls. The difference between the two patterns is caused by two facts: (1) no radiation is

emitted from the ends of the doublet; and (2) maximum radiation comes from the doublet in a direction perpendicular to the antenna axis. This type of radiation pattern is both NONDIRECTIONAL (in a horizontal plane) and DIRECTIONAL (in a vertical plane).

From a practical viewpoint, the doublet antenna can be mounted either vertically or horizontally. The doublet shown in figure 4-14 is mounted vertically, and the radiated energy spreads out about the antenna in every direction in the horizontal plane. Since ordinarily the horizontal plane is the useful plane, this arrangement is termed NONDIRECTIONAL. The directional characteristics of the antenna in other planes is ignored. If the doublet were mounted horizontally, it would have the effect of turning the pattern on edge, reversing the patterns given in figure 4-14. The antenna would then be directional in the horizontal plane. The terms "directional" and "nondirectional" are used for convenience in describing specific radiation patterns. A complete description always involves a figure in three dimensions, as in the radiation pattern of figure 4-14.

Q17. What terms are often used to describe basic half-wave antennas?

Q18. If a basic half-wave antenna is mounted vertically, what type of radiation pattern will be produced?

Q19. In which plane will the half-wave antenna be operating if it is mounted horizontally?

RADIATION PATTERN OF A DIPOLE.—The radiation pattern of a dipole (fig. 4-15) is similar to that of the doublet (fig. 4-14). Increasing the length of the doublet to 1/2 wavelength has the effect of flattening out the radiation pattern. The radiation pattern in the horizontal plane of a dipole is a larger circle than that of the doublet. The vertical-radiation pattern lobes are no longer circular. They are flattened out and the radiation intensity is greater.

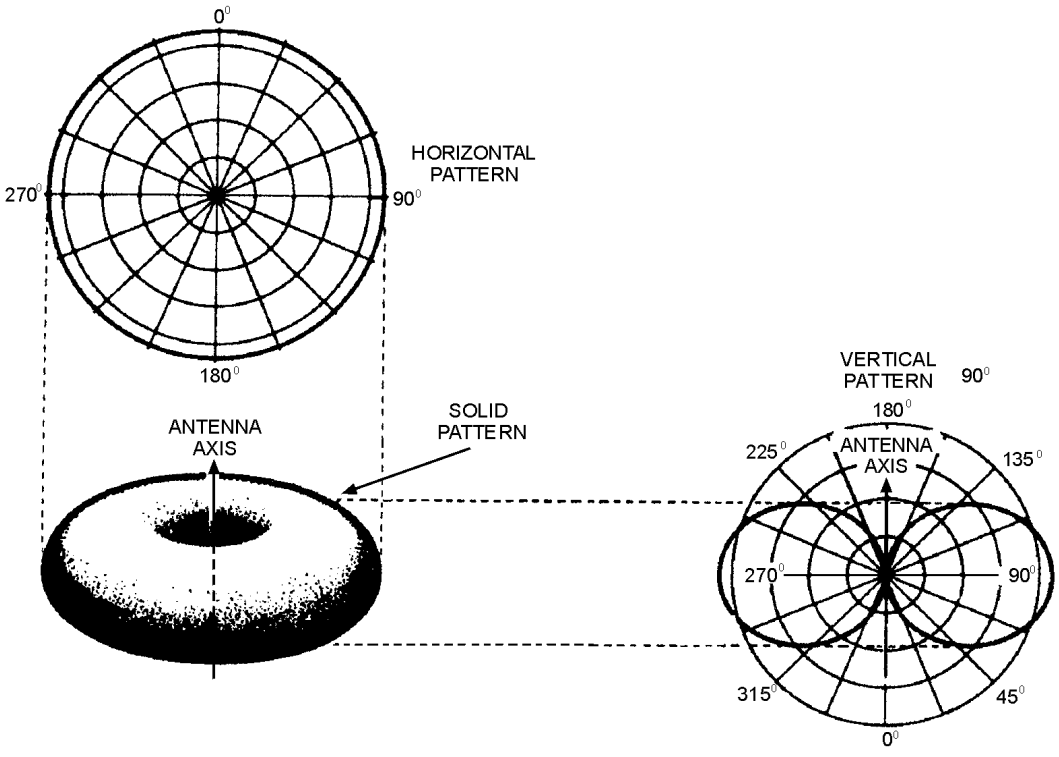

Figure 4-15.—Radiation pattern of a dipole.

Methods of Feeding Energy to an Antenna

Voltage and current distribution for the half-wave antenna (shown in figure 4-16) is the same as that for the antenna discussed earlier in this chapter. A point closely related to the voltage and current distribution on an antenna is the method of feeding the transmitter output to the antenna. The simplest method of feeding energy to the half-wave antenna is to connect one end through a capacitor to the final output stage of the transmitter. This method is often called the END-FEED or VOLTAGE-FEED method. In this method the antenna is fed at a point of high voltage (the end).

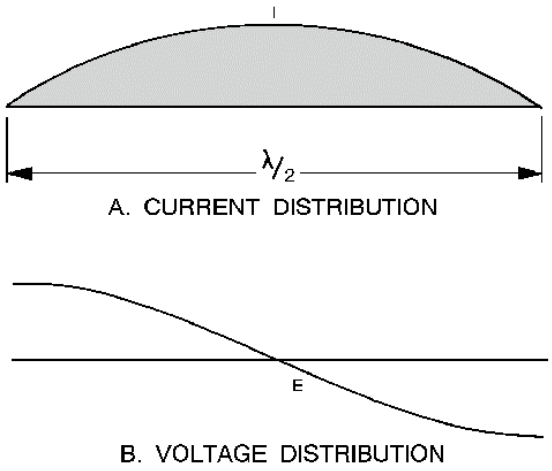

Figure 4-16.—Standing waves of current and voltage.

Energy may also be fed to the half-wave antenna by dividing the antenna at its center and connecting the transmission line from the final transmitter output stage to the two center ends of the halved antenna. Since the antenna is now being fed at the center (a point of low voltage and high current), this type of feed is known as the CENTER-FEED or CURRENT-FEED method. The point of feed is important in determining the type of transmission line to be used.

QUARTER-WAVE ANTENNAS

As you have studied in the previous sections, a 1/2 wavelength antenna is the shortest antenna that can be used in free space. If we cut a half-wave antenna in half and then ground one end, we will have a grounded quarter-wave antenna. This antenna will resonate at the same frequency as the ungrounded half-wave antenna. Such an antenna is referred to as a QUARTER-WAVE or Marconi antenna. Quarter-wave antennas are widely used in the military. Most mobile transmitting and receiving antennas (fig. 4-17) are quarter-wave antennas.

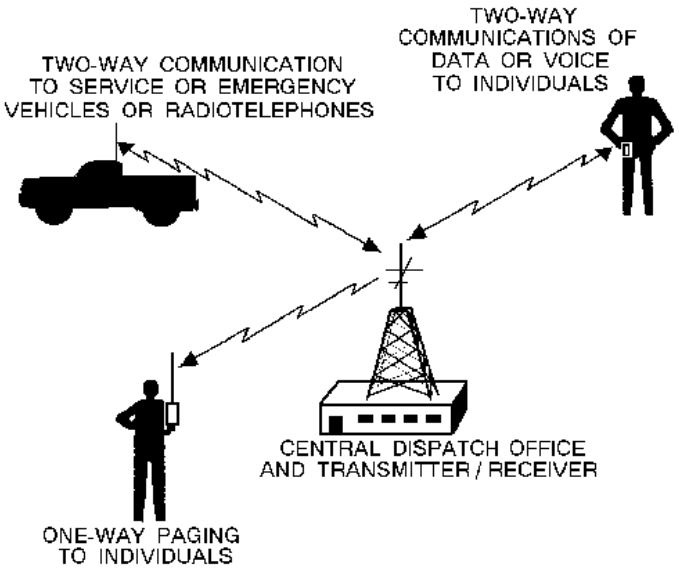

Figure 4-17.—Mobile antennas.

As stated above, a grounded quarter-wave antenna will resonate at the same frequency as an ungrounded half-wave antenna. This is because ground has high conductivity and acts as an electrical mirror image. This characteristic provides the missing half of the antenna, as shown in the bottom part of figure 4-18. In other words, the grounded quarter-wave antenna acts as if another quarter-wave were actually down in the earth.

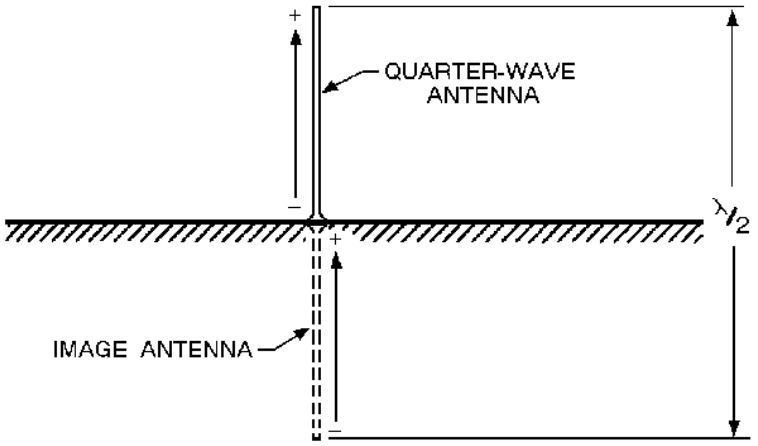

Figure 4-18.—Grounded quarter-wave antenna image.

Characteristics of Quarter-Wave Antennas

The grounded end of the quarter-wave antenna has a low input impedance and has low voltage and high current at the input end, as shown in figure 4-18. The ungrounded end has a high impedance, which causes high voltage and low current. The directional characteristics of a grounded quarter-wave antenna are the same as those of a half-wave antenna in free space.

As explained earlier, ground losses affect radiation patterns and cause high signal losses for some frequencies. Such losses may be greatly reduced if a perfectly conducting ground is provided in the

vicinity of the antenna. This is the purpose of a GROUND SCREEN (figure 4-19, view A) and COUNTERPOISE view B.

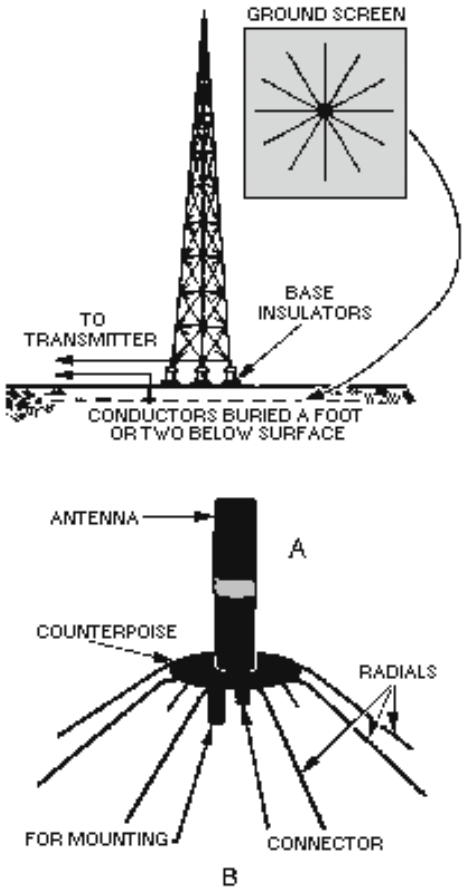

Figure 4-19.—Groundscreen and counterpoise.

The ground screen in view A is composed of a series of conductors buried 1 or 2 feet (0.3 to 0.6 meter) below the surface of the earth and arranged in a radial pattern. These conductors reduce losses in the ground in the immediate vicinity of the antenna. Such a radial system of conductors is usually 1/2 wavelength in diameter.

A counterpoise view B is used when easy access to the base of the antenna is necessary. It is also used when the earth is not a good conducting surface, such as ground that is sandy or solid rock. The counterpoise serves the same purpose as the ground screen but it is usually elevated above the earth. No specific dimensions are necessary in the construction of a counterpoise nor is the number of wires particularly critical. A practical counterpoise may be assembled from a large screen of chicken wire or some similar material. This screen may be placed on the ground, but better results are obtained if it is placed a few feet above the ground.

Q20. Since the radiation pattern of a dipole is similar to that of a doublet, what will happen to the pattern if the length of the doublet is increased?

Q21. What is the simplest method of feeding power to the half-wave antenna?

Q22. What is the radiation pattern of a quarter-wave antenna?

Q23. Describe the physical arrangement of a ground screen.

FOLDED DIPOLE

The use of parasitic elements and various stacking arrangements causes a reduction in the radiation resistance of a center-fed, half-wave antenna. Under these conditions obtaining a proper impedance match between the radiator and the transmission line is often difficult. A convenient method of overcoming these difficulties is to use a FOLDED DIPOLE in place of the center-fed radiator. (See views A and B of figure 4-20).

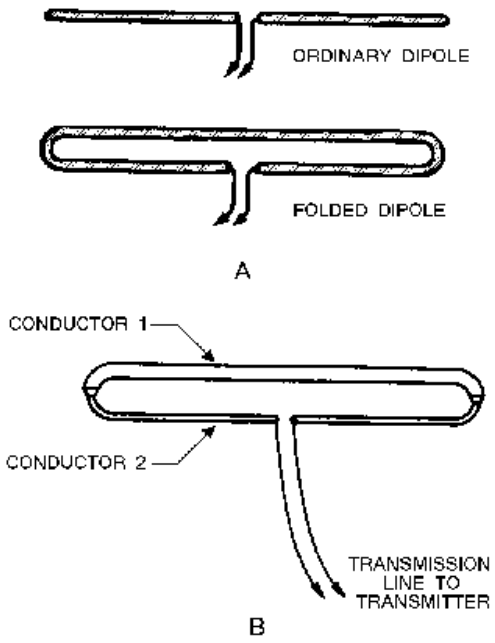

Figure 4-20.—Folded-dipole antennas.

A FOLDED DIPOLE is an ordinary half-wave antenna that has one or more additional conductors connected across its ends. Additional conductors are mounted parallel to the dipole elements at a distance equal to a very small fraction of a wavelength. Spacing of several inches is common.

The feed-point impedance can be further increased by using three or four properly spaced parallel conductors. Standard feed-line SPREADERS are used to maintain this spacing when required. In any folded dipole, the increase of impedance is the square of the number of conductors used in the radiator. Thus, a three-wire dipole has nine times (3^2) the feed-point impedance of a simple center-fed dipole. A second method of stepping up the impedance of a folded dipole is to use two conductors with different radii, as shown in view B.

The directional characteristics of a folded dipole are the same as those of a simple dipole. However, the reactance of a folded dipole varies much more slowly as the frequency is varied from resonance. Because of this the folded dipole can be used over a much wider frequency range than is possible with a simple dipole.

Q24. What is the difference in the amount of impedance between a three-wire dipole and a simple center-fed dipole?

Q25. Which has a wider frequency range, a simple dipole or a folded dipole?

ARRAY ANTENNAS

An array antenna is a special arrangement of basic antenna components involving new factors and concepts. Before you begin studying about arrays, you need to study some new terminology.

DEFINITION OF TERMS

An array antenna is made up of more than one ELEMENT, but the basic element is generally the dipole. Sometimes the basic element is made longer or shorter than a half-wave, but the deviation usually is not great.

A DRIVEN element is similar to the dipole you have been studying and is connected directly to the transmission line. It obtains its power directly from the transmitter or, as a receiving antenna, it delivers the received energy directly to the receiver. A PARASITIC ELEMENT is located near the driven element from which it gets its power. It is placed close enough to the driven element to permit coupling.

A parasitic element is sometimes placed so it will produce maximum radiation (during transmission) from its associated driver. When it operates to reinforce energy coming from the driver toward itself, the parasitic element is referred to as a DIRECTOR. If a parasitic element is placed so it causes maximum energy radiation in a direction away from itself and toward the driven element, that parasitic element is called a REFLECTOR.

If all of the elements in an array are driven, the array is referred to as a DRIVEN ARRAY (sometimes as a CONNECTED ARRAY). If one or more elements are parasitic, the entire system usually is considered to be a PARASITIC ARRAY.

MULTIELEMENT ARRAYS frequently are classified according to their directivity. A BIDIRECTIONAL ARRAY radiates in opposite directions along the line of maximum radiation. A UNIDIRECTIONAL ARRAY radiates in only one general direction.

Arrays can be described with respect to their radiation patterns and the types of elements of which they are made. However, you will find it useful to identify them by the physical placement of the elements and the direction of radiation with respect to these elements. Generally speaking, the term BROADSIDE ARRAY designates an array in which the direction of maximum radiation is perpendicular to the plane containing these elements. In actual practice, this term is confined to those arrays in which the elements themselves are also broadside, or parallel, with respect to each other.

A COLLINEAR ARRAY is one in which all the elements lie in a straight line with no radiation at the ends of the array. The direction of maximum radiation is perpendicular to the axis of the elements.

An END-FIRE ARRAY is one in which the principal direction of radiation is along the plane of the array and perpendicular to the elements. Radiation is from the end of the array, which is the reason this arrangement is referred to as an end-fire array.

Sometimes a system uses the characteristics of more than one of the three types mentioned. For instance, some of the elements may be collinear while others may be parallel. Such an arrangement is

often referred to as a COMBINATION ARRAY or an ARRAY OF ARRAYS. Since maximum radiation occurs at right angles to the plane of the array, the term broadside array is also used.

The FRONT-TO-BACK RATIO is the ratio of the energy radiated in the principal direction compared to the energy radiated in the opposite direction for a given antenna.

PHASING

Various reflected and refracted components of the propagated wave create effects of reinforcement and cancellation. At certain distant points from the transmitter, some of the wave components meet in space. Reception at these points is either impaired or improved. If the different components arrive at a given point in the same phase, they add, making a stronger signal available. If they arrive out of phase, they cancel, reducing the signal strength.

Radiation Pattern

Effects similar to those described in the preceding paragraph can be produced at the transmitting point itself. Consider the antennas shown in figure 4-21, views A and B. View A shows an unobstructed view of the radiation pattern of a single dipole. In view B two dipoles, shown as points 1 and 2, are perpendicular to the plane of the page. They are spaced 1/4 wavelength apart at the operating frequency. The radiation pattern from either antenna 1 or 2, operating alone, would be uniform in all directions in this plane, as shown in view A. Suppose that current is being fed to both antennas from the same transmitter in such a way that the current fed to antenna 2 lags the current in antenna 1 by 90 degrees. Energy radiating from antenna 1 toward receiving location X will reach antenna 2 after 1/4 cycle of operation. The energy from both antennas will add, and propagation toward X will be strong.

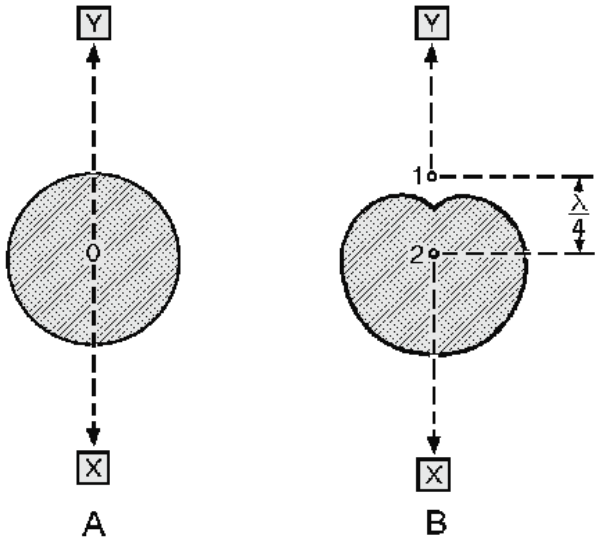

Figure 4-21.—Phasing of antenna in free space.

Radiation from antenna 2 toward receiving location Y will reach antenna 1 after 1/4 cycle. The energy in antenna 1 was 1/4 cycle behind that of antenna 2 to begin with; therefore, the radiation from antenna 1 toward receiving point Y will be exactly 180 degrees out of phase with that of antenna 2. As a result, the radiation fields will cancel and there will be no radiation toward Y.

At receiving points away from the line of radiation, phase differences occur between 0 and 180 degrees, producing varying amounts of energy in that direction. The overall effect is shown by the

radiation pattern shown in view B. The physical phase relationship caused by the 1/4-wavelength spacing between the two elements, as well as the phase of the currents in the elements, has acted to change the radiation pattern of the individual antennas.

Stub Phasing

In the case just discussed, the currents fed to the two antennas from the same transmitter were 90 degrees out of phase. Sections of transmission line, called STUBS, are frequently used for this purpose. These stubs can be adjusted to produce any desired phase relationship between connected elements.

When two collinear half-wave elements are connected directly so their currents are in the same phase, the effect is the same as that of a full-wave antenna, as shown in figure 4-22, view A. The current in the first 1/2 wavelength is exactly 180 degrees out of phase with that in the second 1/2 wavelength. This is the opposite of the desired condition. In the illustration, arrows are used to indicate the direction of current flow in the antenna. (Using arrows is a convenient means of determining the phase on more complicated arrays.)

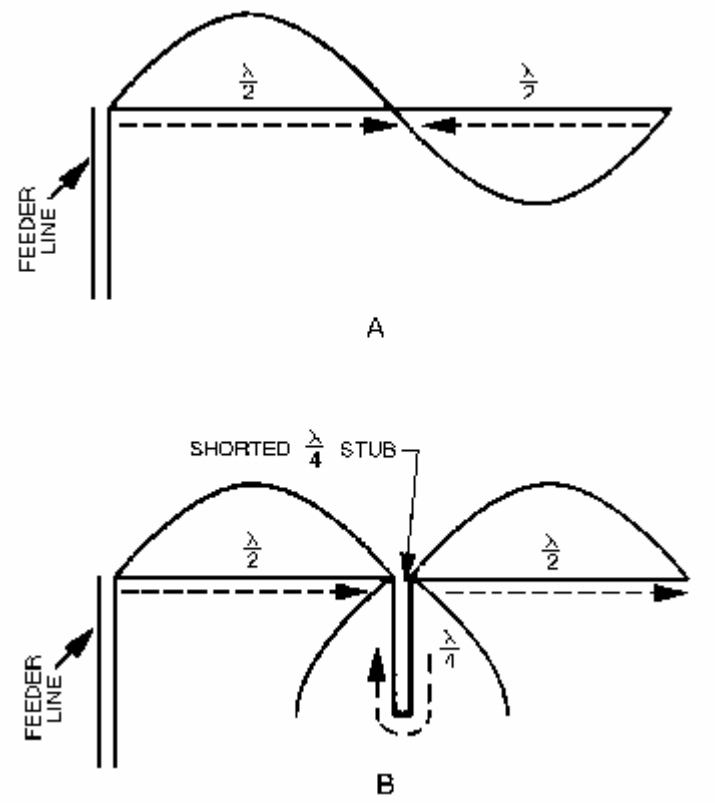

Figure 4-22.—Phasing of connected elements.

When the two elements are connected by a shorted 1/4-wavelength stub, as shown in view B, current travels down one side of the stub and up the other. It travels a distance of a 1/2 wavelength in the stub itself. As a result, the current moves through 1/2 cycle of change. When the current reaches the second element, it is in the desired phase. Since the current on one side of the stub is equal and opposite to the current on the other side, the fields produced here cancel and no radiation is transmitted from the stub itself.

DIRECTIVITY

The DIRECTIVITY of an antenna or an array can be determined by looking at its radiation pattern. In an array propagating a given amount of energy, more radiation takes place in certain directions than in others. The elements in the array can be altered in such a way that they change the pattern and distribute it more uniformly in all directions. The elements can be considered as a group of antennas fed from a common source and facing different directions. On the other hand, the elements could be arranged so that the radiation would be focused in a single direction. With no increase in power from the transmitter, the amount of radiation in a given direction would be greater. Since the input power has no increase, this increased directivity is achieved at the expense of gain in other directions.

Directivity and Interference

In many applications, sharp directivity is desirable although no need exists for added gain. Examine the physical disposition of the units shown in figure 4-23. Transmitters 1 and 2 are sending information to receivers 1 and 2, respectively, along the paths shown by the solid arrows. The distance between transmitter 1 and receiver 1 or between transmitter 2 and receiver 2 is short and does not require high-power transmission. The antennas of the transmitters propagate well in all directions. However, receiver 1 picks up some of the signals from transmitter 2, and receiver 2 picks up some of the signals from transmitter 1, as shown by the broken arrows. This effect is emphasized if the receiving antennas intercept energy equally well in all directions.

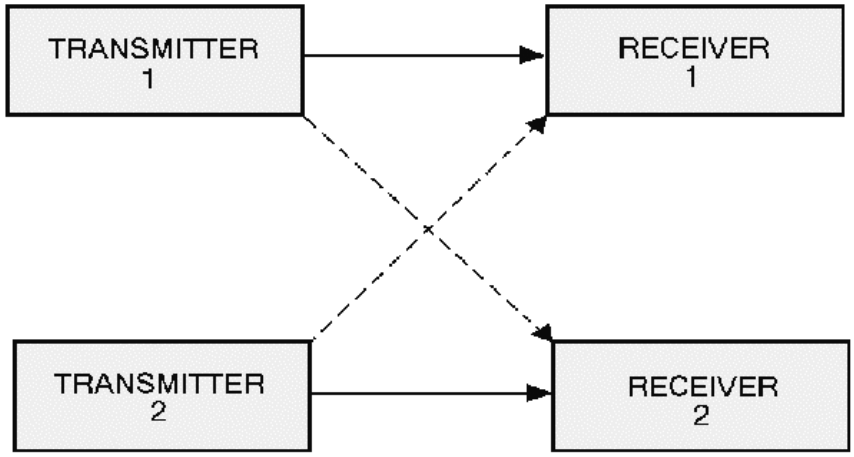

Figure 4-23.—Directivity and interference.

The use of highly directional arrays as radiators from the transmitters tends to solve the problem. The signals are beamed along the paths of the solid arrows and provide very low radiation along the paths of the broken arrows. Further improvement along these lines is obtained by the use of narrowly directed arrays as receiving antennas. The effect of this arrangement is to select the desired signal while discriminating against all other signals. This same approach can be used to overcome other types of radiated interference. In such cases, preventing radiation in certain directions is more important than producing greater gain in other directions.

Look at the differences between the field patterns of the single-element antenna and the array, as illustrated in figure 4-24. View A shows the relative field-strength pattern for a horizontally polarized single antenna. View B shows the horizontal-radiation pattern for an array. The antenna in view A

radiates fairly efficiently in the desired direction toward receiving point X. It radiates equally as efficiently toward Y, although no radiation is desired in this direction. The antenna in view B radiates strongly to point X, but very little in the direction of point Y, which results in more satisfactory operation.

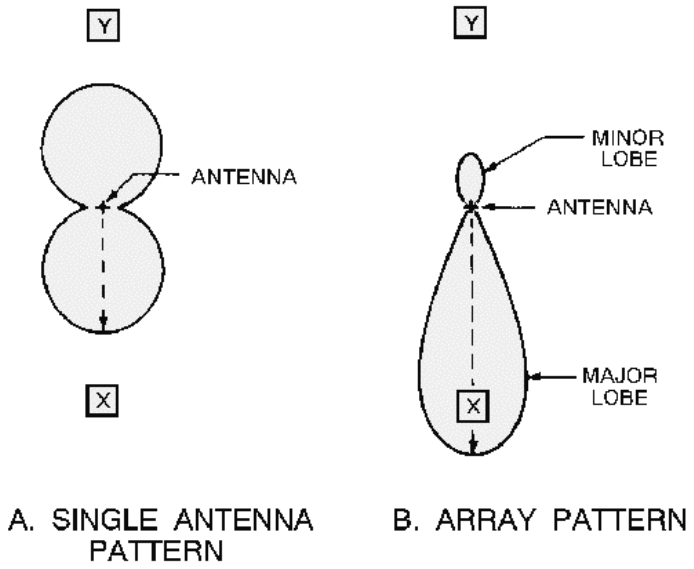

Figure 4-24.—Single antenna versus array.

Major and Minor Lobes

The pattern shown in figure 4-24, view B, has radiation concentrated in two lobes. The radiation intensity in one lobe is considerably stronger than in the other. The lobe toward point X is called a MAJOR LOBE; the other is a MINOR LOBE. Since the complex radiation patterns associated with arrays frequently contain several lobes of varying intensity, you should learn to use appropriate terminology. In general, major lobes are those in which the greatest amount of radiation occurs. Minor lobes are those in which the radiation intensity is least.

Q26. What is the purpose of antenna stubs?

Q27. What is the primary difference between the major and minor lobes of a radiation pattern?

DIRECTIONAL ARRAYS

You have already learned about radiation patterns and directivity of radiation. These topics are important to you because using an antenna with an improper radiation pattern or with the wrong directivity will decrease the overall performance of the system. In the following paragraphs, we discuss in more detail the various types of directional antenna arrays mentioned briefly in the "definition of terms" paragraph above.

Collinear Array

The pattern radiated by the collinear array is similar to that produced by a single dipole. The addition of the second radiator, however, tends to intensify the pattern. Compare the radiation pattern of the dipole (view A of figure 4-25) and the two-element antenna in view B. You will see that each pattern consists of two major lobes in opposite directions along the same axis, QQ1. There is little or no radiation along the

PP1 axis. QQ1 represents the line of maximum propagation. You can see that radiation is stronger with an added element. The pattern in view B is sharper, or more directive, than that in view A. This means that the gain along the line of maximum energy propagation is increased and the beam width is decreased. As more elements are added, the effect is heightened, as shown in view C. Unimportant minor lobes are generated as more elements are added.

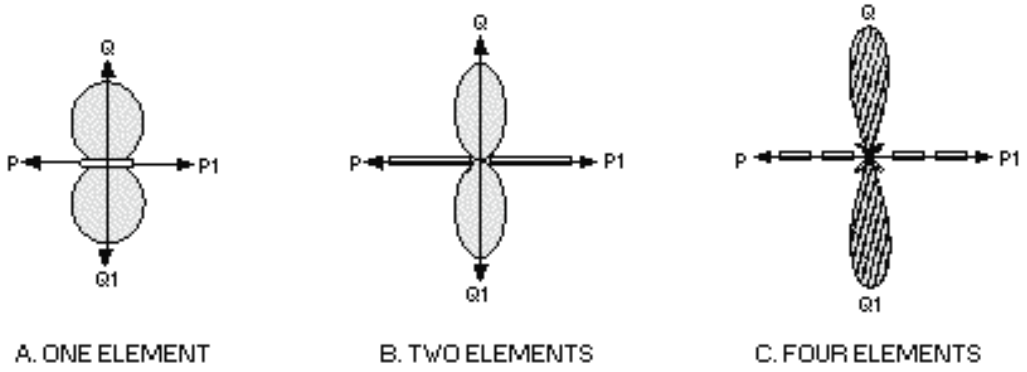

Figure 4-25.—Single half-wave antenna versus two half-wave antennas in phase.

More than four elements are seldom used because accumulated losses cause the elements farther from the point of feeding to have less current than the nearer ones. This introduces an unbalanced condition in the system and impairs its efficiency. Space limitations often are another reason for restricting the number of elements. Since this type of array is in a single line, rather than in a vertically stacked arrangement, the use of too many elements results in an antenna several wavelengths long.

RADIATION PATTERN.—The characteristic radiation pattern of a given array is obtained at the frequency or band of frequencies at which the system is resonant. The gain and directivity characteristics are lost when the antenna is not used at or near this frequency and the array tunes too sharply. A collinear antenna is more effective than an end-fire array when used off its tuned frequency. This feature is considered when transmission or reception is to be over a wide frequency band. When more than two elements are used, this advantage largely disappears.

LENGTH AND PHASING.—Although the 1/2 wavelength is the basis for the collinear element, you will find that greater lengths are often used. Effective arrays of this type have been constructed in which the elements are 0.7 and even 0.8 wavelength long. This type of array provides efficient operation at more than one frequency or over a wider frequency range. Whatever length is decided upon, all of the elements in a particular array should closely adhere to that length. If elements of different lengths are combined, current phasing and distribution are changed, throwing the system out of balance and seriously affecting the radiation pattern.

Q28. What is the maximum number of elements ordinarily used in a collinear array?

Q29. Why is the number of elements used in a collinear array limited?

Q30. How can the frequency range of a collinear array be increased?

Q31. How is directivity of a collinear array affected when the number of elements is increased?

SPACING.—The lower relative efficiency of collinear arrays of many elements, compared with other multi-element arrays, relates directly to spacing and mutual impedance effects. Mutual impedance is

an important factor to be considered when any two elements are parallel and are spaced so that considerable coupling is between them. There is very little mutual impedance between collinear sections. Where impedance does exist, it is caused by the coupling between the ends of adjacent elements. Placing the ends of elements close together is frequently necessary because of construction problems, especially where long lengths of wire are involved.

The effects of spacing and the advantages of proper spacing can be demonstrated by some practical examples. A collinear array consisting of two half-wave elements with 1/4-wavelength spacing between centers has a gain of 1.8 dB. If the ends of these same dipoles are separated so that the distance from center to center is 3/4 wavelengths and they are driven from the same source, the gain increases to approximately 2.9 dB.

A three-dipole array with negligible spacing between elements gives a gain of 3.3 dB. In other words, when two elements are used with wider spacing, the gain obtained is approximately equal to the gain obtainable from three elements with close spacing. The spacing of this array permits simpler construction, since only two dipoles are used. It also allows the antenna to occupy less space. Construction problems usually dictate small-array spacing.

Broadside Arrays

A broadside array is shown in figure 4-26, view A. Physically, it looks somewhat like a ladder. When the array and the elements in it are polarized horizontally, it looks like an upright ladder. When the array is polarized vertically, it looks like a ladder lying on one side (view B). View C is an illustration of the radiation pattern of a broadside array. Horizontally polarized arrays using more than two elements are not common. This is because the requirement that the bottom of the array be a significant distance above the earth presents construction problems. Compared with collinear arrays, broadside arrays tune sharply, but lose efficiency rapidly when not operated on the frequencies for which they are designed.

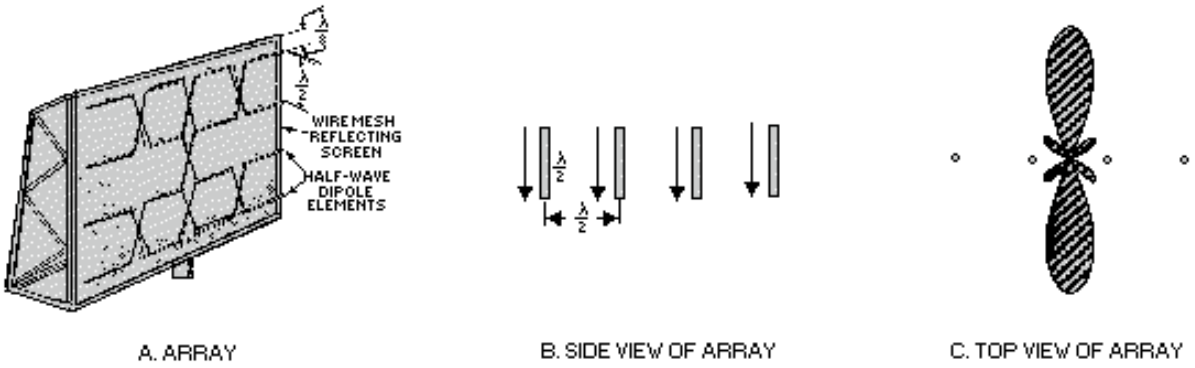

Figure 4-26.—Typical broadside array.

RADIATION PATTERN.—Figure 4-27 shows an end view of two parallel half-wave antennas (A and B) operating in the same phase and located 1/2 wavelength apart. At a point (P) far removed from the antennas, the antennas appear as a single point. Energy radiating toward P from antenna A starts out in phase with the energy radiating from antenna B in the same direction. Propagation from each antenna travels over the same distance to point P, arriving there in phase. The antennas reinforce each other in this direction, making a strong signal available at P. Field strength measured at P is greater than it would be if the total power supplied to both antennas had been fed to a single dipole. Radiation toward point P1 is built up in the same manner.

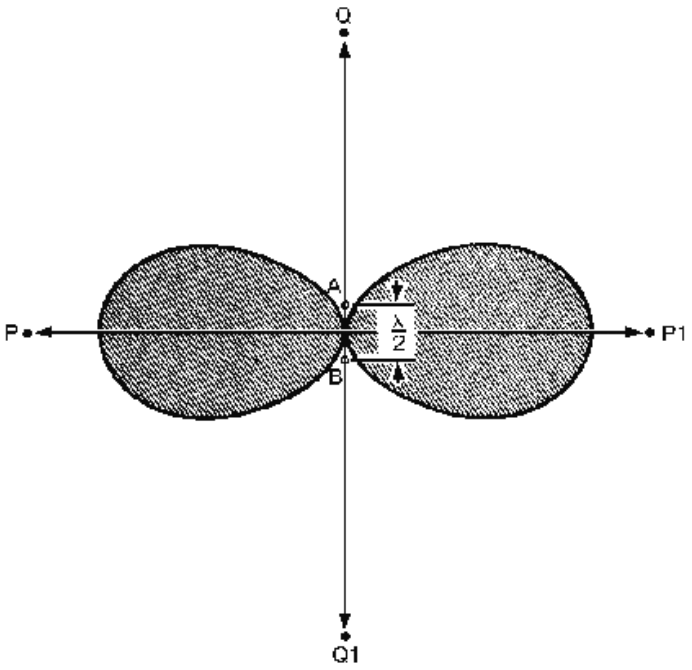

Figure 4-27.—Parallel elements in phase.

Next consider a wavefront traveling toward point Q from antenna B. By the time it reaches antenna A, 1/2 wavelength away, 1/2 cycle has elapsed. Therefore energy from antenna B meets the energy from antenna A 180 degrees out of phase. As a result, the energy moving toward point Q from the two sources cancels. In a like manner, radiation from antenna A traveling toward point Q1 meets and cancels the radiation in the same direction from antenna B. As a result, little propagation takes place in either direction along the QQ1 axis. Most of the energy is concentrated in both directions along the PP1 axis. When both antenna elements are fed from the same source, the result is the basic broadside array.

When more than two elements are used in a broadside arrangement, they are all parallel and in the same plane, as shown in figure 4-26, view B. Current phase, indicated by the arrows, must be the same for all elements. The radiation pattern shown in figure 4-26, view C, is always bi-directional. This pattern is sharper than the one shown in figure 4-27 because of the additional two elements. Directivity and gain depend on the number of elements and the spacing between them.

GAIN AND DIRECTIVITY.—The physical disposition of dipoles operated broadside to each other allows for much greater coupling between them than can occur between collinear elements. Moving the parallel antenna elements closer together or farther apart affects the actual impedance of the entire array and the overall radiation resistance as well. As the spacing between broadside elements increases, the effect on the radiation pattern is a sharpening of the major lobes. When the array consists of only two dipoles spaced exactly 1/2 wavelength apart, no minor lobes are generated at all. Increasing the distance between the elements beyond that point, however, tends to throw off the phase relationship between the original current in one element and the current induced in it by the other element. The result is that, although the major lobes are sharpened, minor lobes are introduced, even with two elements. These, however, are not large enough to be of concern.

If you add the same number of elements to both a broadside array and a collinear array, the gain of the broadside array will be greater. Reduced radiation resistance resulting from the efficient coupling between dipoles accounts for most of this gain. However, certain practical factors limit the number of

elements that may be used. The construction problem increases with the number of elements, especially when they are polarized horizontally.

Q32. What is the primary cause of broadside arrays losing efficiency when not operating at their designed frequency?

Q33. When more than two elements are used in a broadside array, how are the elements arranged?

Q34. As the spacing between elements in a broadside array increases, what is the effect on the major lobes?

End-Fire Arrays

An end-fire array looks similar to a broadside array. The ladder-like appearance is characteristic of both (fig. 4-28, view A). The currents in the elements of the end-fire array, however, are usually 180 degrees out of phase with each other as indicated by the arrows. The construction of the end-fire array is like that of a ladder lying on its side (elements horizontal). The dipoles in an end-fire array are closer together (1/8-wavelength to 1/4 -wavelength spacing) than they are for a broadside array.

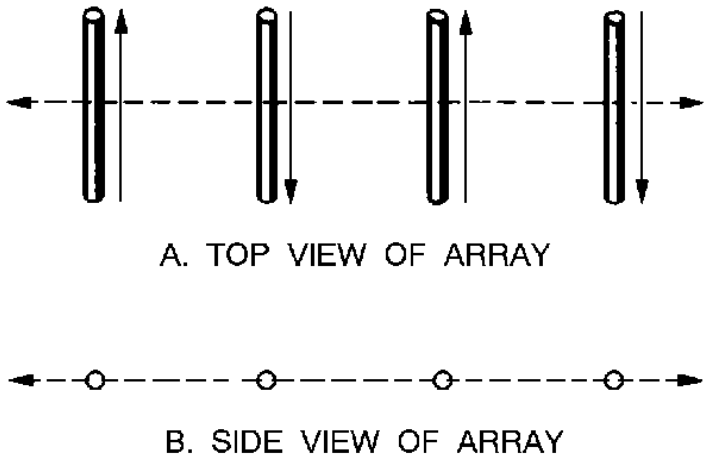

Figure 4-28.—Typical end-fire array.

Closer spacing between elements permits compactness of construction. For this reason an end-fire array is preferred to other arrays when high gain or sharp directivity is desired in a confined space. However, the close coupling creates certain disadvantages. Radiation resistance is extremely low, sometimes as low as 10 ohms, making antenna losses greater. The end-fire array is confined to a single frequency. With changes in climatic or atmospheric conditions, the danger of detuning exists.

RADIATION PATTERN.—The radiation pattern for a pair of parallel half-wave elements fed 180 degrees out of phase is shown in figure 4-29, view A. The elements shown are spaced 1/2 wavelength apart. In practice, smaller spacings are used. Radiation from elements L and M traveling toward point P begins 180 degrees out of phase. Moving the same distance over approximately parallel paths, the respective wavefronts from these elements remain 180 degrees out of phase. In other words, maximum cancellation takes place in the direction of P. The same condition is true for the opposite direction (toward P1). The P to P1 axis is the line of least radiation for the end-fire array.

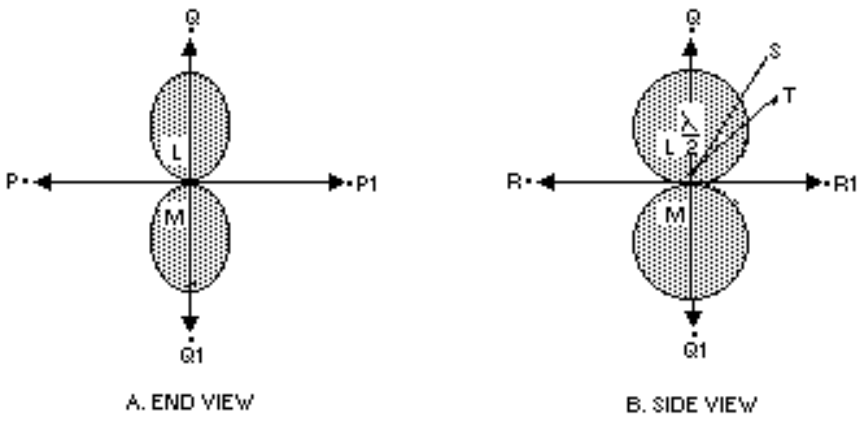

Figure 4-29.—Parallel elements 180 degrees out of phase.

Consider what happens along the QQ1 axis. Energy radiating from element M toward Q reaches element L in about 1/2 cycle (180 degrees) after it leaves its source. Since element L was fed 180 degrees out of phase with element M, the wavefronts are now in the same phase and are both moving toward Q reinforcing each other. Similar reinforcement occurs along the same axis toward Q1. This simultaneous movement towards Q and Q1 develops a bi-directional pattern. This is not always true in end-fire operation. Another application of the end-fire principle is one in which the elements are spaced 1/4 wavelength apart and phased 90 degrees from each other to produce a unidirectional pattern.

In figure 4-29, view A, elements A and B are perpendicular to the plane represented by the page; therefore, only the ends of the antennas appear. In view B the antennas are rotated a quarter of a circle in space around the QQ1 axis so that they are seen in the plane of the elements themselves. Therefore, the PP1 axis, now perpendicular to the page, is not seen as a line. The RR1 axis, now seen as a line, is perpendicular to the PP1 axis as well as to the QQ1 axis. The end-fire array is directional in this plane also, although not quite as sharply. The reason for the greater broadness of the lobes can be seen by following the path of energy radiating from the midpoint of element B toward point S in view B. This energy passes the A element at one end after traveling slightly more than the perpendicular distance between the dipoles. Energy, therefore, does not combine in exact phase toward point S. Although maximum radiation cannot take place in this direction, energy from the two sources combines closely enough in phase to produce considerable reinforcement. A similar situation exists for wavefronts traveling toward T. However, the wider angle from Q to T produces a greater phase difference and results in a decrease in the strength of the combined wave.

Directivity occurs from either one or both ends of the end-fire array, along the axis of the array, as shown by the broken arrows in figure 4-28, view A; hence, the term *end-fire* is used.

The major lobe or lobes occur along the axis of the array. The pattern is sharper in the plane that is at right angles to the plane containing the elements (figure 4-29, view A). If the elements are not exact half-wave dipoles, operation is not significantly affected. However, because of the required balance of phase relationships and critical feeding, the array must be symmetrical. Folded dipoles, such as the one shown in figure 4-20, view A, are used frequently because the impedance at their terminals is higher. This is an effective way of avoiding excessive antenna losses. Another expedient to reduce losses is the use of tubular elements of wide diameter.

GAIN AND DIRECTIVITY.—In end-fire arrays, directivity increases with the addition of more elements and with spacings approaching the optimum. The directive pattern for a two-element,

bi-directional system is illustrated in figure 4-29. View A shows radiation along the array axis in a plane perpendicular to the dipoles, and view B shows radiation along the array axis in the plane of the elements. These patterns were developed with a 180-degree phase difference between the elements. Additional elements introduce small, minor lobes.

With a 90-degree phase difference in the energy fed to a pair of end-fire elements spaced approximately 1/4 wavelength apart, unidirectional radiation can be obtained. The pattern perpendicular to the plane of the two elements is shown in figure 4-30, view A. The pattern shown in view B, taken in the same plane, is for a six-element array with 90-degree phasing between adjacent elements. Since both patterns show relative gain only, the increase in gain produced by the six-element array is not evident. End-fire arrays are the only unidirectional arrays wholly made up of driven elements.

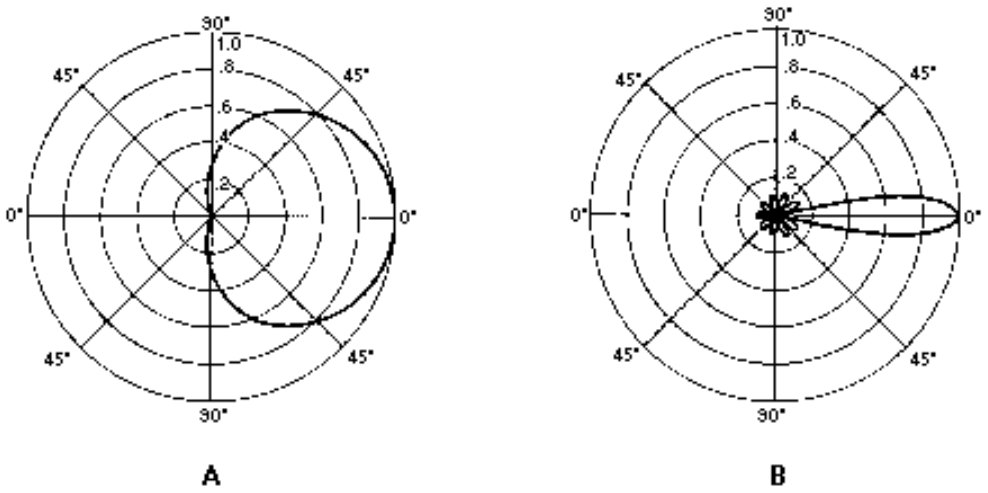

Figure 4-30.—Unidirectional end-fire arrays.

Q35. What are some disadvantages of the end-fire array?

Q36. Where does the major lobe in the end-fire array occur?

Q37. To maintain the required balance of phase relationships and critical feeding, how must the end-fire array be constructed?

Parasitic Arrays

If a small light bulb were placed in the center of a large room, the illumination would be very poor. However, if a reflector were placed behind the bulb, the space in front of the reflector would be brighter and the space behind the reflector would be dimmer. The light rays would be concentrated. Also, if a lens were placed in front of the bulb, the light would be even more concentrated and a very bright spot would appear on the wall in front of the lens. A flashlight is a practical combination of the small bulb, the reflector, and the lens. The energy from an antenna can be reflected and concentrated in a similar manner.

Although we do not usually discuss the gain of a flashlight, we can continue the comparison of an antenna and a flashlight to explain the meaning of antenna gain. Suppose the spot on the wall in front of the flashlight becomes 10 times brighter than it was when only the open bulb was used. The lens and reflector have then produced a 10-fold gain in light. For antennas, the simple half-wave antenna corresponds to the open bulb in the flashlight. Suppose an antenna system concentrates the radio waves so

that at a particular point the field strength is 10 times more than it would be at the same distance from a half-wave antenna. The antenna system is then said to have a gain of 10.

Parasitic arrays represent another method of achieving high antenna gains. A parasitic array consists of one or more parasitic elements placed in parallel with each other and, in most cases, at the same line-of-sight level. The parasitic element is fed inductively by radiated energy coming from the driven element connected to the transmitter. It is in NO way connected directly to the driven element.

When the parasitic element is placed so that it radiates away from the driven element, the element is a director. When the parasitic element is placed so that it radiates toward the driven element, the parasitic element is a reflector.

The directivity pattern resulting from the action of parasitic elements depends on two factors. These are (1) the tuning, determined by the length of the parasitic element; and (2) the spacing between the parasitic and driven elements. To a lesser degree, it also depends on the diameter of the parasitic element, since diameter has an effect on tuning.

OPERATION.—When a parasitic element is placed a fraction of a wavelength away from the driven element and is of approximately resonant length, it will re-radiate the energy it intercepts. The parasitic element is effectively a tuned circuit coupled to the driven element, much as the two windings of a transformer are coupled together. The radiated energy from the driven element causes a voltage to be developed in the parasitic element, which, in turn, sets up a magnetic field. This magnetic field extends over to the driven element, which then has a voltage induced in it. The magnitude and phase of the induced voltage depend on the length of the parasitic element and the spacing between the elements. In actual practice the length and spacing are arranged so that the phase and magnitude of the induced voltage cause a unidirectional, horizontal-radiation pattern and an increase in gain.

In the parasitic array in figure 4-31, view A, the parasitic and driven elements are spaced 1/4 wavelength apart. The radiated signal coming from the driven element strikes the parasitic element after 1/4 cycle. The voltage developed in the parasitic element is 180 degrees out of phase with that of the driven element. This is because of the distance traveled (90 degrees) and because the induced current lags the inducing flux by 90 degrees (90 + 90 = 180 degrees). The magnetic field set up by the parasitic element induces a voltage in the driven element 1/4 cycle later because the spacing between the elements is 1/4 wavelength. This induced voltage is in phase with that in the driven element and causes an increase in radiation in the direction indicated in figure 4-31, view A. Since the direction of the radiated energy is stronger in the direction away from the parasitic element (toward the driven element), the parasitic element is called a reflector. The radiation pattern as it would appear if you were looking down on the antenna is shown in view B. The pattern as it would look if viewed from the ends of the elements is shown in view C.

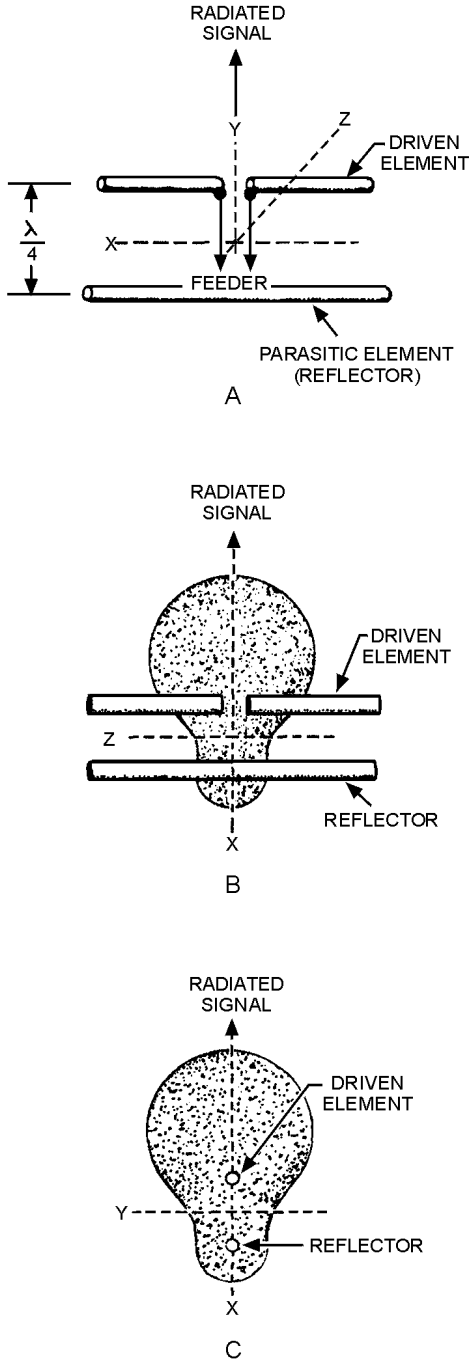

Figure 4-31.—Patterns obtained using a reflector with proper spacing.

Because the voltage induced in the reflector is 180 degrees out of phase with the signal produced at the driven element, a reduction in signal strength exists behind the reflector. Since the magnitude of an induced voltage never quite equals that of the inducing voltage, even in very closely coupled circuits, the energy behind the reflector (minor lobe) is not reduced to 0.

The spacing between the reflector and the driven element can be reduced to about 15 percent of a wavelength. The parasitic element must be made electrically inductive before it will act as a reflector. If

this element is made about 5 percent longer than 1/2 wavelength, it will act as a reflector when the spacing is 15 percent of a wavelength.

Changing the spacing and length can change the radiation pattern so that maximum radiation is on the same side of the driven element as the parasitic element. In this instance the parasitic element is called a director.

Combining a reflector and a director with the driven element causes a decrease in back radiation and an increase in directivity. This combination results in the two main advantages of a parasitic array—unidirectivity and increased gain. If the parasitic array is rotated, it can pick up or transmit in different directions because of the reduction of transmitted energy in all but the desired direction. An antenna of this type is called a ROTARY ARRAY. Size for size, both the gain and directivity of parasitic arrays are greater than those of driven arrays. The disadvantage of parasitic arrays is that their adjustment is critical and they do not operate over a wide frequency range.

GAIN AND DIRECTIVITY.—Changing the spacing between either the director or the reflector and the driven element results in a change in the radiation pattern. More gain and directivity are obtained by changing the length of the parasitic elements.

The FRONT-TO-BACK RATIO of an array is the proportion of energy radiated in the principal direction of radiation to the energy radiated in the opposite direction. A high front-to-back ratio is desirable because this means that a minimum amount of energy is radiated in the undesired direction. Since completely suppressing all such radiation is impossible, an infinite ratio cannot be achieved. In actual practice, however, rather high values can be attained. Usually the length and spacing of the parasitic elements are adjusted so that a maximum front-to-back ratio is obtained, rather than maximum gain in the desired direction.

Q38. What two factors determine the directivity pattern of the parasitic array?

Q39. What two main advantages of a parasitic array can be obtained by combining a reflector and a director with the driven element?

Q40. The parasitic array can be rotated to receive or transmit in different directions. What is the name given to such an antenna?

Q41. What are the disadvantages of the parasitic array?

Multielement Parasitic Array

A MULTIELEMENT PARASITIC array is one that contains two or more parasitic elements with the driven element. If the array contains two parasitic elements (a reflector and a director) in addition to the driven element, it is usually known as a THREE-ELEMENT ARRAY. If three parasitic elements are used, the array is known as a FOUR-ELEMENT ARRAY, and so on. Generally speaking, if more parasitic elements are added to a three-element array, each added element is a director. The field behind a reflector is so small that additional reflectors would have little effect on the overall radiation pattern. In radar, from one to five directors are used.

CONSTRUCTION.—The parasitic elements of a multi-element parasitic array usually are positioned as shown in figure 4-32, views A and B. Proper spacings and lengths are determined experimentally. A folded dipole (view B) is often used as the driven element to obtain greater values of radiation resistance.

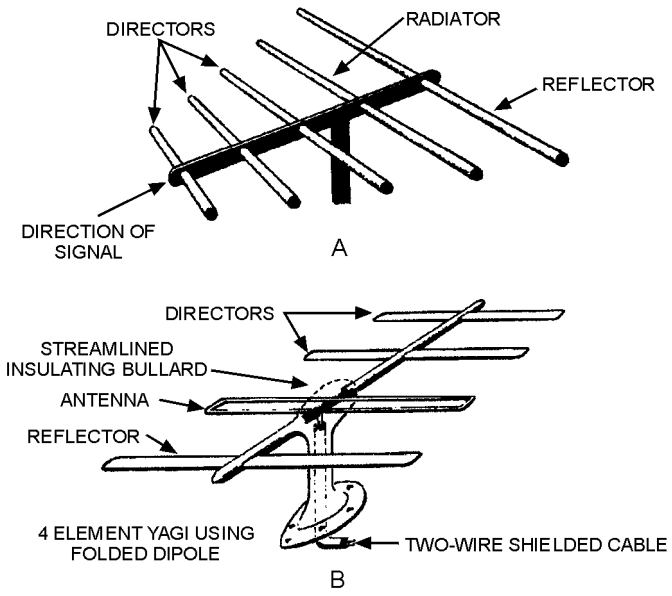

Figure 4-32.—Yagi antenna.

YAGI ANTENNAS.—An example of a multielement parasitic array is the YAGI ANTENNA (figure 4-32, views A and B). The spacings between the elements are not uniform. The radiation from the different elements arrives in phase in the forward direction, but out of phase by various amounts in the other directions.

The director and the reflector in the Yagi antenna are usually welded to a conducting rod or tube at their centers. This support does not interfere with the operation of the antenna. Since the driven element is center-fed, it is not welded to the supporting rod. The center impedance can be increased by using a folded dipole as the driven element.

The Yagi antenna shown in figure 4-32, view A, has three directors. In general, the greater number of parasitic elements used, the greater the gain. However, a greater number of such elements causes the array to have a narrower frequency response as well as a narrower beamwidth. Therefore, proper adjustment of the antenna is critical. The gain does not increase directly with the number of elements used. For example, a three-element Yagi array has a relative power gain of 5 dB. Adding another director results in a 2 dB increase. Additional directors have less and less effect.

A typical Yagi array used for receiving and transmitting energy is shown with a support frame in figure 4-33. This antenna is used by the military services. It operates at frequencies of from 12 to 50 megahertz and consists of two separate arrays (one high-frequency and one low-frequency antenna array) mounted on one frame. The various elements are indicated in the figure. The high-frequency (hf) array consists of one reflector, one driven element, and two directors; the low-frequency (lf) array has the same arrangement with one less director. The lengths of the elements in the high-frequency array are shorter than those in the low-frequency array. The physical lengths of the elements in the individual arrays are equal, but the electrical lengths can be varied by means of the tuning stubs at the center of the elements. The array can be rotated in any desired direction by a remotely controlled, electrically driven, antenna rotator.

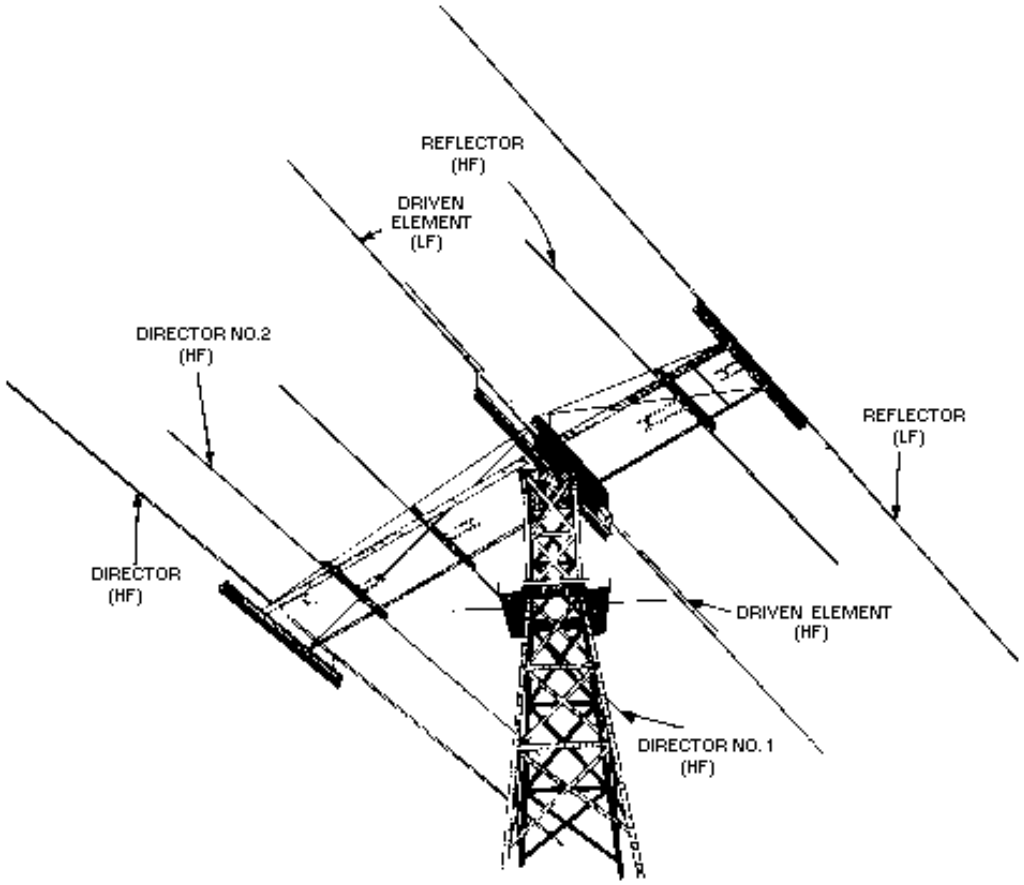

Figure 4-33.—A typical parasitic array used for transmitting and receiving.

Q42. What is the advantage of adding parasitic elements to a Yagi array?

Q43. The Yagi antenna is an example of what type of array?

SPECIAL ANTENNAS

In this section we will cover some special communications and radar antennas. Some of these antennas we touch on briefly since they are covered thoroughly in other courses.

Previously discussed antennas operate with standing waves of current and voltage along the wires. This section deals principally with antenna systems in which the current is practically uniform in all parts of the antenna. In its basic form, such an antenna consists of a single wire grounded at the far end through a resistor. The resistor has a value equal to the characteristic impedance of the antenna. This termination, just as in the case of an ordinary transmission line, eliminates standing waves. The current, therefore, decreases uniformly along the wire as the terminated end is approached. This decrease is caused by the loss of energy through radiation. The energy remaining at the end of the antenna is dissipated in the terminating resistor. For such an antenna to be a good radiator, its length must be fairly long. Also, the wire must not be too close to the ground. The return path through the ground will cause cancellation of the radiation. If the wire is sufficiently long, it will be practically nonresonant over a wide range of operating frequencies.

LONG-WIRE ANTENNA

A LONG-WIRE ANTENNA is an antenna that is a wavelength or longer at the operating frequency. In general, the gain achieved with long-wire antennas is not as great as the gain obtained from the multielement arrays studied in the previous section. But the long-wire antenna has advantages of its own. The construction of long-wire antennas is simple, both electrically and mechanically, with no particularly critical dimensions or adjustments. The long-wire antenna will work well and give satisfactory gain and directivity over a frequency range up to twice the value for which it was cut. In addition, it will accept power and radiate it efficiently on any frequency for which its overall length is not less than approximately 1/2 wavelength. Another factor is that long-wire antennas have directional patterns that are sharp in both the horizontal and vertical planes. Also, they tend to concentrate the radiation at the low vertical angles. Another type of long-wire antenna is the BEVERAGE ANTENNA, also called a WAVE ANTENNA. It is a horizontal, long-wire antenna designed especially for the reception and transmission of low-frequency, vertically polarized ground waves. It consists of a single wire, two or more wavelengths long, supported 3 to 6 meters above the ground, and terminated in its characteristic impedance, as shown in figure 4-34.

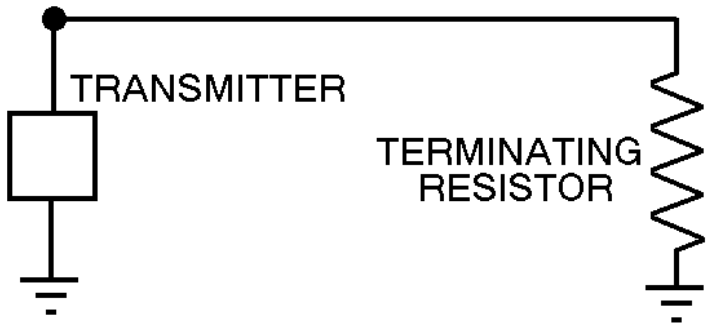

Figure 4-34.—Beverage antenna.

Q44. To radiate power efficiently, a long-wire antenna must have what minimum overall length?

Q45. What is another name for the Beverage antenna?

V ANTENNA

A V ANTENNA is a bi-directional antenna used widely in military and commercial communications. It consists of two conductors arranged to form a V. Each conductor is fed with currents of opposite polarity.

The V is formed at such an angle that the main lobes reinforce along the line bisecting the V and make a very effective directional antenna (see figure 4-35). Connecting the two-wire feed line to the apex of the V and exciting the two sides of the V 180 degrees out of phase cause the lobes to add along the line of the bisector and to cancel in other directions, as shown in figure 4-36. The lobes are designated 1, 2, 3, and 4 on leg AA', and 5, 6, 7, and 8 on leg BB'. When the proper angle between AA' and BB' is chosen, lobes 1 and 4 have the same direction and combine with lobes 7 and 6, respectively. This combination of two major lobes from each leg results in the formation of two stronger lobes, which lie along an imaginary line bisecting the enclosed angle. Lobes 2, 3, 5, and 8 tend to cancel each other, as do the smaller lobes, which are approximately at right angles to the wire legs of the V. The resultant waveform pattern is shown at the right of the V antenna in figure 4-36.

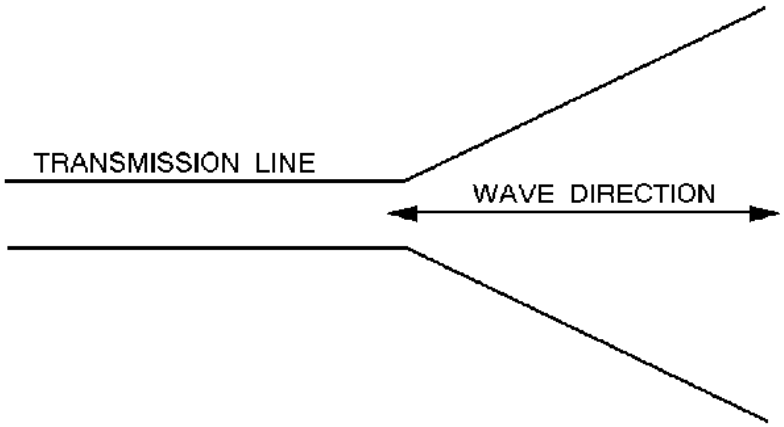

Figure 4-35.—Basic V antenna.

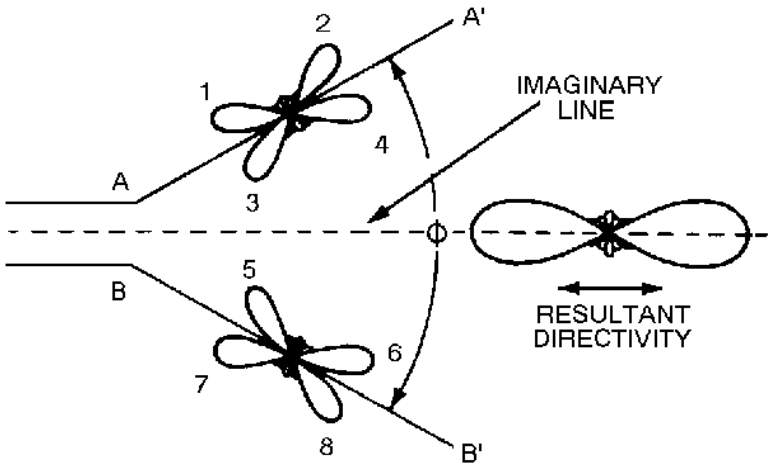

Figure 4-36.—Formation of directional radiation pattern from a resonant V antenna.

Q46. What is the polarity of the currents that feed the V antenna?

RHOMBIC ANTENNA

The highest development of the long-wire antenna is the RHOMBIC ANTENNA (see figure 4-37). It consists of four conductors joined to form a rhombus, or diamond shape. The antenna is placed end to end and terminated by a noninductive resistor to produce a uni-directional pattern. A rhombic antenna can be made of two obtuse-angle V antennas that are placed side by side, erected in a horizontal plane, and terminated so the antenna is nonresonant and unidirectional.

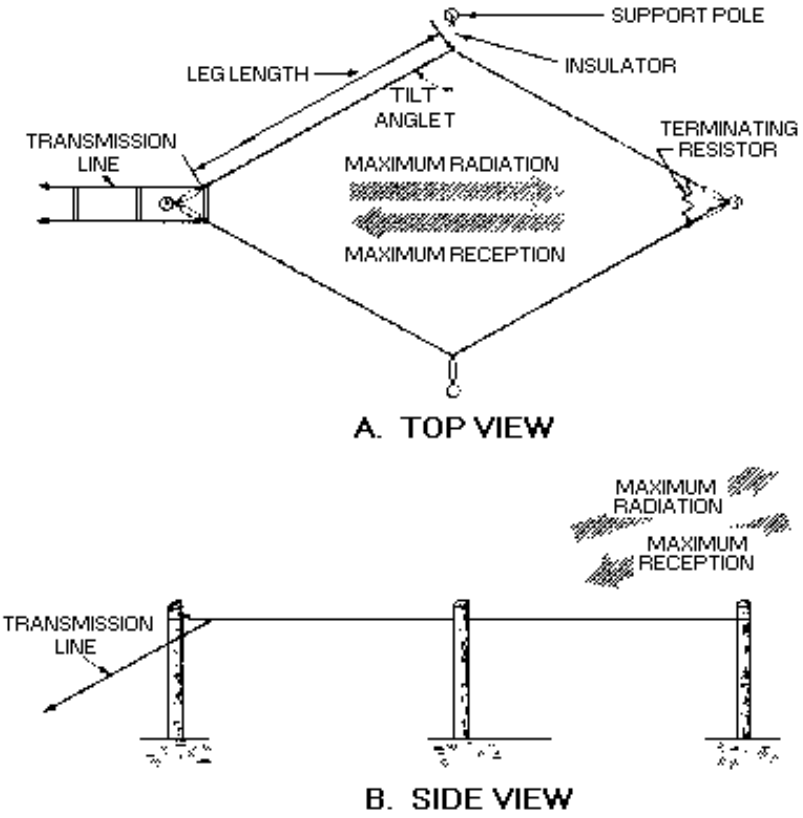

Figure 4-37.—Basic rhombic antenna.

The rhombic antenna is WIDELY used for long-distance, high-frequency transmission and reception. It is one of the most popular fixed-station antennas because it is very useful in point-to-point communications.

Advantages

The rhombic antenna is useful over a wide frequency range. Although some changes in gain, directivity, and characteristic impedance do occur with a change in operating frequency, these changes are small enough to be neglected.

The rhombic antenna is much easier to construct and maintain than other antennas of comparable gain and directivity. Only four supporting poles of common heights from 15 to 20 meters are needed for the antenna.

The rhombic antenna also has the advantage of being noncritical as far as operation and adjustment are concerned. This is because of the broad frequency characteristics of the antenna.

Still another advantage is that the voltages present on the antenna are much lower than those produced by the same input power on a resonant antenna. This is particularly important when high transmitter powers are used or when high-altitude operation is required.

Disadvantages

The rhombic antenna is not without its disadvantages. The principal one is that a fairly large antenna site is required for its erection. Each leg is made at least 1 or 2 wavelengths long at the lowest operating frequency. When increased gain and directivity are required, legs of from 8 to 12 wavelengths are used. These requirements mean that high-frequency rhombic antennas have wires of several hundred feet in length. Therefore, they are used only when a large plot of land is available.

Another disadvantage is that the horizontal and vertical patterns depend on each other. If a rhombic antenna is made to have a narrow horizontal beam, the beam is also lower in the vertical direction. Therefore, obtaining high vertical-angle radiation is impossible except with a very broad horizontal pattern and low gain. Rhombic antennas are used, however, for long-distance sky wave coverage at the high frequencies. Under these conditions low vertical angles of radiation (less than 20 degrees) are desirable. With the rhombic antenna, a considerable amount of the input power is dissipated uselessly in the terminating resistor. However, this resistor is necessary to make the antenna unidirectional. The great gain of the antenna more than makes up for this loss.

Radiation Patterns

Figure 4-38 shows the individual radiation patterns produced by the four legs of the rhombic antenna and the resultant radiation pattern. The principle of operation is the same as for the V and the half-rhombic antennas.

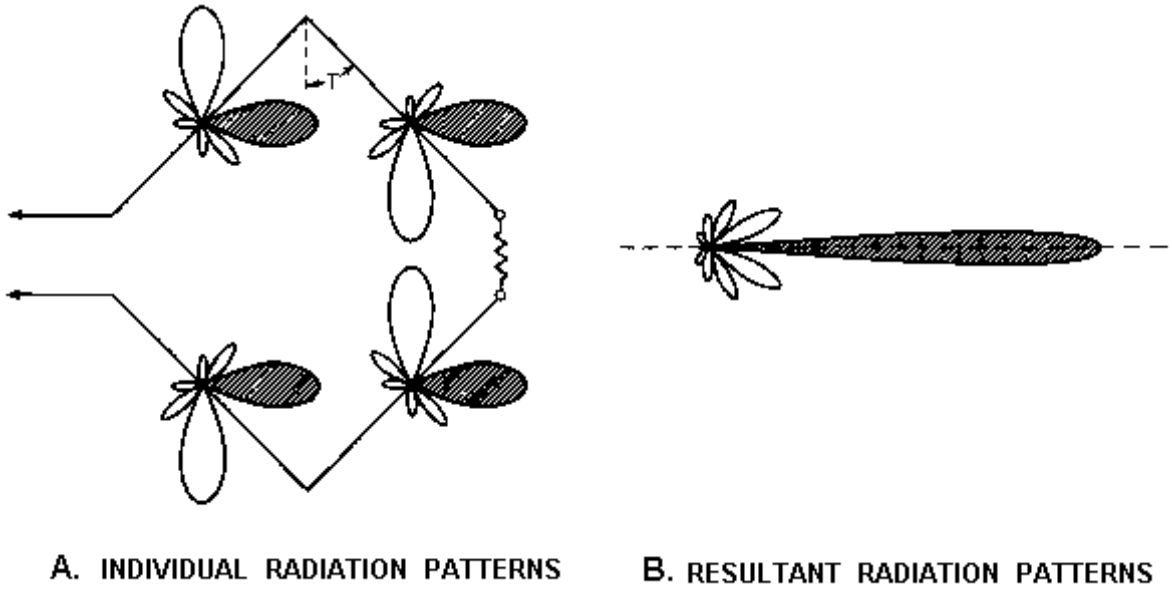

Figure 4-38.—Formation of a rhombic antenna beam.

Terminating Resistor

The terminating resistor plays an important part in the operation of the rhombic antenna. Upon it depend the unidirectivity of the antenna and the lack of resonance effects. An antenna should be properly terminated so it will have a constant impedance at its input. Terminating the antenna properly will also allow it to be operated over a wide frequency range without the necessity for changing the coupling adjustments at the transmitter. Discrimination against signals coming from the rear is of great importance

for reception. The reduction of back radiation is perhaps of lesser importance for transmission. When an antenna is terminated with resistance, the energy that would be radiated backward is absorbed in the resistor.

Q47. What is the main disadvantage of the rhombic antenna?

TURNSTILE ANTENNA

The TURNSTILE ANTENNA is one of the many types that has been developed primarily for omnidirectional vhf communications. The basic turnstile consists of two horizontal half-wave antennas mounted at right angles to each other in the same horizontal plane. When these two antennas are excited with equal currents 90 degrees out of phase, the typical figure-eight patterns of the two antennas merge to produce the nearly circular pattern shown in figure 4-39, view A. Pairs of such antennas are frequently stacked, as shown in figure 4-40. Each pair is called a BAY. In figure 4-40 two bays are used and are spaced 1/2 wavelength apart, and the corresponding elements are excited in phase. These conditions cause a part of the vertical radiation from each bay to cancel that of the other bay. This results in a decrease in energy radiated at high vertical angles and increases the energy radiated in the horizontal plane. Stacking a number of bays can alter the vertical radiation pattern, causing a substantial gain in a horizontal direction without altering the overall horizontal directivity pattern. Figure 4-39, view B, compares the circular vertical radiation pattern of a single-bay turnstile with the sharp pattern of a four-bay turnstile array. A three-dimensional radiation pattern of a four-bay turnstile antenna is shown in figure 4-39, view C.

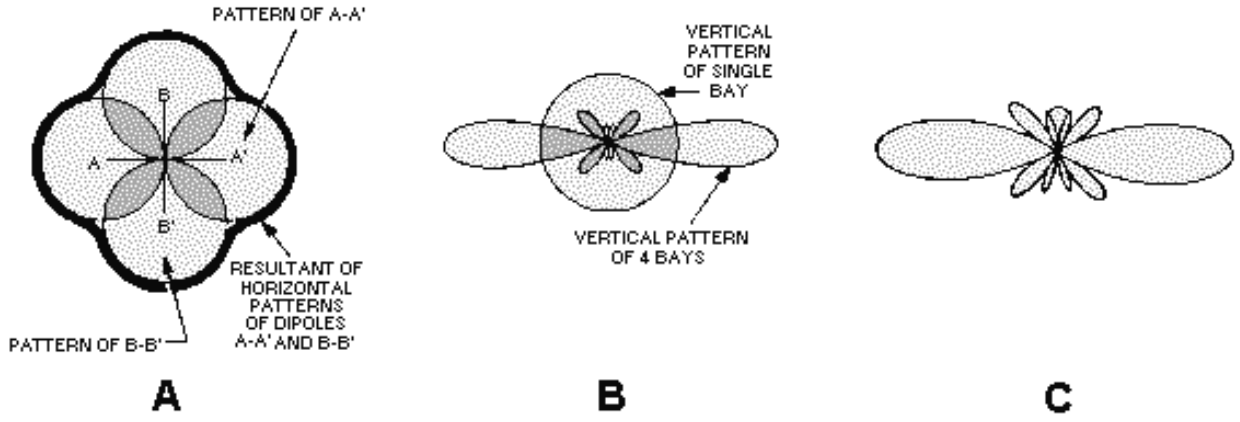

Figure 4-39.—Turnstile antenna radiation pattern.

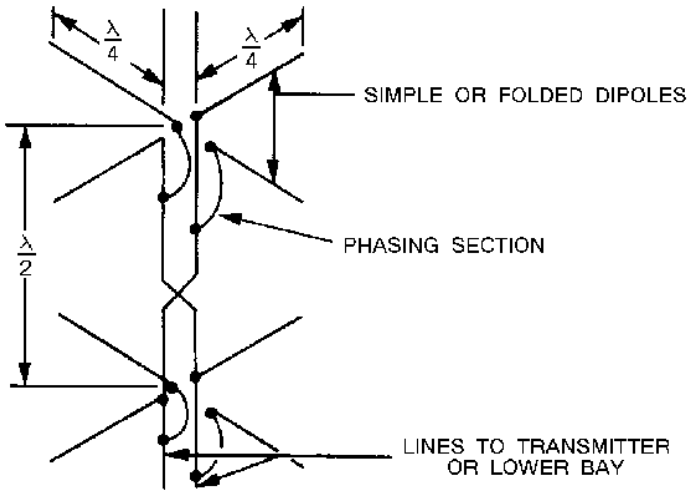

Figure 4-40.—Stacked turnstile antennas.

GROUND-PLANE ANTENNA

A vertical quarter-wave antenna several wavelengths above ground produces a high angle of radiation that is very undesirable at vhf and uhf frequencies. The most common means of producing a low angle of radiation from such an antenna is to work the radiator against a simulated ground called a GROUND PLANE. A simulated ground may be made from a large metal sheet or several wires or rods radiating from the base of the radiator. An antenna so constructed is known as a GROUND-PLANE ANTENNA. Two ground-plane antennas are shown in figure 4-41, views A and B.

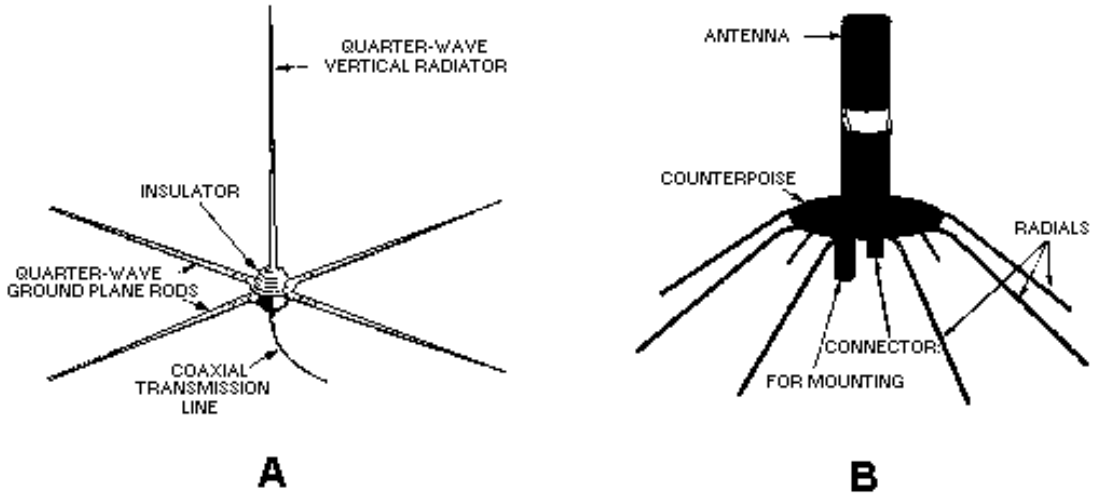

Figure 4-41.—Ground-plane antennas.

CORNER REFLECTOR

When a unidirectional radiation pattern is desired, it can be obtained by the use of a corner reflector with a half-wave dipole. A CORNER-REFLECTOR ANTENNA is a half-wave radiator with a reflector. The reflector consists of two flat metal surfaces meeting at an angle immediately behind the radiator. In other words, the radiator is set in the plane of a line bisecting the corner angle formed by the reflector

sheets. The construction of a corner reflector is shown in figure 4-42. Corner-reflector antennas are mounted with the radiator and the reflector in the horizontal position when horizontal polarization is desired. In such cases the radiation pattern is very narrow in the vertical plane, with maximum signal being radiated in line with the bisector of the corner angle. The directivity in the horizontal plane is approximately the same as for any half-wave radiator having a single-rod type reflector behind it. If the antenna is mounted with the radiator and the corner reflector in the vertical position, as shown in view A, maximum radiation is produced in a very narrow horizontal beam. Radiation in a vertical plane will be the same as for a similar radiator with a single-rod type reflector behind it.

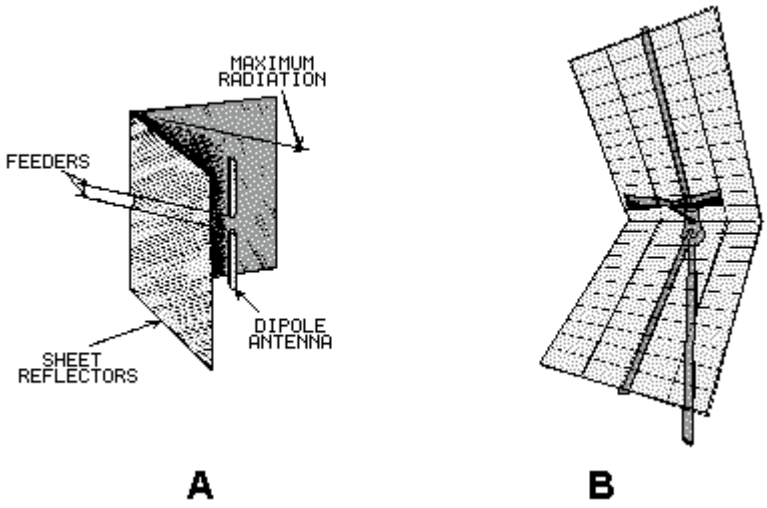

Figure 4-42.—Corner-reflector antennas.

Q48. What is the primary reason for the development of the turnstile antenna?

RF SAFETY PRECAUTIONS

Although electromagnetic radiation from transmission lines and antennas is usually of insufficient strength to electrocute personnel, it can lead to other accidents and compound injuries. Voltages may be induced in ungrounded metal objects, such as wire guys, wire cable (hawser), hand rails, or ladders. If you come in contact with these objects, you could receive a shock or rf burn. This shock can cause you to jump or fall into nearby mechanical equipment or, when working aloft, to fall from an elevated work area. Take care to ensure that all transmission lines or antennas are deenergized before working near or on them.

Either check or have someone check all guys, cables, rails, and ladders around your work area for rf shock dangers. Use working aloft "chits" and safety harnesses for your own safety. Signing a "working aloft chit" signifies that all equipment is in a nonradiating status. The person who signs the chit should ensure that no rf danger exists in areas where you or other personnel will be working.

Nearby ships or parked aircraft are another source of rf energy that you must consider when you check a work area for safety. Combustible materials can be ignited and cause severe fires from arcs or heat generated by rf energy. Also, rf radiation can detonate ordnance devices by inducing currents in the internal wiring of the devices or in the external test equipment or leads connected to them.

ALWAYS obey rf radiation warning signs and keep a safe distance from radiating antennas. The six types of warning signs for rf radiation hazards are shown in figure 4-43.

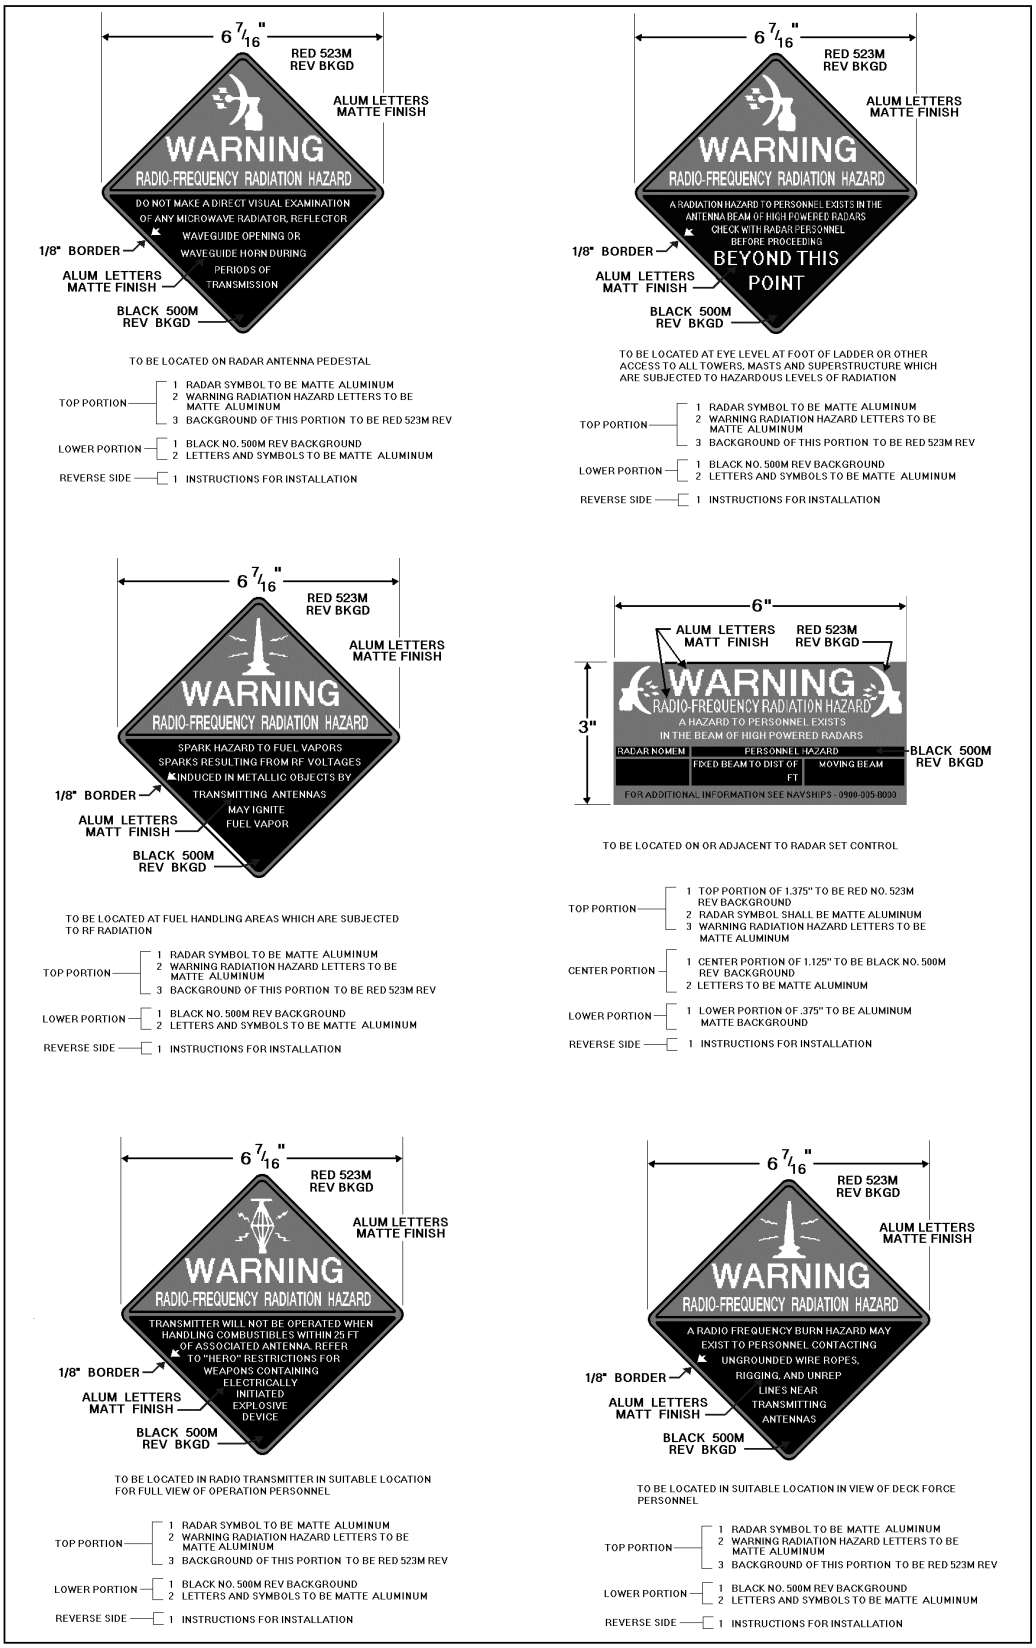

Figure 4-43.—Examples of rf radiation warning signs.

RF BURNS

Close or direct contact with rf transmission lines or antennas may result in rf burns. These are usually deep, penetrating, third-degree burns. To heal properly, these burns must heal from the inside to the skin's surface. To prevent infection, you must give proper attention to all rf burns, including the small "pinhole" burns. Petrolatum gauze can be used to cover these burns temporarily, before the injured person reports to medical facilities for further treatment.

DIELECTRIC HEATING

DIELECTRIC HEATING is the heating of an insulating material by placing it in a high-frequency electric field. The heat results from internal losses during the rapid reversal of polarization of molecules in the dielectric material.

In the case of a human in an rf field, the body acts as a dielectric. If the power in the rf field exceeds 10 milliwatts per centimeter, a person in that field will have a noticeable rise in body temperature. The eyes are highly susceptible to dielectric heating. For this reason, you should not look directly into devices radiating rf energy. The vital organs of the body also are susceptible to dielectric heating. For your own safety, you must NOT stand directly in the path of rf radiating devices.

PRECAUTIONS WHEN WORKING ALOFT

When radio or radar antennas are energized by transmitters, you must not go aloft unless advance tests show that little or no danger exists. A casualty can occur from even a small spark drawn from a charged piece of metal or rigging. Although the spark itself may be harmless, the "surprise" may cause you to let go of the antenna involuntarily and you may fall. There is also a shock hazard if nearby antennas are energized.

Rotating antennas also might cause you to fall when you are working aloft. Motor safety switches controlling the motion of rotating antennas must be tagged and locked open before you go aloft near such antennas.

When working near a stack, you should draw and wear the recommended oxygen breathing apparatus. Among other toxic substances, stack gas contains carbon monoxide. Carbon monoxide is too unstable to build up to a high concentration in the open, but prolonged exposure to even small quantities is dangerous.

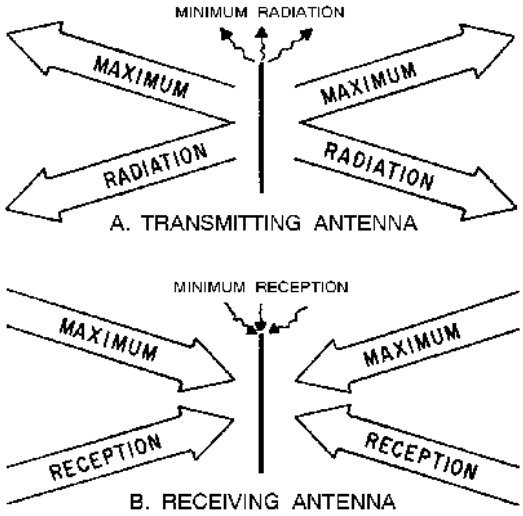
SUMMARY

This chapter has presented information on the various types of antennas. The information that follows summarizes the important points of this chapter.

An **ANTENNA** is a conductor, or system of conductors, that radiates or receives energy in the form of electromagnetic waves.

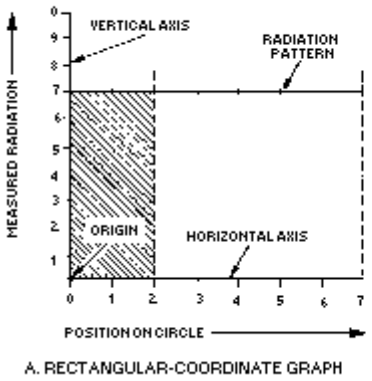
HERTZ (half-wave) and **MARCONI** (quarter-wave) are the two basic classifications of antennas.

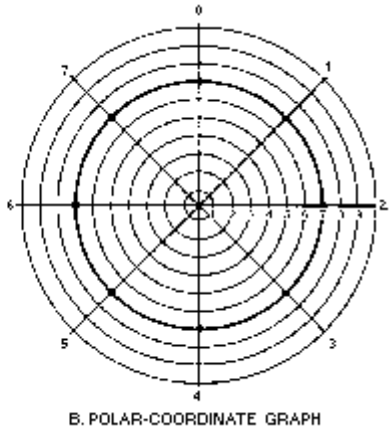
RECIPROCITY of antennas means that the various properties of the antenna apply equally to transmitting and receiving.



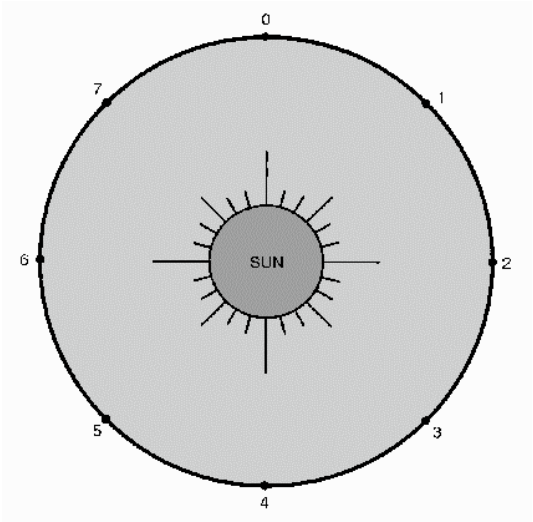
RADIATION RESISTANCE is the amount of resistance which, if inserted in place of the antenna, would consume the same amount of power that is actually radiated by the antenna.

RADIATION PATTERNS can be plotted on a rectangular- or polar-coordinate graph. These patterns are a measurement of the energy leaving an antenna.

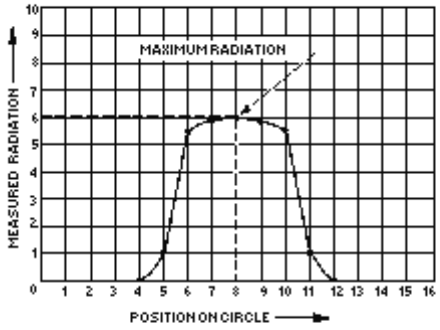




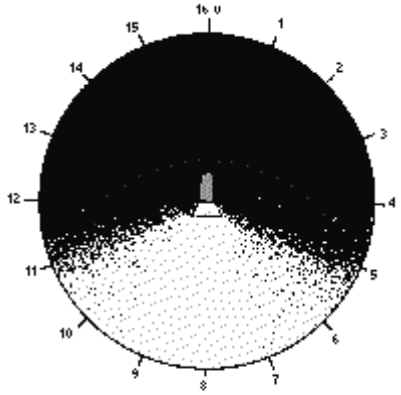
An **ISOTROPIC RADIATOR** radiates energy equally in all directions.



An **ANISOTROPIC RADIATOR** radiates energy directionally.



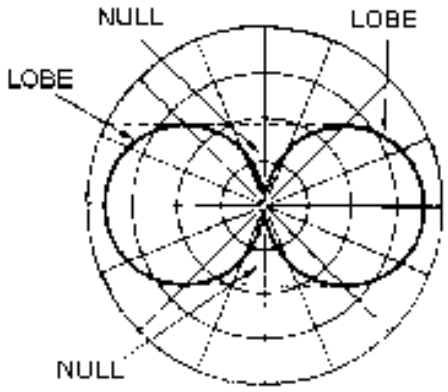
A



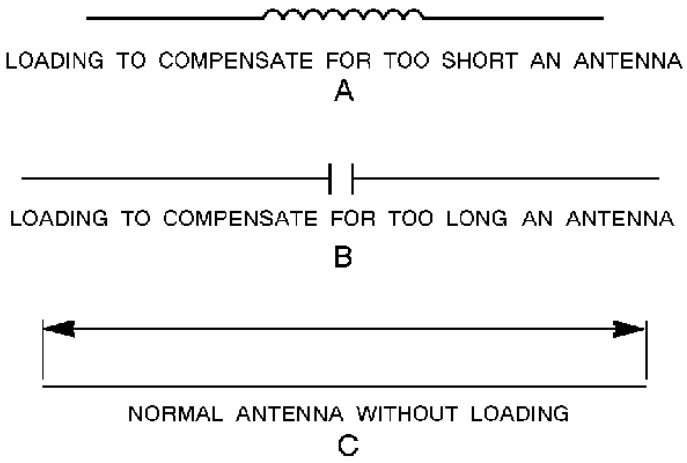
B

A **LOBE** is the area of a radiation pattern that is covered by radiation.

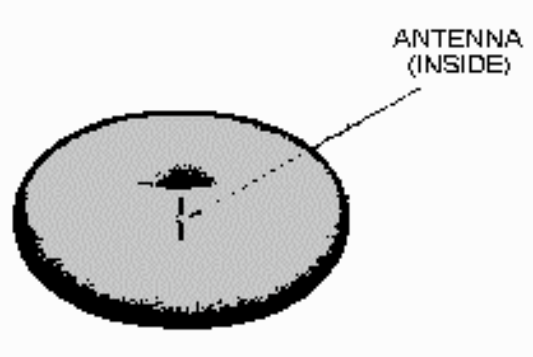
A **NULL** is the area of a radiation pattern that has minimum radiation.



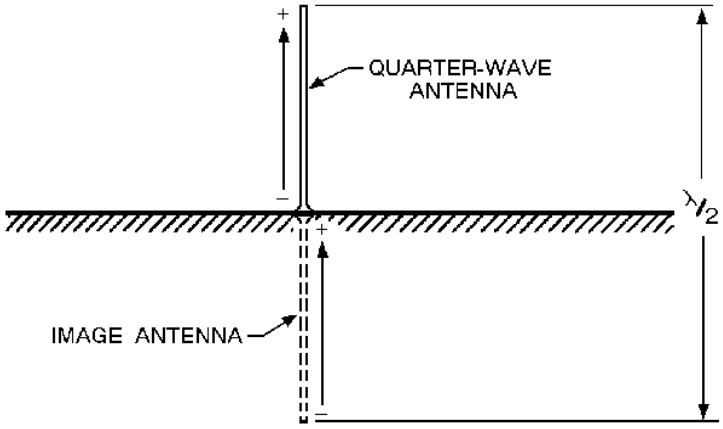
ANTENNA LOADING is the method used to change the electrical length of an antenna. This keeps the antenna in resonance with the applied frequency. It is accomplished by inserting a variable inductor or capacitor in series with the antenna.



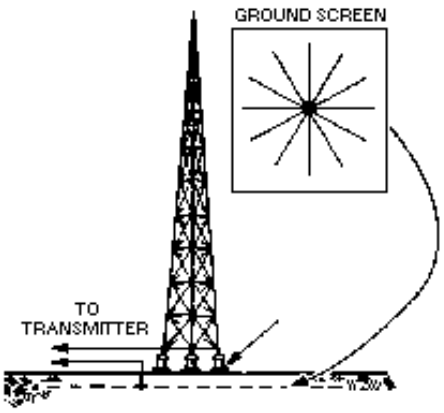
A **HALF-WAVE ANTENNA (Hertz)** consists of two lengths of rod or tubing, each a quarter-wave long at a certain frequency, which radiates a doughnut pattern.

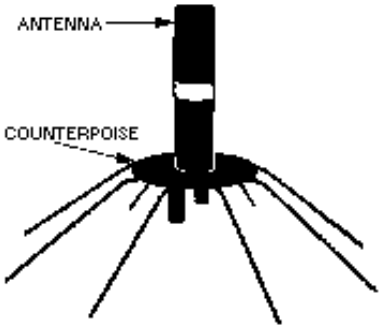


A **QUARTER-WAVE ANTENNA (Marconi)** is a half-wave antenna cut in half with one end grounded. The ground furnishes the missing half of the antenna.

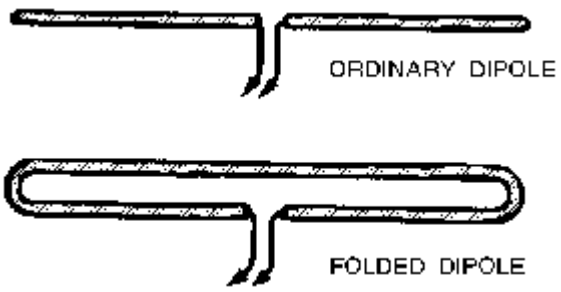


The **GROUND SCREEN** and the **COUNTERPOISE** are used to reduce losses caused by the ground in the immediate vicinity of the antenna. The ground screen is buried below the surface of the earth. The counterpoise is installed above the ground.





The **FOLDED DIPOLE** consists of a dipole radiator, which is connected in parallel at its ends to a half-wave radiator.



AN **ARRAY** is a combination of half-wave elements operating together as a single antenna. It provides more gain and greater directivity than single element antennas.

A **DRIVEN ARRAY** derives its power directly from the source.

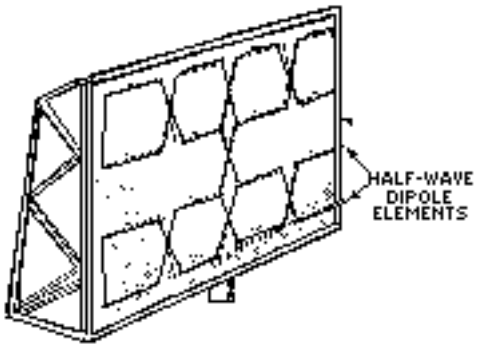
A **PARASITIC ARRAY** derives its power by coupling the energy from other elements of the antenna.

The **BIDIRECTIONAL ARRAY** radiates energy equally in two opposing directions.

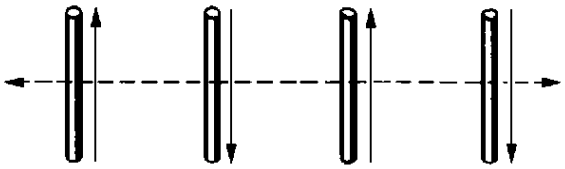
The **UNIDIRECTIONAL ARRAY** radiates energy efficiently in a single direction.

The **COLLINEAR ARRAY** has elements in a straight line. Maximum radiation occurs at right angles to this line.

The **BROADSIDE ARRAY** has elements parallel and in the same plane. Maximum radiation develops in the plane at right angles to the plane of the elements.



The **END-FIRE ARRAY** has elements parallel to each other and in the same plane. Maximum radiation occurs along the axis of the array.



A. TOP VIEW OF ARRAY

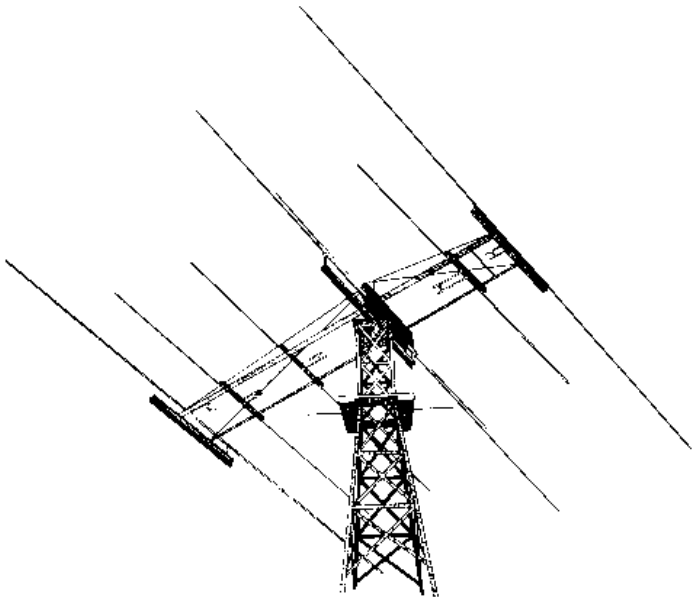
B. SIDE VIEW OF ARRAY

MATCHING STUBS are used between elements to maintain current in the proper phase.

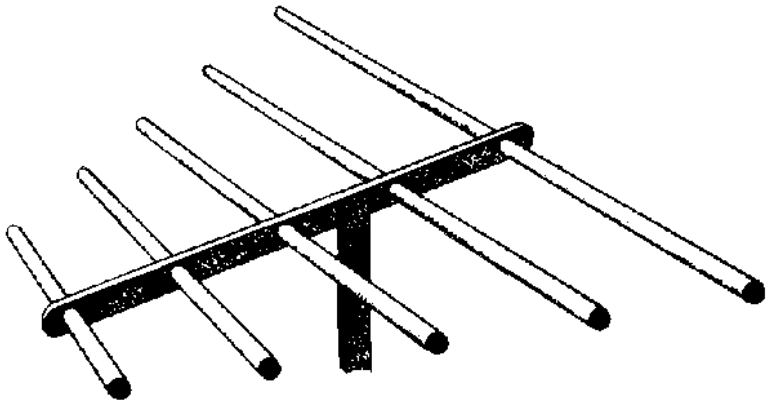
The **GAIN OF A COLLINEAR ANTENNA** is greatest when the elements are spaced from 0.4 to 0.5 wavelength apart or when the number of elements is increased.

The **OPTIMUM GAIN OF A BROADSIDE ARRAY** is obtained when the elements are spaced 0.65 wavelength apart.

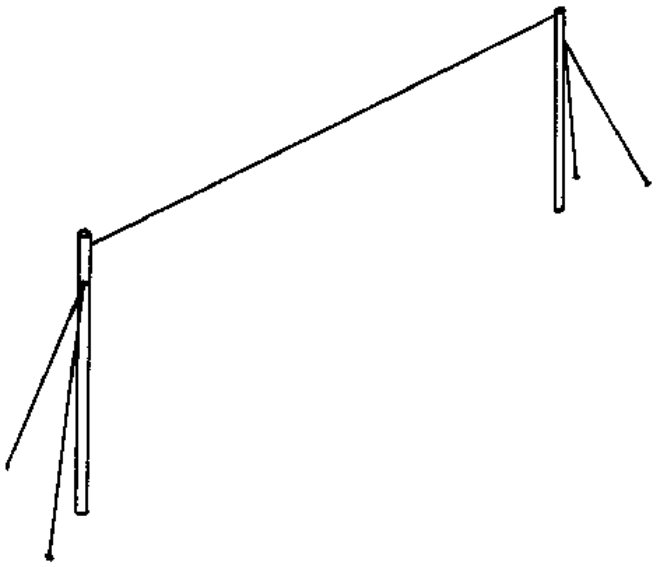
A **PARASITIC ARRAY** consists of one or more parasitic elements with a driven element. The amount of power gain and directivity depends on the lengths of the parasitic elements and the spacing between them.



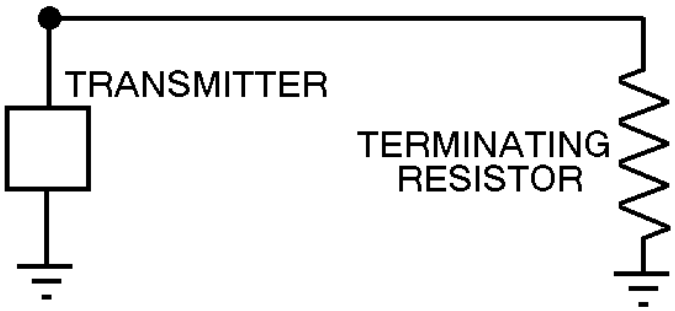
MULTIELEMENT ARRAYS, such as the YAGI, have a narrow frequency response as well as a narrow beamwidth.



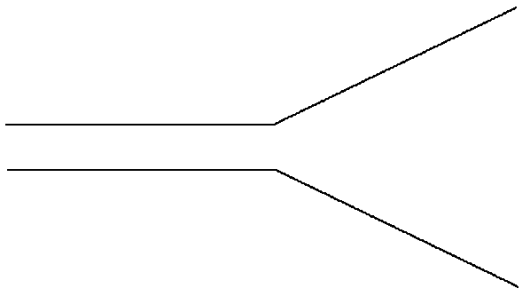
A **LONG-WIRE ANTENNA** is an antenna that is a wavelength or more long at the operating frequency. These antennas have directive patterns that are sharp in both the horizontal and vertical planes.



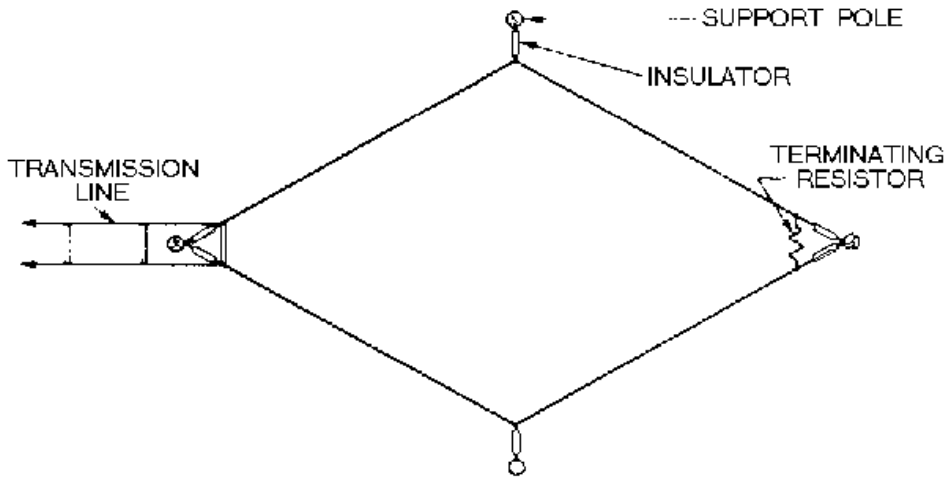
BEVERAGE ANTENNAS consist of a single wire that is two or more wavelengths long.



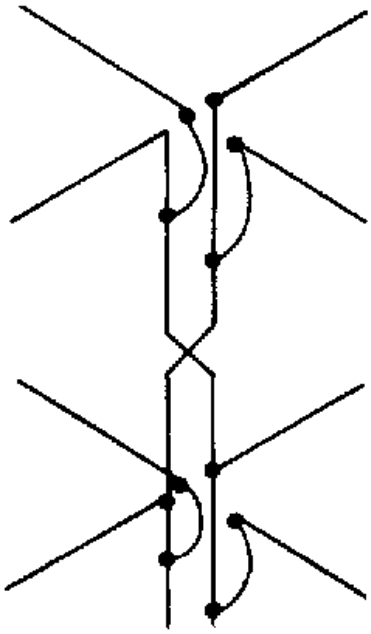
A **V ANTENNA** is a bi-directional antenna consisting of two horizontal, long wires arranged to form a V.



The **RHOMBIC ANTENNA** uses four conductors joined to form a rhombus shape. This antenna has a wide frequency range, is easy to construct and maintain, and is noncritical as far as operation and adjustment are concerned.



The **TURNSTILE ANTENNA** consists of two horizontal, half-wire antennas mounted at right angles to each other.



ANSWERS TO QUESTIONS Q1. THROUGH Q48.

A1. Half-wave (Hertz) and quarter-wave (Marconi).

A2. Coupling device, feeder, and antenna.

A3. Frequency of operation of the transmitter, amount of power to be radiated, and general direction of the receiving set.

A4. One-half the wavelength.

A5. Current and voltage loops.

A6. Current and voltage nodes.

A7. Reciprocity of antennas.

A8. Electric (E) field.

A9. Circular polarization.

A10. Vertical polarization.

A11. Less interference is experienced by man-made noise sources.

A12. Vertical polarization.

A13. 73 ohms.

A14. Anisotropic radiator.

A15. Isotropic radiator.

A16. Anisotropic radiator.

A17. Dipole, doublet and Hertz.

A18. Nondirectional.

A19. Vertical plane.

A20. The pattern would flatten.

A21. To connect one end through a capacitor to the final output stage of the transmitter.

A22. A circular radiation pattern in the horizontal plane, or same as a half wave.

A23. It is composed of a series of conductors arranged in a radial pattern and buried 1 to 2 feet below the ground.

A24. Nine times the feed-point impedance.

A25. Folded dipole.

A26. To produce desired phase relationship between connected elements.

A27. Major lobes have the greatest amount of radiation.

A28. Four.

A29. As more elements are added, an unbalanced condition in the system occurs which impairs efficiency.

A30. By increasing the lengths of the elements of the array.

A31. Directivity increases.

A32. Lower radiation resistance.

A33. Parallel and in the same plane.

A34. They sharpen.

A35. Extremely low radiation resistance, confined to one frequency, and affected by atmospheric conditions.

A36. Along the major axis

A37. Symmetrically.

A38. Length of the parasitic element (tuning) and spacing between the parasitic and driven elements.

A39. Increased gain and directivity.

A40. Rotary array.

A41. Their adjustment is critical and they do not operate over a wide frequency range.

A42. Increased gain.

A43. Multielement parasitic array.

A44. One-half wavelength.

A45. Wave antenna.

A46. Opposite.

A47. It requires a large antenna site.

A48. For omnidirectional vhf communications.

APPENDIX I

GLOSSARY

ABSORPTION—(1) Absorbing light waves. Does not allow any reflection or refraction. (2) Atmospheric absorption of rf energy with no reflection or refraction (adversely affects long distance communications).

ACOUSTICS—The science of sound.

AMPLITUDE—The portion of a cycle measured from a reference line to a maximum value above (or to a maximum value below) the line.

ANGLE OF INCIDENCE—The angle between the incident wave and the normal.

ANGLE OF REFLECTION—The angle between the reflected wave and the normal.

ANGLE OF REFRACTION—The angle between the normal and the path of a wave through the second medium.

ANGSTROM UNIT—The unit used to define the wavelength of light waves.

ANISOTROPIC—The property of a radiator to emit strong radiation in one direction.

ANTENNA—A conductor or set of conductors used either to radiate rf energy into space or to collect rf energy from space.

ARRAY OF ARRAYS—Same as COMBINATION ARRAY.

BAY—Part of an antenna array.

BEVERAGE ANTENNA—A horizontal, longwire antenna designed for reception and transmission of low-frequency, vertically polarized ground waves.

BIDIRECTIONAL ARRAY—An array that radiates in opposite directions along the line of maximum radiation.

BROADSIDE ARRAY—An array in which the direction of maximum radiation is perpendicular to the plane containing the elements.

CENTER-FEED METHOD—Connecting the center of an antenna to a transmission line, which is then connected to the final (output) stage of the transmitter.

CHARACTERISTIC IMPEDANCE—The ratio of voltage to current at any given point on a transmission line. Represented by a value of impedance.

COAXIAL LINE—A type of transmission line that contains two concentric conductors.

COLLINEAR ARRAY—An array with all the elements in a straight line. Maximum radiation is perpendicular to the axis of the elements.

COMBINATION ARRAY—An array system that uses the characteristics of more than one array.

COMPLEMENTARY (SECONDARY) COLORS OF LIGHT—The colors of light produced when two of the primaries are mixed in overlapping beams of light. The complementary colors of light are magenta, yellow, and cyan.

COMPLEX WAVE—A wave produced by combining two or more pure tones at the same time.

COMPRESSION WAVES—Longitudinal waves that have been compressed (made more dense) as they move away from the source.

CONDUCTANCE—The opposite of resistance in transmission lines. The minute amount of resistance that is present in the insulator of a transmission line.

CONNECTED ARRAY—Another term for DRIVEN ARRAY.

COPPER LOSSES—The I^2R loss in a conductor caused by the current flow through the resistance of the conductor.

CORNER-REFLECTOR ANTENNA—A half-wave antenna with a reflector consisting of two flat metal surfaces meeting at an angle behind the radiator.

COUNTERPOISE—A network of wire that is connected to a quarter-wave antenna at one end and provides the equivalent of an additional 1/4 wavelength.

COUPLING DEVICE—A coupling coil that connects the transmitter to the feeder.

CREST (TOP)—The peak of the positive alternation (maximum value above the line) of a wave.

CRITICAL ANGLE—The maximum angle at which radio waves can be transmitted and still be refracted back to earth.

CRITICAL FREQUENCY—The maximum frequency at which a radio wave can be transmitted vertically and still be refracted back to earth.

CURRENT-FEED METHOD—Same as CENTER-FEED METHOD.

CURRENT STANDING-WAVE RATIO (ISWR)—The ratio of maximum to minimum current along a transmission line.

CYCLE—One complete alternation of a sine wave that has a maximum value above and a maximum value below the reference line.

DAMPING—Reduction of energy by absorption.

DENSITY—(1) The compactness of a substance. (2) Mass per unit volume.

DETECTOR—The device that responds to a wave or disturbance.

DIELECTRIC HEATING—The heating of an insulating material by placing it in a high frequency electric field.

DIELECTRIC LOSSES—The losses resulting from the heating effect on the dielectric material between conductors.

DIFFRACTION—The bending of the paths of waves when the waves meet some form of obstruction.

DIFFUSION—The scattering of reflected light waves (beams) from an object, such as white paper.

DIPOLE—A common type of half-wave antenna made from a straight piece of wire cut in half. Each half operates at a quarter wavelength of the output.

DIRECTIONAL—Radiation that varies with direction.

DIRECTOR—The parasitic element of an array that reinforces energy coming from the driver toward itself.

DIRECTIVITY—The property of an array that causes more radiation to take place in certain directions than in others.

DISPERSION—The refraction of light waves that causes the different frequencies to bend at slightly different angles.

DISTRIBUTED CONSTANTS—The constants of inductance, capacitance, and resistance in a transmission line. The constants are spread along the entire length of the line and cannot be distinguished separately.

DOPPLER EFFECT—The apparent change in frequency or pitch when a sound source moves either toward or away from a listener.

DOUBLET—Another name for the dipole antenna.

DRIVEN ARRAY—An array in which all of the elements are driven.

DRIVEN ELEMENT—An element of an antenna (transmitting or receiving) that is connected directly to the transmission line.

ECHO—The reflection of the original sound wave as it bounces off a distant surface.

ELASTICITY—The ability of a substance to return to its original state.

ELECTROMAGNETIC FIELD—The combination of an electric (E) field and a magnetic (H) field.

ELECTROMAGNETIC INTERFERENCE—Man-made or natural interference that degrades the quality of reception of radio waves.

ELECTROMAGNETIC RADIATION—The radiation of radio waves into space.

ELECTRIC (E) FIELD—The field produced as a result of a voltage charge on a conductor or antenna.

ELEMENT—A part of an antenna that can be either an active radiator or a parasitic radiator.

END-FEED METHOD—Connecting one end of an antenna through a capacitor to the final output stage of a transmitter.

END-FIRE ARRAY—An array in which the direction of radiation is parallel to the axis of the array.

FADING—Variations in signal strength by atmospheric conditions.

FEEDER—A transmission line that carries energy to the antenna.

FLAT LINE—A transmission line that has no standing waves. This line requires no special tuning device to transfer maximum power.

FLEXIBLE COAXIAL LINE—A coaxial line made with a flexible inner conductor insulated from the outer conductor by a solid, continuous insulating material.

FOLDED DIPOLE—An ordinary half-wave antenna (dipole) that has one or more additional conductors connected across the ends parallel to each other.

FOUR-ELEMENT ARRAY—An array with three parasitic elements and one driven element.

FREE-SPACE LOSS—The loss of energy of a radio wave because of the spreading of the wavefront as it travels from the transmitter.

FREQUENCY—The number of cycles that occur in one second. Usually expressed in hertz.

FREQUENCY DIVERSITY—Transmitting (and receiving) of radio waves on two different frequencies simultaneously.

FRONT-TO-BACK RATIO—The ratio of the energy radiated in the principal direction to the energy radiated in the opposite direction.

FUNDAMENTAL FREQUENCY—The basic frequency or first harmonic frequency.

GAIN—The ratio between the amount of energy propagated from an antenna that is directional to the energy from the same antenna that would be propagated if the antenna were not directional.

GENERATOR END—See INPUT END.

GROUND PLANE—The portion of a groundplane antenna that acts as ground.

GROUND-PLANE ANTENNA—A type of antenna that uses a ground plane as a simulated ground to produce low-angle radiation.

GROUND REFLECTION LOSS—The loss of rf energy each time a radio wave is reflected from the Earth's surface.

GROUND SCREEN—A series of conductors buried below the surface of the earth and arranged in a radial pattern. Used to reduce losses in the ground.

GROUND WAVES—Radio waves that travel near the surface of the Earth.

HALF-WAVE DIPOLE ANTENNA—An antenna consisting of two rods (1/4 wavelength each) in a straight line, that radiates electromagnetic energy.

HARMONIC—A frequency that is a whole number multiple of a smaller base frequency.

HERTZ ANTENNA—A half-wave antenna installed some distance above ground and positioned either vertically or horizontally.

HORIZONTAL AXIS—On a graph, the straight line axis plotted from left to right.

HORIZONTAL PATTERN—The part of a radiation pattern that is radiated in all directions along the horizontal plane.

HORIZONTALLY POLARIZED—Waves that are radiated with their E field component parallel to the Earth's surface.

INCIDENT WAVE—(1) The wave that strikes the surface of a medium. (2) The wave that travels from the sending end to the receiving end of a transmission line.

INDUCTION FIELD—The electromagnetic field produced about an antenna when current and voltage are present on the same antenna.

INDUCTION LOSSES—The losses that occur when the electromagnetic field around a conductor cuts through a nearby metallic object and induces a current into that object.

INFRASONIC (SUBSONIC)—Sounds below 15 hertz.

INPUT END—The end of a two-wire transmission line that is connected to a source.

INPUT IMPEDANCE—The impedance presented to the transmitter by the transmission line and its load.

INTENSITY (OF SOUND)—The measurement of the amplitude of sound energy. Sometimes mistakenly called loudness.

INTERCEPT—The point where two lines drawn on a graph cross each other.

INTERFERENCE—Any disturbance that produces an undesirable response or degrades a wave.

IONOSPHERE—The most important region of the atmosphere extending from 31 miles to 250 miles above the earth. Contains four cloud-like layers that affect radio waves.

IONOSPHERIC STORMS—Disturbances in the earth's magnetic field that make communications practical only at lower frequencies.

IONIZATION—The process of upsetting electrical neutrality.

ISOTROPIC RADIATION—The radiation of energy equally in all directions.

LEAKAGE CURRENT—The small amount of current that flows between the conductors of a transmission line through the dielectric.

LIGHT RAYS—Straight lines that represent light waves emitting from a source.

LOAD END—See OUTPUT END.

LOADING—See LUMPED-IMPEDANCE TUNING.

LOBE—An area of a radiation pattern plotted on a polar-coordinate graph that represents maximum radiation.

LONG-WIRE ANTENNA—An antenna that is a wavelength or more long at its operating frequency.

LONGITUDINAL WAVES—Waves in which the disturbance (back and forth motion) takes place in the direction of propagation. Sometimes called compression waves.

LOOP—The curves of a standing wave or antenna that represent amplitude of current or voltage.

LOWEST USABLE FREQUENCY—The minimum operating frequency that can be used for communications between two points.

LUMPED CONSTANTS—The properties of inductance, capacitance, and resistance in a transmission line.

LUMPED-IMPEDANCE TUNING—The insertion of an inductor or capacitor in series with an antenna to lengthen or shorten the antenna electrically.

MAGNETIC (H) FIELD—The field produced when current flows through a conductor or antenna.

MAJOR LOBE—The lobe in which the greatest amount of radiation occurs.

MARCONI ANTENNA—A quarter-wave antenna oriented perpendicular to the earth and operated with one end grounded.

MAXIMUM USABLE FREQUENCY— Maximum frequency that can be used for communications between two locations for a given time of day and a given angle of incidence.

MEDIUM—The substance through which a wave travels from one point to the next. Air, water, wood, etc., are examples of a medium.

MINOR LOBE—The lobe in which the radiation intensity is less than a major lobe.

MULTIELEMENT ARRAY—An array consisting of one or more arrays and classified as to directivity.

MULTIELEMENT PARASITIC ARRAY— An array that contains two or more parasitic elements and a driven element.

MULTIPATH—The multiple paths a radio wave may follow between transmitter and receiver.

NATURAL HORIZON—The line-of-sight horizon.

NEGATIVE ALTERNATION—The portion of a sine wave below the reference line.

NODE—The fixed minimum points of voltage or current on a standing wave or antenna.

NOISE (OF SOUND)—An unwanted disturbance caused by spurious waves that originate from man-made or natural sources.

NONDIRECTIONAL—See OMNIDIRECTIONAL.

NONLUMINOUS BODIES—Objects that either reflect or diffuse light that falls upon them.

NONRESONANT LINE—A transmission line that has no standing waves of current or voltage.

NORMAL—The imaginary line perpendicular to the point at which the incident wave strikes the reflecting surface. Also called the perpendicular.

NULL—On a polar-coordinate graph, the area that represents minimum or 0 radiation.

OMNIDIRECTIONAL—Transmitting in all directions.

OPAQUE—A type of substance that does not transmit any light rays.

OPEN-ENDED LINE—A transmission line that has an infinitely large terminating impedance.

OPTIMUM WORKING FREQUENCY—The most practical operating frequency that can be used with the least amount of problems; roughly 85 percent of the maximum usable frequency.

ORIGIN—The point on a graph where the vertical and horizontal axes cross each other.

OUTPUT END—The end of a transmission line that is opposite the source.

OUTPUT IMPEDANCE—The impedance presented to the load by the transmission line and its source.

PARALLEL RESONANT CIRCUIT—A circuit that acts as a high impedance at resonance.

PARALLEL-WIRE—A type of transmission line consisting of two parallel wires.

PARASITIC ARRAY—An array that has one or more parasitic elements.

PARASITIC ELEMENT—The passive element of an antenna array that is connected to neither the transmission line nor the driven element.

PERIOD—The amount of time required for completion of one full cycle.

PITCH—A term used to describe the frequency of a sound heard by the human ear.

PLANE OF POLARIZATION—The plane (vertical or horizontal) with respect to the earth in which the E field propagates.

POINT OF ZERO DISPLACEMENT—See REFERENCE LINE.

POLAR-COORDINATE GRAPH—A graph whose axes consist of a series of circles with a common center and a rotating radius extending from the center of the concentric circles.

POSITIVE ALTERNATION—The portion of a sine wave above the reference line.

POWER LOSS—The heat loss in a conductor as current flows through it.

POWER STANDING-WAVE RATIO (PSWR)—The ratio of the square of the maximum and minimum voltages of a transmission line.

PRIMARY COLORS (OF LIGHT)—The three primary colors of light (red, green, and blue), from which all other colors may be derived.

PRISM—A triangular-shaped glass that refracts and disperses light waves into component wavelengths.

PROPAGATION—Waves traveling through a medium.

QUALITY (OF SOUND)—The factor that distinguishes tones of pitch and loudness.

QUARTER-WAVE ANTENNA—Same as the Marconi antenna.

RADIATION FIELD—The electromagnetic field that detaches itself from an antenna and travels through space.

RADIATION LOSSES—The losses that occur when magnetic lines of force about a conductor are projected into space as radiation and are not returned to the conductor as the cycle alternates.

RADIATION PATTERN—A plot of the radiated energy from an antenna.

RADIATION RESISTANCE—The resistance, which if inserted in place of an antenna, would consume the same amount of power as that radiated by the antenna.

RADIO FREQUENCIES—Electromagnetic frequencies that fall between 3 kilohertz and 300 gigahertz and are used for radio communications.

RADIO HORIZON—The boundary beyond the natural horizon in which radio waves cannot be propagated over the earth's surface.

RADIO WAVE—(1) A form of radiant energy that can neither be seen nor felt. (2) An electromagnetic wave generated by a transmitter.

RAREFIED WAVE—A longitudinal wave that has been expanded or rarefied (made less dense) as it moves away from the source.

RECEIVER—The object that responds to a wave or disturbance. Same as detector.

RECEIVING ANTENNA—The device used to pick up an rf signal from space.

RECEIVING END—See OUTPUT END.

RECIPROCITY—The property of interchangeability of the same antenna for transmitting and receiving.

RECTANGULAR-COORDINATE GRAPH—A graph in which straight-line axes (horizontal and vertical) are perpendicular.

REFERENCE LINE—The position a particle of matter would occupy if it were not disturbed by wave motion.

REFLECTED WAVE—(1) The wave that reflects back from a medium. (2) Waves traveling from the load back to the generator on a transmission line. (3) The wave moving back to the sending end of a transmission line after reflection has occurred.

REFLECTION WAVES—Waves that are neither transmitted nor absorbed, but are reflected from the surface of the medium they encounter.

REFLECTOR—The parasitic element of an array that causes maximum energy radiation in a direction toward the driven element.

REFRACTION—The changing of direction as a wave leaves one medium and enters another medium of a different density.

RERADIATION—The reception and retransmission of radio waves caused by turbulence in the troposphere.

RESONANCE—The condition produced when the frequency of vibrations are the same as the natural frequency (of a cavity). The vibrations reinforce each other.

RESONANT LINE—A transmission line that has standing waves of current and voltage.

REST POSITION—See REFERENCE LINE.

REVERBERATION—The multiple reflections of sound waves.

RHOMBIC ANTENNA—A diamond-shaped antenna used widely for long-distance, high-frequency transmission and reception.

RIGID COAXIAL LINE—A coxial line consisting of a central, insulated wire (inner conductor) mounted inside a tubular outer conductor.

SCATTER ANGLE—The angle at which the receiving antenna must be aimed to capture the scattered energy of tropospheric scatter.

SELF-INDUCTION—The phenomenon caused by the expanding and collapsing fields of an electron which encircles other electrons and retards the movement of the encircled electrons.

SELF-LUMINOUS BODIES—Objects that produce their own light.

SENDING END—See INPUT END.

SERIES RESONANT CIRCUIT—A circuit that acts as a low impedance at resonance.

SHIELDED PAIR—A line consisting of parallel conductors separated from each other and surrounded by a solid dielectric.

SHORT-CIRCUITED LINE—A transmission line that has a terminating impedance equal to 0.

SINK—See OUTPUT END.

SKIN EFFECT—The flow of ac current near the surface of a conductor at rf frequencies.

SKIP DISTANCE—The distance from a transmitter to the point where the sky wave is first returned to earth.

SKIP ZONE—A zone of silence between the point where the ground wave becomes too weak for reception and the point where the sky wave is first returned to earth.

SKY WAVES—Radio waves reflected back to earth from the ionosphere.

SONIC—Pertaining to sounds capable of being heard by the human ear.

SOURCE—(1) The object that produces waves or disturbance. (2) The name given to the end of a two-wire transmission line that is connected to a source.

SPACE DIVERSITY—Reception of radio waves by two or more antennas spaced some distance apart.

SPACE WAVE—A radio wave that travels directly from the transmitter to the receiver and remains in the troposphere.

SPECTRUM—(1) The entire range of electromagnetic waves. (2) VISIBLE. The range of electromagnetic waves that stimulate the sense of sight. (3) ELECTROMAGNETIC. The entire range of electromagnetic waves arranged in order of their frequencies.

SPORADIC E LAYER—Irregular cloud-like patches of unusually high ionization. Often forms at heights near the normal E layer.

SPREADER—Insulator used with transmission lines and antennas to keep the parallel wires separated.

STANDING WAVE—The distribution of voltage and current formed by the incident and reflected waves which have minimum and maximum points on a resultant wave that appears to stand still.

STANDING-WAVE RATIO (SWR)—The ratio of the maximum (voltage, current) to the minimum (voltage, current) of a transmission line. Measures the perfection of the termination of the line.

STRATOSPHERE—Located between the troposphere and the ionosphere. Has little effect on radio waves.

STUB—Short section of a transmission line used to match the impedance of a transmission line to an antenna. Can also be used to produce desired phase relationships between connected elements of an antenna.

SUDDEN IONOSPHERIC DISTURBANCE—An irregular ionospheric disturbance that can totally blank out hf radio communications.

SUPERSONIC—Speed greater than the speed of sound.

SURFACE WAVE—A radio wave that travels along the contours of the earth, thereby being highly attenuated.

TEMPERATURE INVERSION—The condition in which warm air is formed above a layer of cool air that is near the earth's surface.

THREE-ELEMENT ARRAY—An array with two parasitic elements (reflector and director) and a driven element.

TONES—Musical sounds.

TRANSLUCENT—A type of substance, such as frosted glass, through which some light rays can pass but through which objects cannot be seen clearly.

TRANSMISSION LINE—A device designed to guide electrical energy from one point to another.

TRANSMITTING ANTENNA—The device used to send the transmitted signal energy into space.

TRANSPARENT—A type of substance, such as glass, that transmits almost all of the light waves that fall upon it.

TRANSMISSION MEDIUMS—The various types of lines and waveguides used as transmission lines.

TRANSMITTER END—See INPUT END.

TRANSVERSE WAVE MOTION—The up and down motion of a wave as the wave moves outward.

TROPOSPHERE—The portion of the atmosphere closest to the earth's surface, where all weather phenomena take place.

TROPOSPHERIC SCATTER—The propagation of radio waves in the troposphere by means of scatter.

TROUGH (BOTTOM)—The peak of the negative alternation (maximum value below the line).

TUNED LINE—Another name for the resonant line. This line uses tuning devices to eliminate the reactance and to transfer maximum power from the source to the line.

TURNSTILE ANTENNA—A type of antenna used in vhf communications that is omnidirectional and consists of two horizontal half-wave antennas mounted at right angles to each other in the same horizontal plane.

TWISTED PAIR—A line consisting of two insulated wires twisted together to form a flexible line without the use of spacers.

TWO-WIRE OPEN LINE—A parallel line consisting of two wires that are generally spaced from 2 to 6 inches apart by insulating spacers.

TWO-WIRE RIBBON (TWIN LEAD)—A parallel line similar to a two-wire open line except that uniform spacing is assured by embedding the two wires in a low-loss dielectric.

ULTRASONIC—Sounds above 20,000 hertz.

UNIDIRECTIONAL ARRAY—An array that radiates in only one general direction.

UNTUNED LINE—Another name for the flat or nonresonant line.

V ANTENNA—A bi-directional antenna, shaped like a V, which is widely used for communications.

VELOCITY—The rate at which a disturbance travels through a medium.

VERTICAL AXIS—On a graph, the straight line axis oriented from bottom to top.

VERTICAL PATTERN—The part of a radiation pattern that is radiated in the vertical plane.

VERTICALLY POLARIZED—Waves radiated with the E field component perpendicular to the earth's surface.

VOLTAGE-FEED METHOD—Same as END FEED METHOD.

VOLTAGE STANDING-WAVE RATIO (VSWR)—The ratio of maximum to minimum voltage of a transmission line.

WAVE ANTENNA—Same as BEVERAGE ANTENNA.

WAVE MOTION—A recurring disturbance advancing through space with or without the use of a physical medium.

WAVE TRAIN—A continuous series of waves with the same amplitude and wavelength.

WAVEFRONT—A small section of an expanding sphere of electromagnetic radiation, perpendicular to the direction of travel of the energy.

WAVEGUIDE—A hollow metal tube used as a transmission line to guide energy from one point to another.

WAVELENGTH—(1) The distance in space occupied by 1 cycle of a radio wave at any given instant. (2) The distance a disturbance travels during one period of vibration.

YAGI ANTENNA—A multielement parasitic array. Elements lie in the same plane as those of the end-fire array.

MODULE 10 INDEX

A

Absorption in the ionosphere, 2-24
Absorption of light, 1-31
Acoustics, sound waves, 1-23
Amplitude, wave motion, 1-7
Antennas, 4-1
    antenna characteristics, 4-8
    array antennas, 4-25
    operation of basic antennas, 4-18
    principles of antenna radiation, 4-2
    radiation of electromagnetic energy, 4-6
    rf safety precautions, 4-47
    special antennas, 4-40
Atmospheric propagation, 2-11
    diffraction, 2-13
    reflection, 2-11
    refraction, 2-12

B

Basic antennas, operation of, 4-18
Broadside arrays, 4-31
Bums, if, 4-50

C

Characteristic impedance of a transmission line, 3-14
Collinear array, 4-29
Color and frequencies, 1-27
Color and light, 1-28
Comparison of light waves and sound waves, 1-32
Corner reflector, 4-46
Current and voltage distribution on an antenna, 4-4
Cycle, wave motion, 1-8

D

Density and velocity of transmission, sound waves, 1-22
Determining characteristic impedance, 3-26
Dielectric heating, 4-49
Diffraction, atmospheric propagation, 2-13
Diffraction, wave motion, 1-16

Assignment Questions

Information: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook assignment: Chapter 1, “Wave Propagation,” pages 1-1 through 1-48.

1-1. What is the major advantage of the telegraph over earlier methods of communication?

1. Range
2. Speed
3. Security
4. Reliability

1-2. The spreading out of radio waves is referred to as propagation and is used in which of the following Navy equipment?

1. Detection
2. Communication
3. Radar and navigation
4. Each of the above

1-3. Radio-frequency waves CANNOT be seen for which of the following reasons?

1. Because radio-frequency energy is low powered
2. Because radio-frequency waves are below the sensitivity range of the human eye
3. Because the human eye detects only magnetic energy
4. Because radio-frequency waves are above the sensitivity range of the human eye

1-4. Radio waves travel at what speed?

1. Speed of sound
2. Speed of light
3. Speed of the Earth's rotation
4. Speed of the Earth's orbit around the sun

1-5. Which of the following types of energy CANNOT be seen, heard, or felt?

1. Radio waves
2. Sound waves
3. Heat waves
4. Light waves

1-6. A stone dropped into water creates a series of expanding circles on the surface of the water. This is an example of which of the following types of wave motion?

1. Transverse
2. Concentric
3. Longitudinal
4. Compression

1-7. A sound wave that moves back and forth in the direction of propagation is an example of which of the following types of wave motion?

1. Composite
2. Concentric
3. Transverse
4. Longitudinal

1-8. Which of the following terms is used for the vehicle through which a wave travels from point to point?

1. Medium
2. Source
3. Detector
4. Receiver

1-9. Which of the following is NOT an element necessary to propagate sound?

1. Medium
2. Source
3. Detector
4. Reference

1-10. If a wave has a velocity of 4,800 feet per second and a wave-length of 5 feet, what is the frequency of the wave?

1. 9.6 Hz
2. 96 Hz
3. 960 Hz
4. 9,600 Hz

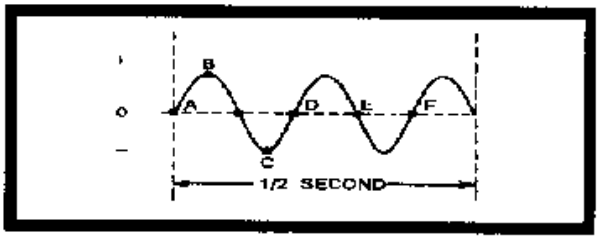

Figure 1-A.—Waveform.

IN ANSWERING QUESTIONS 1-11 THROUGH 1-15, REFER TO FIGURE 1-A.

1-11. The waveform in the figure is what type of wave?

1. Sine
2. Square
3. Sawtooth
4. Trapezoidal

1-12. The distance between which of the following points represents the completion of a full cycle of alternating current?

1. A to C
2. B to D
3. C to E
4. D to F

1-13. The distance between which of the following points represents a full wavelength?

1. A to D
2. A to E
3. D to E
4. E to F

1-14. What is the frequency of the wave?

1. 0.5 Hz
2. 2.5 Hz
3. 5.0 Hz
4. 7.5 Hz

1-15. What is the period of the wave?

1. 100 milliseconds
2. 200 milliseconds
3. 250 milliseconds
4. 500 milliseconds

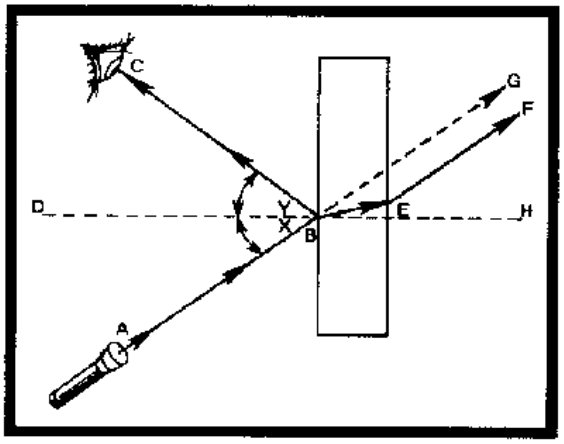

Figure 1-B.—Wave angles.

IN ANSWERING QUESTIONS 1-16 THROUGH 1-19, REFER TO FIGURE 1-B.

1-16. What line in the figure indicates the incident wave?

1. A to B
2. B to E
3. C to B
4. D to H

1-17. Angle "x" is which of the following angles?

1. Normal
2. Incidence
3. Reflection
4. Refraction

1-18. Line E to F represents which of the following waves?

1. Normal
2. Incident
3. Refracted
4. Reflected

1-19. Line D to H represents which of the following references?

1. Normal
2. Perpendicular
3. Both 1 and 2 above
4. Reflected line

1-20. Which of the following statements about a wave is the law of reflection?

1. The angle of incidence is equal to the refracted wave
2. The angle of incidence is not equal to the refracted wave
3. The angle of incidence is equal to the angle of reflection
4. The angle of incidence is not equal to the angle of reflection

1-21. If a wave passes first through a dense medium and then through a less dense medium, which of the following angle-of-refraction conditions exists?

1. The angle of refraction is greater than the angle of incidence
2. The angle of refraction is less than the angle of incidence
3. The angle of refraction is equal to the angle of incidence
4. The wave will pass through in a straight line

1-22. The reception of an AM-band radio signal over mountains can be explained by which of the following principles of wave propagation?

1. Reflection
2. Refraction
3. Diffraction
4. Doppler effect

1-23. What wave propagation principle accounts for the apparent increase in frequency as a train whistle approaches and the apparent decrease in frequency as it moves away?

1. Refraction
2. Reflection
3. Diffraction
4. Doppler effect

1-24. Longitudinal wave disturbances that travel through a medium are known as what type of waves?

1. Air
2. Sound
3. Radio
4. Light

1-25. What are the three audible frequency ranges?

1. Subsonic, sonic, and supersonic
2. Infrasonic, sonic, and ultrasonic
3. Infrasonic, subsonic, and ultrasonic
4. Infrasonic, subsonic, and supersonic

1-26. If a bell is placed in a jar and the air in the jar is replaced with a gas of a higher density, what is the effect, if any, on the speed of the sound when the bell is rung?

1. The sound stops
2. The sound travels faster
3. The sound travels slower
4. The sound is not affected

1-27. Varying which of the following wave characteristics will cause the length of sound waves to vary?

1. Phase
2. Quality
3. Amplitude
4. Frequency

1-28. What are the three basic characteristics of sound?

1. Amplitude, intensity, and quality
2. Amplitude, pitch, and tone
3. Pitch, intensity, and quality
4. Pitch, frequency, and quality

1-29. If several musical instruments are playing the same note, you should be able to distinguish one instrument from another because of which of the following characteristics of sound?

1. Quality
2. Overtones
3. Frequency
4. Intensity

1-30. Through which of the following mediums will sound travel fastest, at the indicated temperature?

1. Air at 68º F
2. Lead at 20º C
3. Steel at 32º F
4. Steel at 20º C

1-31. In sound terminology, which of the following terms is the same as a wave reflection?

1. Echo
2. Image
3. Acoustics
4. Refraction

1-32. Multiple reflections of sound waves are referred to as

1. noise
2. acoustics
3. interference
4. reverberation

1-33. Two out-of-phase waves of the same frequency that are moving through the same medium are said to present which of the following types of interference?

1. Additive
2. Constructive
3. Both 1 and 2 above
4. Subtractive

1-34. A cavity that vibrates at its own natural frequency and produces a sound that is louder than at other frequencies is demonstrating which of the following sound characteristics?

1. Noise
2. Quality
3. Resonance
4. Reverberation

1-35. Energy in the form of light can be produced through which of the following means?

1. Chemical
2. Electrical
3. Mechanical
4. Each of the above

1-36. The scientist, J. C. Maxwell, developed the theory that small packets of electromagnetic energy called photons produce

1. sound
2. noise
3. echoes
4. light

1-37. A large volume of light radiating in a given direction is referred to as a

1. ray
2. beam
3. shaft
4. pencil

1-38. Which of the following units of measurement is/are used to measure very short wavelengths of light?

1. Angstrom (Å)
2. Millimicron
3. Both 1 and 2 above
4. Millimeter

1-39. What are the primary colors of light?

1. Red, blue, and yellow
2. Red, blue, and green
3. Red, violet, and indigo
4. Blue, green, and violet

1-40. What are the secondary colors of light?

1. Orange, yellow, and blue-green
2. Magenta, yellow, and cyan
3. Purple, yellow, and black
4. Red, white, and blue

1-41. What causes sunlight to separate into different wavelengths and display a rainbow of colors when passed through a prism?

1. Refraction
2. Reflection
3. Dispersion
4. Diffraction

1-42. The sun, gas flames, and electric light filaments are visible because they are

1. opaque
2. transparent
3. nonluminous
4. self-luminous

1-43. Substances that transmit almost all of the light waves falling upon them possess which of the following properties?

1. Opaqueness
2. Transparence
3. Translucence
4. Self-lumination

1-44. Some substances are able to transmit light waves but objects cannot be seen through them. Which of the following properties does this statement describe?

1. Opaqueness
2. Transparence
3. Translucence
4. Self-lumination

1-45. The speed of light depends on the medium through which light travels. For which of the following reasons does light travel through empty space faster than through an object such as glass?

1. Space is less dense than glass
2. Space is more dense than glass
3. Glass reflects the light back to the source
4. Glass refracts the light, causing the light to travel in all directions

1-46. If a light wave strikes a sheet of glass at a perpendicular angle, what is the effect, if any, on the light wave?

1. The wave is completely absorbed
2. The wave is reflected back toward the source
3. The wave is refracted as it passes through the glass
4. The wave is unchanged and continues in a straight line

1-47. The amount of absorption of the light that strikes an object is determined by the object's

1. color
2. purity
3. density
4. complexity

1-48. In a comparison of waves of light and sound as they travel from an air into water, how is the speed of (a) light waves and (b) sound waves affected?

1. (a) Increased (b) increased
2. (a) Increased (b) decreased
3. (a) Decreased (b) decreased
4. (a) Decreased (b) increased

1-49. Which of the following waves are NOT a form of electromagnetic energy?

1. Heat waves
2. Sound waves
3. Light waves
4. Radio waves

1-50. The electromagnetic spectrum represents the entire range of electromagnetic waves arranged in the order of their

1. color
2. frequency
3. visibility
4. application

1-51. Which of the following portions of the frequency spectrum contains the highest frequency?

1. X-ray
2. Radar
3. Light
4. Cosmic

1-52. Which of the following electronic devices is used to radiate and/or collect electromagnetic waves?

1. Antenna
2. Receiver
3. Transmitter
4. Transmission line

1-53. The electric field and magnetic field combine to form which of the following types of waves?

1. Spherical
2. Elliptical
3. Electromagnetic
4. Each of the above

1-54. The magnetic field radiated from an antenna is produced by what electrical property?

1. Voltage
2. Current
3. Reactance
4. Resistance

1-55. The electric field radiated from an antenna is produced by what electrical property?

1. Voltage
2. Current
3. Reactance
4. Resistance

1-56. Applying rf energy to the elements of an antenna results in what phase relationship between voltage and current?

1. Voltage lags current by 90 degrees
2. Voltage leads current by 90 degrees
3. Voltage and current are 180 degrees out of phase
4. Voltage and current are in phase

1-57. What field exists close to the conductor of an antenna and carries the current?

1. Electric
2. Magnetic
3. Induction
4. Radiation

1-58. What field travels through space after being detached from the current-carrying rod of an antenna?

1. Electric
2. Magnetic
3. Induction
4. Radiation

1-59. Electric and magnetic fields on an antenna reach their maximum intensity at which of the following times?

1. When they are a full cycle apart
2. When they are three-quarter cycle apart
3. When they are a half-cycle apart
4. When they are a quarter-cycle apart

ASSIGNMENT 2

Textbook assignment: Chapter 2, "Radio Wave Propagation," pages 2-1 through 2-47.

2-1. The induction field is made up of which of the following fields?

1. E field only
2. H field only
3. Both E and H fields

2-2. After the radiation field leaves an antenna, what is the relationship between the E and H fields with respect to (a) phase and (b) physical displacement in space?

1. (a) In phase (b) 90 degrees
2. (a) Out of phase (b) 90 degrees
3. (a) In phase (b) 180 degrees
4. (a) Out of phase (b) 180 degrees

2-3. What is the first harmonic of a radio wave that has a fundamental frequency of 2,000 kHz?

1. 6,000 kHz
2. 2,000 kHz
3. 3,000 kHz
4. 4,000 kHz

2-4. In a radio wave with a fundamental frequency of 1.5 kHz, which of the following frequencies is NOT a harmonic?

1. 6,000 kHz
2. 5,000 kHz
3. 3,000 kHz
4. 4,000 kHz

2-5. A radio wave with a frequency of 32 kHz is part of which of the following frequency bands?

1. The lf band
2. The mf band
3. The hf band
4. The vhf band

2-6. A frequency of 3.5 GHz falls into what rf band?

1. High
2. Very high
3. Super high
4. Extremely high

2-7. A radio wavelength expressed as 250 meters may also be expressed as how many feet?

1. 410
2. 820
3. 1,230
4. 1,640

2-8. An increase in the frequency of a radio wave will have what effect, if any, on the velocity of the radio wave?

1. Increase
2. Decrease
3. None

2-9. An increase in frequency of a radio wave will have what effect, if any, on the wavelength of the radio wave?

1. Increase
2. Decrease
3. None

2-10. What is the frequency, in kiloHertz, of a radio wave that is 40 meters long?

1. 75
2. 750
3. 7,500
4. 75,000

2-11. What is the approximate wavelength, in feet, of a radio wave with a frequency of 5,000 kHz?

1. 197 feet
2. 1,970 feet
3. 19,700 feet
4. 197,000 feet

2-12. The polarity of a radio wave is determined by the orientation of (a) what moving field with respect to (b) what reference?

1. (a) Electric (b) earth
2. (a) Electric (b) antenna
3. (a) Magnetic (b) antenna
4. (a) Magneti (b) earth

2-13. Energy radiated from an antenna is considered horizontally polarized under which of the following conditions?

1. If the wavefront is in the horizontal plane
2. If the magnetic field is in the horizontal plane
3. If the electric field is in the horizontal plane
4. If the induction field is in the horizontal plane

2-14. The ability of a reflecting surface to reflect a specific radio wave depends on which of the following factors?

1. Striking angle
2. Wavelength of the wave
3. Size of the reflecting area
4. All of the above

THIS SPACE LEFT BLANK INTENTIONALLY.

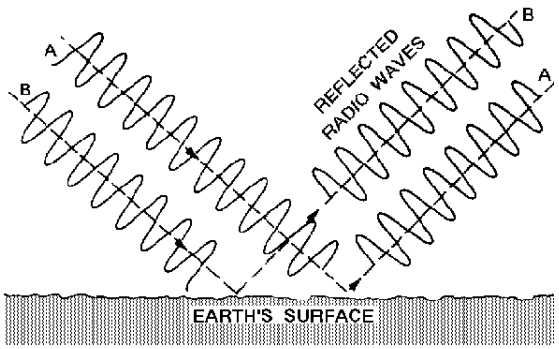

Figure 2-A.—Reflected radio waves.

IN ANSWERING QUESTION 2-15, REFER TO FIGURE 2-A.

2-15. If the two reflected radio waves shown in the figure are received at the same instant at the receiving site, what will be the effect, if any, on signal quality?

1. A stronger signal will be produced
2. A weak or fading signal will be produced
3. The signal will be completely canceled out
4. None

2-16. The bending of a radio wave because of a change in its velocity through a medium is known as

1. refraction
2. reflection
3. deflection
4. diffraction

2-17. Radio communications can be diffracted to exceptionally long distances through the use of (a) what frequency band at (b) what relative power level?

1. (a) Very low frequency (b) Low power
2. (a) Very high frequency (b) Low power
3. (a) Very low frequency (b) High power
4. (a) Very high frequency (b) High power

2-18. Electrically charged particles that affect the propagation of radio waves are found in what atmospheric layer?

1. Troposphere
2. Ionosphere
3. Chronosphere
4. Stratosphere

2-19. Most weather phenomena take place in which of the following region of the atmosphere?

1. Troposphere
2. Ionosphere
3. Chronosphere
4. Stratosphere

2-20. Radio wave propagation has the least effect because of its constancy on which of the following atmospheric layers?

1. Troposphere
2. Ionosphere
3. Chronosphere
4. Stratosphere

2-21. Long range, surface-wave communications are best achieved when the signal is transmitted over seawater with (a) what polarization at (b) what relative frequency?

1. (a) Vertical (b) Low
2. (a) Vertical (b) High
3. (a) Horizontal (b) High
4. (a) Horizontal (b) Low

2-22. The Navy's long-range vlf broadcasts are possible because of the advantages of which of the following types of propagation?

1. Diffraction
2. Ionospheric refraction
3. Repeated reflection and refraction
4. Both 2 and 3 above

2-23. A space wave (a) is primarily a result of refraction in what atmospheric layer and (b) extends approximately what distance beyond the horizon?

1. (a) Ionosphere
   (b) One-tenth farther
2. (a) Ionosphere
   (b) One-third farther
3. (a) Troposphere
   (b) One-third farther
4. (a) Troposphere
   (b) One-tenth farther

2-24. The signal of a space wave is sometimes significantly reduced at the receiving site because of which of the following interactions?

1. Space-wave refraction
2. Space-wave reflections
3. Ground-wave diffraction
4. Ground-wave reflections

2-25. For long-range communications in the hf band, which of the following types of waves is most satisfactory?

1. Sky wave
2. Space wave
3. Surface wave
4. Reflected ground wave

2-26. Ionization in the atmosphere is produced chiefly by which of the following types of radiation?

1. Alpha radiation
2. Cosmic radiation
3. Infrared radiation
4. Ultraviolet radiation

2-27. Ultraviolet waves of higher frequencies produce ionized layers at what relative altitude(s)?

1. Lower
2. Higher
3. Both 1 and 2 above

2-28. The density of ionized layers is normally greatest during which of the following periods?

1. At night
2. Before sunrise
3. Between early morning and late afternoon
4. Between afternoon and sunset

2-29. Compared to the other ionospheric layers at higher altitudes, the ionization density of the D layer is

1. about the same
2. relatively low
3. relatively high

2-30. What two layers in the ionosphere recombine and largely disappear at night?

1. D and F
2. D and E
3. E and F2
4. F1 and F2

2-31. For hf-radio communications covering long distances, what is the most important layer of the ionosphere?

1. C
2. D
3. E
4. F

2-32. Refraction of a sky wave in the ionosphere is influenced by which of the following factors?

1. Ionospheric density
2. Frequency of the wave
3. Angle of incidence of the wave
4. All of the above

2-33. A 10-MHz wave entering the ionosphere at an angle greater than its critical angle will pass through the ionosphere and be lost in space unless which of the following actions is taken?

1. The ground wave is canceled
2. The frequency of the wave is increased
3. The frequency of the wave is decreased
4. The ground wave is reinforced

2-34. The distance between the transmitter and the nearest point at which refracted waves return to earth is referred to as the

1. skip distance
2. return distance
3. reception distance
4. ground-wave distance

2-35. When ground-wave coverage is LESS than the distance between the transmitter and the nearest point at which the refracted waves return to earth, which of the following reception possibilities should you expect?

1. No sky-wave
2. Weak ground wave
3. A zone of silence
4. Strong ground wave

2-36. The greatest amount of absorption takes place in the ionosphere under which of the following conditions?

1. When sky wave intensity is the greatest
2. When collision of particles is least
3. When the density of the ionized layer is the greatest
4. When precipitation is greatest

2-37. Which of the following layers provide the greatest amount of absorption to the ionospheric wave?

1. D and E
2. D and F1
3. E and F1
4. F1 and F2

2-38. If the signal strength of an incoming signal is reduced for a prolonged period, what type of fading is most likely involved?

1. Selective
2. Multipath
3. Absorption
4. Polarization

2-39. Radio waves that arrive at a receiving site along different paths can cause signal fading if these waves have different

1. velocities
2. amplitudes
3. phase relationships
4. modulation percentages

2-40. The technique of reducing multipath fading by using several receiving antennas at different locations is known as what type of diversity?

1. Space
2. Receiver
3. Frequency
4. Modulation

2-41. The amount of rf energy lost because of ground reflections depends on which of the following factors?

1. Angle of incidence
2. Ground irregularities
3. Frequency of the wave
4. Each of the above

2-42. Receiving sites located near industrial areas can expect to have exceptionally large losses in signal quality as a result of which of the following propagation situations?

1. Absorption
2. Multihop refraction
3. Natural interference
4. Man-made interference

2-43. Which of the following ionospheric variation causes densities to vary with the axial rotation of the sun?

1. Daily variation
2. Seasonal variation
3. 27-day sunspot cycle
4. 11-year sunspot cycle

2-44. Which of the following ionospheric variation causes densities to vary with the position of the earth in its orbit around the sun?

1. Daily variation
2. Seasonal variation
3. 27-day sunspot cycle
4. 11-year sunspot cycle

2-45. Which of the following ionospheric variation causes densities to vary with the time of the day?

1. Daily variation
2. Seasonal variation
3. 27-day sunspot cycle
4. 11-year sunspot cycle

2-46. What relative range of operating frequencies is required during periods of maximum sunspot activity?

1. Lower
2. Medium
3. Higher

2-47. What factor significantly affects the frequency of occurrence of the sporadic-E layer?

1. Seasons
2. Latitude
3. Weather conditions
4. Ionospheric storms

2-48. What effect can the sporadic-E layer have on the propagation of sky waves?

1. Causes multipath interference
2. Permits long distance communications at unusually high frequencies
3. Permits short-distance communications in the normal skip zone
4. Each of the above

2-49. A sudden and intense burst of ultraviolet light is especially disruptive to communications in which of the following frequency bands?

1. Hf
2. Mf
3. Lf
4. Vlf

2-50. The density of what ionosphere layer increases because of a violent eruption on the surface of the sun?

1. D
2. E
3. F1
4. F2

2-51. Which irregular variation in ionospheric conditions can cause a waiting period of several days before communications return to normal?

1. Sporadic E
2. Ionospheric storms
3. Sudden ionospheric disturbance
4. Each of the above

2-52. For a radio wave entering the atmosphere of the earth at a given angle, the highest frequency at which refraction will occur is known by which of the following terms?

1. Usable frequency
2. Refraction frequency
3. Maximum usable frequency
4. Optimum working frequency

2-53. The most consistent communications can be expected at which of the following frequencies?

1. Critical frequency
2. Maximum usable frequency
3. Maximum working frequency
4. Optimum working frequency

2-54. If the optimum working frequency for a communications link is 4,250 kHz, what is the approximate maximum usable frequency?

1. 4,500 kHz
2. 5,000 kHz
3. 5,500 kHz
4. 6,000 kHz

2-55. In determining the success of radio transmission, which of the following factors is the LEAST predictable?

1. Antenna capabilities
2. Weather conditions along the path of communication
3. Density of ionized layers
4. Presence of ionized layers

2-56. At frequencies above 100 MHz, the greatest attenuation of rf energy from raindrops is caused by which of the following factors?

1. Ducting
2. Heat loss
3. Scattering
4. Absorption

2-57. Under certain conditions, such as ducting, line-of-sight radio waves often propagate for distances far beyond their normal ranges because of which of the following factors?

1. Low cloud masses
2. Ionospheric storms
3. Temperature inversions
4. Frequency fluctuations

2-58. When ducting is present in the atmosphere, multihop refraction of line-of-sight transmission can occur because of which of the following factors?

1. Operating frequency of the transmitter
2. Height of the transmitting antenna
3. Angle of incidence of the radio wave
4. Each of the above

2-59. A propagation technique used to extend uhf transmission range beyond the horizon uses which of the following propagation characteristics?

1. Ground reflection
2. Ionospheric scatter
3. Tropospheric scatter
4. Atmospheric refraction

2-60. Communications by tropospheric scatter can be affected by which of the following conditions?

1. Sunspot activity
2. Atmospheric conditions
3. Ionospheric disturbances
4. All of the above

2-61. What effect, if any, does the radiation angle of a transmitting antenna have on the reception of communications by tropospheric scatter?

1. The lower the angle, the weaker the signal
2. The lower the angle, the stronger the signal
3. The lower the angle, the more susceptible the signal is to distortion
4. None

2-62. Which of the following descriptions of tropospheric scatter signal reception is NOT true?

1. Receiver signal strength decreases as the turbulence height is increased
2. The level of reception depends on the number of turbulences causing scatter
3. The energy received is the portion of the wave reradiated by the turbulence
4. Increased communications distance enables more turbulence to act on the signal, thereby raising the received signal level

2-63. The tropospheric scatter signal is often characterized by very rapid fading caused by which of the following factors?

1. Extreme path lengths
2. Multipath propagation
3. Turbulence in the atmosphere
4. Angle of the transmitted beam

2-64. For which of the following communications situations would turbulence in the troposphere scatter transmission?

1. 10 MHz, range 200 miles
2. 30 MHz, range 800 miles
3. 50 MHz, range 600 miles
4. 100 MHz, range 400 miles

ASSIGNMENT 3

Textbook assignment: Chapter 3, "Principles of Transmission Lines," pages 3-1 through 3-58.

3-1. A transmission line is designed to perform which of the following functions?

1. Disperse energy in all directions
2. Detune a transmitter to match the load
3. Guide electrical energy from point to point
4. Replace the antenna in a communications system

3-2. All transmission lines must have two ends, the input end and the output end. What other name is given to the input end?

1. Sending end
2. Generator end
3. Transmitter end
4. Each of the above

3-3. A measurement of the voltage to current ratio (E_{in}/I_{in}) at the input end of a transmission line is called the

1. input-gain rate
2. input impedance
3. output impedance
4. voltage-gain ratio

3-4. Which of the following lines is NOT a transmission medium?

1. Load line
2. Coaxial line
3. Two-wire line
4. Twisted-pair line

3-5. Electrical power lines are most often made of which of the following types of transmission lines?

1. Twin-lead line
2. Shielded-pair line
3. Two-wire open line
4. Two-wire ribbon line

3-6. Uniform capacitance throughout the length of the line is an advantage of which of the following transmission lines?

1. Coaxial line
2. Twisted pair
3. Shielded pair
4. Two-wire open line

3-7. What is the primary advantage of a rigid coaxial line?

1. Low radiation losses
2. Inexpensive construction
3. Low high-frequency losses
4. Each of the above

3-8. Which of the following wave-guides is seldom used because of its large energy loss characteristics?

1. Metallic
2. Dielectric
3. Elliptical
4. Cylindrical

3-9. To some degree, transmission lines always exhibit which of the following types of losses?

1. I^2R
2. Inductor
3. Dielectric
4. Each of the above

3-10. Skin effect is classified as which of the following types of loss?

1. Copper
2. Voltage
3. Induction
4. Dielectric

3-11. What transmission-line loss is caused by magnetic lines of force not returning to the conductor?

1. Copper
2. Radiation
3. Induction
4. Dielectric

3-12. What is the electrical wave-length of 1 cycle if the frequency is 60 hertz?

1. 125,000 meters
2. 1,250,000 meters
3. 5,000,000 meters
4. 20,000,000 meters

3-13. A transmission line 10 meters in length is considered to be electrically long at which of the following frequencies?

1. 60 kilohertz
2. 600 kilohertz
3. 6 megahertz
4. 60 megahertz

3-14. The conductance value of a transmission line represents which of the following values?

1. Expected value of current flow through the insulation
2. Expected value of voltage supplied by the transmitter
3. Value of the lump and distributed constants of the line divided by impedance
4. Value of the lump and distributed constants of the line divided by impedance

3-15. Electrical constants in a transmission line are distributed in which of the following ways?

1. Into a single device
2. Along the length of the line
3. According to the thickness of the line
4. According to the cross-sectional area of the line

3-16. Leakage current in a two-wire transmission line is the current that flows through what component?

1. The resistor
2. The inductor
3. The insulator
4. The conductor

3-17. Conductance is the reciprocal of what electrical property?

1. Inductance
2. Resistance
3. Capacitance
4. Reciprocity

3-18. A transmission line that has current flowing through it has which, if any, of the following fields about it?

1. Electric field only
2. Magnetic field only
3. Both electric and magnetic fields
4. None of the above

3-19. Maximum transfer of energy from the source to the transmission line takes place when what impedance relationship exists between the source and the transmission line?

1. When the load impedance equals source impedance
2. When the load impedance is twice the source impedance
3. When the load impedance is half the source impedance
4. When the load impedance is one-fourth the source impedance

3-20. The characteristic impedance (Z_0) of a transmission line is calculated by using which of the following ratios?

1. R_s to R_{load} of the line
2. I_{max} to I_{min} at every point along the line
3. E to I at every point along the line
4. E_{in} to E_o of the line

3-21. For a given voltage, what determines the amount of current that will flow in a transmission line?

1. Conductance
2. Spacing of the wires
3. Diameter of the wires
4. Characteristic impedance

3-22. When the impedance of a transmission line is measured, which of the following values frequently is NOT considered?

1. Inductance
2. Resistance
3. Conductance
4. Capacitance

3-23. The characteristic impedance of a long transmission line may be determined by using which of the following methods?

1. Trial and error
2. Calculating the impedance of the entire line
3. Calculating the impedances at each end of the line
4. Adding the impedances of successive short sections

3-24. When should lumped values for transmission-line constants be used to calculate characteristic impedance?

1. When the line is short compared to one wavelength
2. When the line is long compared to one wavelength
3. When the line is infinitely long

3-25. In actual practice, the characteristic impedance of a transmission line is usually within which of the following resistance ranges?

1. 0 to 0.9 ohm
2. 1 to 49 ohms
3. 50 to 600 ohms
4. 601 to 1,000 ohms

3-26. The input impedance of a transmission line is affected by which of the following properties?

1. Radiation loss
2. Series inductance
3. Parallel capacitance
4. Each of the above

3-27. When a dc voltage is applied to a transmission line and the load absorbs all the energy, what is the resulting relationship between current and voltage?

1. They are in phase with each other
2. They are equal to Z_0 of the line
3. They are out of phase with each other
4. They are evenly distributed along the line

3-28. The initial waves that travel from the source to the load of a transmission line are referred to as what type of waves?

1. Incident
2. Refracted
3. Reflected
4. Diffracted

3-29. Waves that travel from the output end to the input end of a transmission line are referred to as what type of waves?

1. Incident
2. Refracted
3. Reflected
4. Diffracted

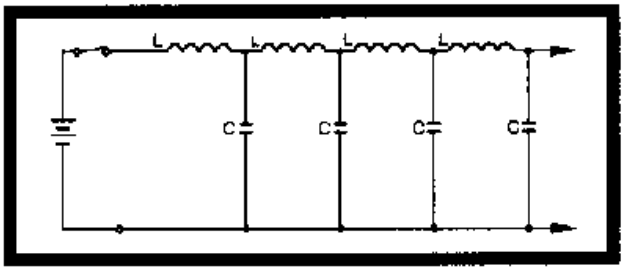

Figure 3-A.—Equivalent infinite transmission line.

IN ANSWERING QUESTION 3-30, REFER TO FIGURE 3-A.

3-30. When a dc voltage is applied to the equivalent infinite line in the figure, which of the following conditions occurs along the length of the line?

1. Standing waves of voltage form
2. Standing waves of current form
3. Current flows indefinitely
4. Voltage appears for a short time

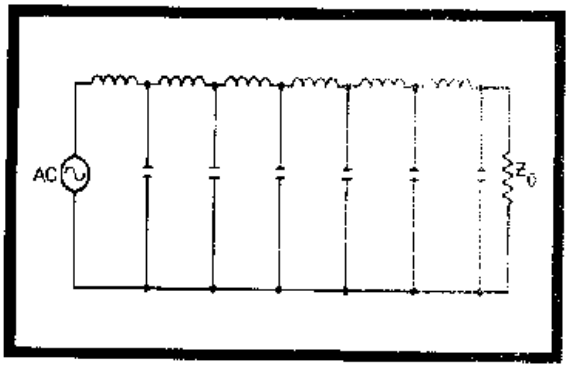

Figure 3-B.—Equivalent transmission line.

IN ANSWERING QUESTION 3-31, REFER TO FIGURE 3-B.

3-31. Compared to a dc input, what relative amount of time is required for an ac input voltage to travel the length of the line shown in the circuit?

1. Less
2. Same
3. More

3-32. The instantaneous voltage on an infinite transmission line can be plotted against time by using which of the following instruments?

1. A wavemeter
2. A multimeter
3. An oscilloscope
4. A spectrum analyzer

3-33. On an infinite transmission line with an ac voltage applied, which of the following is an accurate description of the effective voltage distribution along the line?

1. Voltage is 0 at all points
2. Voltage is constant at all points
3. Voltage varies at a sine-wave rate
4. Voltage varies at double the sine-wave rate

3-34. The velocity of propagation on a transmission line is controlled by which of the following line characteristics?

1. Conductance
2. Inductance only
3. Capacitance only
4. Capacitance and inductance

3-35. The total charge on a transmission line is equal to the current multiplied by which of the following factors?

1. Time
2. Power
3. Voltage
4. Resistance

3-36. With only capacitance and inductance of the line given, the time (T) required for a voltage change to travel down a transmission line can be found by what formula? The characteristic impedance for an infinite transmission line can be figured using which of the following ratios?

1. $T = \sqrt{\frac{L}{C}}$
3. $T = L + C$
2. $T = \sqrt{LC}$
4. $T = L - C$

3-37. The characteristic impedance for an infinite transmission line can be figured using which of the following ratios?

1. Input current to velocity
2. Input voltage to input current
3. Input voltage to line resistance
4. Input current to line resistance

3-38. The characteristic impedance of a transmission line can be figured by using which of the following formulas?

1. $Z_0 = \frac{1}{LC}$
3. $Z_0 = \frac{C}{L}$
2. $Z_0 = \sqrt{LC}$
4. $Z_0 = \sqrt{\frac{L}{C}}$

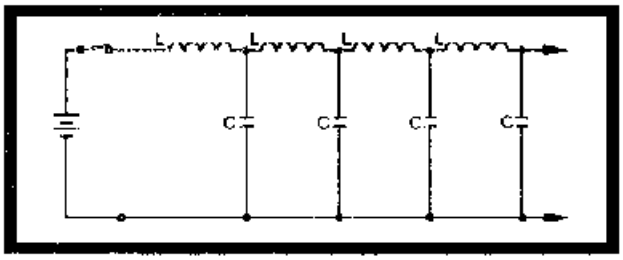

Figure 3-C.—Equivalent transmission line.

IN ANSWERING QUESTIONS 3-39 AND 3-40, REFER TO FIGURE 3-C. ASSUME THAT THE LINE IS 1,200 FEET LONG. A 150-FOOT SECTION IS MEASURED TO DETERMINE L AND C. THE 150-FOOT SECTION HAS AN INDUCTANCE OF 0.36 MILLIHENRIES AND A CAPACITANCE OF 1,000 PICOFARADS.

3-39. What is the characteristic impedance of the line?

1. 400 ohms
2. 600 ohms
3. 800 ohms
4. 900 ohms

3-40. What is the velocity of the wave on the 150-foot section?

1. 210,000,000 fps
2. 225,000,000 fps
3. 250,000,000 fps
4. 275,000,000 fps

3-41. If a transmission line is open-ended, which of the following conditions describes its terminating impedance?

1. Finite
2. Infinitely large
3. Equal to load impedance
4. Equal to source impedance

3-42. When a transmission line is not terminated in its characteristic impedance (Z_0), what happens to the incident energy that is NOT transferred to the load?

1. It is returned along the transmission line
2. It is radiated into space
3. It is absorbed by the line
4. It is converted to heat energy

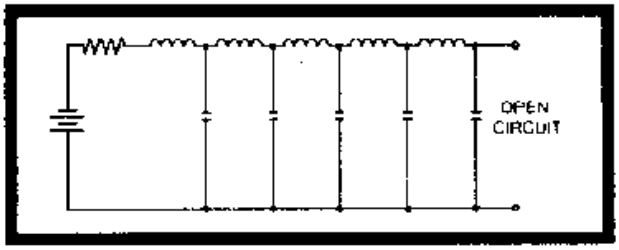

Figure 3-D.—Open-ended transmission line.

IN ANSWERING QUESTIONS 3-43 AND 3-44, REFER TO FIGURE 3-D.

3-43. When the dc voltage reaches the open end of the transmission line in the figure and is reflected, it has which, if any, of the following changes?

1. Increased amplitude
2. Decreased amplitude
3. The opposite polarity
4. None of the above

3-44. When the dc current reaches the open end of the transmission line and is reflected, it has which, if any, of the following changes?

1. Increased amplitude
2. Decreased amplitude
3. The opposite polarity
4. None of the above

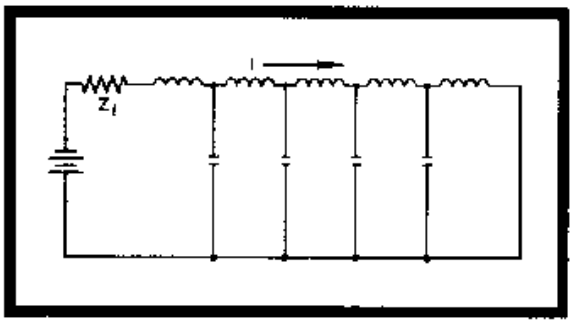

Figure 3-E.—Short-circuited transmission line.

IN ANSWERING QUESTIONS 3-45 AND 3-46, REFER TO FIGURE 3-E.

3-45. When the dc voltage reaches the shorted end of the transmission line, it is reflected. It has which, if any, of the following changes?

1. Increased amplitude
2. Decreased amplitude
3. The opposite polarity
4. None

3-46. When the dc current reaches the shorted end of the transmission line, it is reflected. It has which, if any, of the following changes?

1. Decrease amplitude
2. Increase amplitude
3. Increased polarity
4. None of the above

3-47. In an open-ended transmission line with an ac signal applied, what is the phase relationship between the incident and reflected voltage waves?

1. In phase
2. 45 degrees out of phase
3. 90 degrees out of phase
4. 180 degrees out of phase

3-48. The resultant of the incident and reflected voltage waves is called the standing wave. Its value is figured by using which of the following procedures?

1. Adding the effective values of the two waveforms
2. Algebraically adding the instantaneous values of the two waveforms
3. Algebraically subtracting the instantaneous values of the two waveforms
4. Taking the square root of the product of the incident and reflected voltages

3-49. On an open-ended transmission line that is carrying an ac signal, what is the total number of moving voltage waves?

1. One
2. Two
3. Three
4. Four

3-50. At the end of an open-ended transmission line, which, if any, of the following voltage waves is at its maximum value?

1. Incident
2. Reflected
3. Resultant
4. None

3-51. On a transmission line that is carrying an ac signal, what is the relative value of the resultant voltage wave 1/4 wavelength from the open end?

1. Maximum positive
2. Maximum negative
3. Zero

3-52. In an open-ended transmission line, the resultant ac current waveform is always zero at what point(s)?

1. At the open end only
2. 1/2 wavelength from the open-end only
3. At the open end and 1/2 wavelength from the open-end

3-53. The resultant waveform obtained by adding the incident wave to the reflected wave is referred to as a/an

1. standing wave
2. negative wave
3. algebraic wave
4. concentrated wave

3-54. On an open-ended transmission line, what is the phase relationship between the standing waves of voltage and current?

1. In phase
2. 45 degrees out of phase
3. 90 degrees out of phase
4. 180 degrees out of phase

3-55. Which of the following conditions exist at the end of a shorted transmission line?

1. Maximum voltage and minimum current
2. Maximum voltage and maximum current
3. Minimum voltage and maximum current
4. Minimum voltage and minimum current

3-56. Transmission line is considered to be nonresonant (flat) when it is terminated in which of the following ways?

1. In an impedance equal to Z_0
2. In an impedance that is infinite
3. In an inductive reactance greater than Z_0
4. In a capacitive reactance greater than Z_0

3-57. Of the following terms, which one is used for the nonresonant transmission line?

1. A tuned line
2. A shorted line
3. An untuned line
4. A terminated line

3-58. A transmission line that is resonant is sometimes referred to as which of the following types of lines?

1. Tuned
2. Matched
3. Untuned
4. Unmatched

3-59. A short-circuited section of transmission line that is an odd number of quarter-wavelengths long shows the same characteristics as which of the following devices?

1. A series-resonant circuit
2. A parallel-resonant circuit
3. An inductive reactance equal to Z_0
4. A capacitive reactance equal to Z_0

3-60. Which of the following circuits appears as a very high resistance at resonance?

1. Nonresonant
2. Series-resonant
3. Parallel-resonant
4. Each of the above

3-61. When a series-resonant circuit is resonant at a frequency above the generator frequency, it acts as what type of circuit?

1. Open
2. Resistive
3. Inductive
4. Capacitive

3-62. Which of the following sections of transmission line can be used as a parallel-resonant circuit?

1. A shorted 1/4-wavelength section
2. An open 1/4-wavelength section
3. A shorted 1/2-wavelength section
4. An open 3/4-wavelength section

3-63. A generator connected to an open-ended line greater than 1/4 wave-length but less than 1/2 wave-length senses which of the following circuit component characteristics?

1. Zero reactance
2. Low resistance
3. Inductive reactance
4. Capacitive reactance

3-64. Which of the following conditions of current (I) and impedance (Z) exist at even quarter-wave points on a shorted transmission line?

1. Low I, low Z
2. Low I, high Z
3. High I, high Z
4. High I, low Z

3-65. What is the maximum distance, in wavelengths (λ), between adjacent zero-current points on an open-circuited line?

1. 1 λ
2. 1/2 λ
3. 1/4 λ
4. 1/8 λ

3-66. When a line is terminated in a capacitance, the capacitor performs which, if any, of the following circuit actions?

1. It absorbs all the energy
2. It reflects all the energy
3. It reacts as if it were a short
4. None

3-67. When a transmission line is terminated in an inductive reactance, which, if any, of the following phase shifts takes place with respect to the current and voltage?

1. Only voltage is phase-shifted
2. Only current is phase-shifted
3. Both voltage and current are phase-shifted
4. None

3-68. When a transmission line is terminated in a resistance greater than Z_0, which of the following conditions exist?

1. The end of the line appears as an open circuit
2. Standing waves appear on the line
3. Voltage is maximum and current is minimum at the end of the line
4. Each of the above

3-69. On a transmission line, reflections begin at which of the following locations?

1. At the load
2. At the source
3. At the middle
4. At the half-wavelength point

3-70. The ratio of maximum voltage to minimum voltage on a transmission line is referred to as the

1. rswr
2. pswr
3. vswr
4. iswr

3-71. Which of the following ratios samples the magnetic field along a line?

1. Vswr
2. Pswr
3. Iswr
4. Rswr

ASSIGNMENT 4

Textbook assignment: Chapter 4, "Antennas," pages 4-1 through 4-60.

4-1. Radio energy is transmitted through which of the following mediums?

1. Rock
2. Soil
3. Water
4. Space

4-2. Energy is transmitted from a transmitter into space using which of the following devices?

1. A receiver
2. A delay line
3. A receiving antenna
4. A transmitting antenna

4-3. Transmitted rf energy takes what form as it is sent into space?

1. A magnetic field only
2. An electric field only
3. An electromagnetic field
4. A static dielectric field

4-4. The dimensions of a transmitting antenna are determined by which of the following factors?

1. Transmitted power
2. Transmitted frequency
3. Distance to the receiver
4. Antenna height above the ground

4-5. A device used to radiate or receive electromagnetic wave energy is referred to as a/an

1. feeder
2. antenna
3. transmitter
4. coupling device

4-6. An antenna that can be mounted to radiate rf energy either vertically or horizontally is classified as which of the following types?

1. Hertz
2. Marconi
3. Quarter-wave
4. Both 2 and 3 above

4-7. A complete antenna system consists of which of the following components?

1. A feeder, a coupling device, and a transmitter
2. A feeder line, a coupling device, and an antenna
3. An antenna, a transmission line, and a receiver
4. An impedance-matching device, a feeder, and a transmission line

4-8. What component in an antenna system transfers energy from the transmitter to the antenna?

1. A feeder
2. A delay line
3. A choke joint
4. A rotating joint

4-9. The type, size, and shape of an antenna are determined by which of the following factors?

1. Power output of the transmitter
2. Transmitter frequency
3. Direction to the receiver
4. Each of the above

4-10. Moving electric and magnetic fields in space have what (a) phase and (b) angular relationships?

1. (a) In phase
   (b) Perpendicular
2. (a) In phase
   (b) Displaced 45º
3. (a) Out of phase
   (b) Displaced 45º
4. (a) Out of phase
   (b) Perpendicular

4-11. What is the length of each half of the wire for a dipole antenna?

1. Wavelength
2. 3/4 wavelength
3. 1/2 wavelength
4. 1/4 wavelength

4-12. On a dipole antenna, the sinusoidal variation in charge magnitude lags the sinusoidal variation in current by what amount?

1. 1 cycle
2. 1/2 cycle
3. 1/4 cycle
4. 1/8 cycle

4-13. On a standing wave, the points of high current and voltage are identified by which of the following terms?

1. Peaks
2. Nodes
3. Poles
4. Loops

4-14. The presence of standing waves indicates which of the following conditions of an antenna?

1. Resonance
2. Saturation
3. Nonresonance
4. Minimum efficiency

4-15. The antenna property that allows the same antenna to both transmit and receive energy is

1. gain
2. resonance
3. reciprocity
4. directivity

4-16. There is a ratio between the amount of energy propagated in certain directions by a directional antenna compared to the energy that would be propagated in these directions if the antenna were not directional. This ratio is known as which of the following antenna characteristics?

1. Gain
2. Directivity
3. Reciprocity
4. Polarization

4-17. The polarization plane of the radiation field is determined by which of the following fields?

1. Electric field only
2. Magnetic field only
3. Electromagnetic field

4-18. For best reception of a signal from a horizontally polarized antenna, the receiving antenna should be mounted so that it has what relationship with the transmitting antenna?

1. 0 degrees
2. 45 degrees
3. 90 degrees
4. 135 degrees

4-19. An electric field that rotates as it travels through space exhibits what type of polarization?

1. Vertical
2. Spherical
3. Elliptical
4. Horizontal

4-20. For ground-wave transmissions, what type of polarization is required?

1. Vertical
2. Spherical
3. Elliptical
4. Horizontal

4-21. For high-frequency operation, which of the following antenna polarization patterns is preferred?

1. Vertically polarized
2. Spherically polarized
3. Elliptically polarized
4. Horizontally polarized

4-22. Omnidirectional transmission is obtained from which of the following antennas?

1. Elliptically polarized
2. Horizontal half-wave
3. Vertical half-wave
4. Each of the above

4-23. With an antenna height of 40 feet and a transmitter frequency of 90 megahertz, which of the following antenna radiation patterns is best for transmitting over bodies of water?

1. Vertically polarized
2. Spherically polarized
3. Elliptically polarized
4. Horizontally polarized

4-24. To select a desired signal and discriminate against interfering signals from strong vhf and uhf broadcast transmissions, which of the following actions should you take?

1. Increase receiver gain
2. Make the transmitting antenna bi-directional
3. Use a vertically polarized receiving antenna
4. Use narrowly directional arrays as receiving antennas

4-25. A vertically mounted transmission line is LEAST affected by which of the following antenna radiation patterns?

1. Vertically polarized
2. Spherically polarized
3. Horizontally polarized
4. Elliptically polarized

4-26. An antenna with which of the following radiation resistance values will exhibit reduced efficiency?

1. 39 ohms
2. 82 ohms
3. 107 ohms
4. 150 ohms

4-27. An isotropic radiator radiates energy in which of the following patterns?

1. Vertical
2. Bi-directional
3. Unidirectional
4. Omnidirectional

4-28. An ordinary flashlight is an example of what type of radiator?

1. Isotropic
2. Polarized
3. Anisotropic
4. Stroboscopic

THIS SPACE LEFT BLANK INTENTIONALLY.

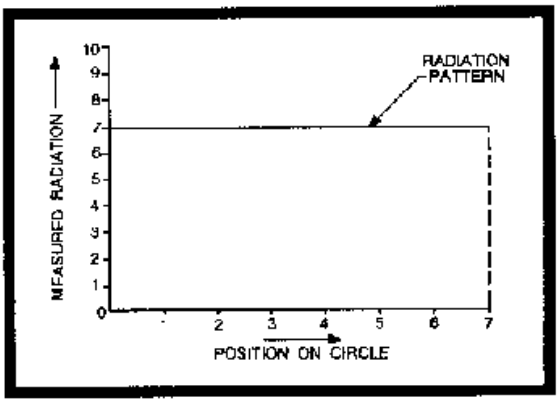

Figure 4-A.—Rectangular-coordinate graph.

IN ANSWERING QUESTION 4-29, REFER TO FIGURE 4-A.

4-29. How many points on the graph can represent the value of 7 radiation units at position 2 of the circle?

1. One
2. Two
3. Three
4. Four

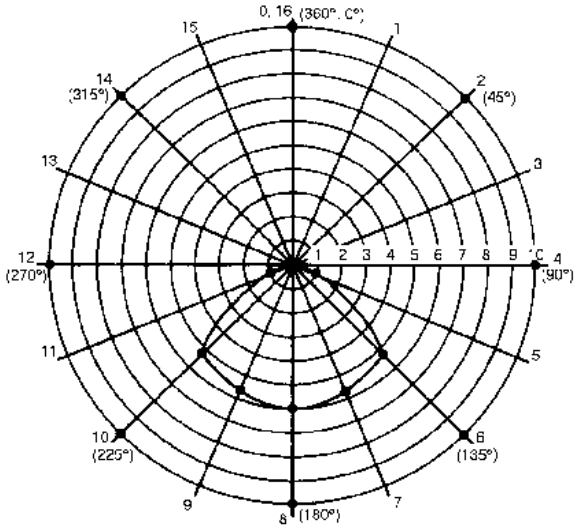

Figure 4-B.—Polar-coordinate graph.

IN ANSWERING QUESTIONS 4-30 AND 4-31, REFER TO FIGURE 4-B.

4-30. Compared with the rectangular-coordinate graph, the polar-coordinate graph has the advantage of showing which of the following antenna characteristics?

1. Polarization
2. Radiation pattern
3. Phase relationship
4. Gain versus directivity

4-31. The area enclosed by the radiation pattern is the

1. lobe
2. null
3. axis
4. coordinate

4-32. Inserting an inductor or capacitor in series with an antenna is one method of electrically changing the electrical length of an antenna. What is this method called?

1. Loading
2. Inserting
3. Unloading
4. Decoupling

4-33. Many complex antennas are constructed from what basic antenna?

1. The Marconi antenna
2. The full-wave antenna
3. The half-wave antenna
4. The quarter-wave antenna

4-34. On an energized half-wave antenna, which of the following electrical conditions exist?

1. Voltage is maximum at the ends
2. Voltage is minimum at the ends
3. Current is maximum at the ends
4. Impedance is minimum at the center

4-35. Which of the following radiation patterns is/are exhibited by a simple vertical doublet antenna?

1. Nondirectional in the horizontal plane
2. Directional in the vertical plane
3. Both 1 and 2 above
4. Spherical in all planes

4-36. A method of feeding energy to a half-wave antenna is to connect one end through a capacitor to the output stage. What is this method of feeding called?

1. End feed
2. Voltage feed
3. Both 1 and 2 above
4. Current feed

4-37. An antenna supplied by the center-feed method is fed at what point?

1. Low voltage and low current
2. Low voltage and high current
3. High voltage and low current
4. High voltage and high current

4-38. The basic Marconi antenna has which of the following characteristics?

1. One-quarter wavelength and ungrounded
2. One-half wavelength and grounded at one end
3. One-half wavelength and insulated from ground
4. One-quarter wavelength and grounded at one end

4-39. The Marconi antenna behaves as a dipole for which of the following reasons?

1. It is fed at one end
2. An image antenna is formed by reflections from the ground
3. A quarter-wavelength of conductor is buried in the ground and forms the rest of the dipole
4. The applied signal is rectified so that only half the signal will appear on the quarter-wave antenna

4-40. A series of conductors arranged in a radial pattern and buried in the ground beneath the antenna is referred to as a

1. ground spur
2. counterpoise
3. ground screen
4. ground reflector

4-41. A folded dipole can be used instead of a simple, center-fed dipole for which of the following purposes?

1. Matching voltage
2. Matching impedance
3. Increasing directivity
4. Decreasing directivity

4-42. An antenna arrangement that has elements aligned in a straight line is referred to as what type array?

1. Isotropic
2. Collinear
3. Line-of-sight
4. Unidirectional

4-43. To have current in two adjoining collinear half-wave elements in proper phase, they must be connected by which of the following stubs?

1. A shorted half-wave stub
2. An open quarter-wave stub
3. A shorted eighth-wave stub
4. A shorted quarter-wave stub

4-44. To select a desired signal and discriminate against interfering signals, the receiving antenna should have which of the following characteristics?

1. Be omnidirectional
2. Be highly directional
3. Be vertically polarized
4. Be horizontally polarized

4-45. Adding more elements to a collinear antenna array produces which of the following effects?

1. Increased gain
2. Decreased gain
3. Decreased directivity
4. Mismatched impedances

4-46. What is the maximum number of elements ordinarily used in a collinear array?

1. One
2. Two
3. Three
4. Four

4-47. Constructing a collinear array with elements longer than 1/2 wavelength has which of the following effects on antenna characteristics?

1. Increased gain
2. Decreased gain
3. Increased frequency range
4. Decreased frequency range

4-48. In a two-element collinear array, maximum gain is obtained when the center-to-center spacing between the ends of the elements is approximately what electrical distance?

1. Wavelength
2. 0.15 wavelength
3. 0.5 wavelength
4. 0.75 wavelength

4-49. Compared with collinear arrays, broadside arrays have which of the following advantages?

1. Sharper tuning
2. Broader bandwidth
3. Broader frequency response
4. Less coupling between dipole

4-50. Optimum gain is obtained from a broadside array when the spacing of its elements is which of the following distances?

1. One-half wavelength
2. One-quarter wavelength
3. Greater than one-half wavelength
4. Slightly less than one-quarter

4-51. An end-fire array physically resembles the collinear array except that it is more compact. What disadvantage does the endfire array possess?

1. It has lower gain
2. It has low radiation resistance
3. It has loose coupling
4. Each of the above

4-52. What is the range of electrical spacing between the elements of an end-fire array?

1. 3/4 to 1 wavelength
2. 1/2 to 3/4 wavelength
3. 1/4 to 1/2 wavelength
4. 1/8 to 1/4 wavelength

4-53. The end-fire array produces what type of lobes, if any, along the axis of the array?

1. Minor lobes
2. Major lobes
3. None

4-54. Assuming that the elements are correctly spaced, the directivity of an end-fire array may be increased by which of the following actions?

1. Increasing the frequency
2. Decreasing the frequency
3. Decreasing the number of elements
4. Increasing the number of elements

4-55. A unidirectional pattern can be obtained from an end-fire array by using what phase relationship between the energy fed to adjacent elements?

1. 0º
2. 45º
3. 90º
4. 180º

4-56. Energy is fed to a parasitic element using what method?

1. Direct coupling
2. Inductive coupling
3. Capacitive coupling
4. Transmission-line coupling

4-57. The directivity pattern resulting from the action of parasitic elements depends on which of the following element characteristics?

1. Length of the element
2. Diameter of the element
3. Spacing between parasitic and driven elements
4. Each of the above

4-58. The advantages of unidirectivity and increased gain can best be obtained by using which of the following elements in a parasitic array?

1. Driven elements only
2. Reflector and director elements only
3. Reflector, director, and driven elements
4. Driven and director elements only

4-59. The ratio of energy radiated by an array in the principal direction of radiation to the energy radiated in the opposite direction describes which of the following relationships?

1. Side-to-side ratio
2. Front-to-back ratio
3. Driven-to-parasitic ratio
4. Reflector-to-director ratio

4-60. The Yagi antenna is an example of what type of antenna array?

1. Driven
2. End-fire
3. Multielement parasitic
4. Single-element parasitic

4-61. The addition of parasitic elements to the Yagi antenna has which of the following effects on antenna characteristics?

1. Increased gain
2. Narrower beam width
3. Narrower frequency response
4. Each of the above

4-62. An antenna which is designed especially for vertically-polarized ground waves at low frequencies is the

1. Yagi antenna
2. Marconi antenna
3. Beverage antenna
4. V antenna

4-63. What is the phase relationship of the signals that feed the V antenna?

1. 0º
2. 45º
3. 90º
4. 180º

4-64. A rhombic antenna is essentially a combination of which of the following antennas?

1. Two stacked long-wire radiators
2. Two V antennas placed side by side
3. Two collinear arrays in parallel
4. Four parallel half-wave radiators

4-65. A rhombic antenna has which of the following advantages?

1. Simple construction
2. Wide frequency range
3. Noncritical adjustment
4. Each of the above

4-66. The principal disadvantage of the rhombic antenna is its

1. poor directivity
2. large antenna site
3. low antenna voltage
4. high-frequency inefficiency

4-67. The unidirectional radiation pattern of the rhombic antenna is caused by which of the following antenna characteristics?

1. Size
2. Shape
3. Termination resistance
4. Frequency of the input energy

4-68. Horizontal half-wave antennas mounted at right angles to each other in the same horizontal plane make up which of the following antennas?

1. Rhombic
2. Flat-top
3. Turnstile
4. Ground-plane

4-69. The most common means of obtaining a low-radiation angle from a vertical quarter-wave antenna is by what procedure?

1. Decreasing power
2. Increasing frequency
3. Adding a ground plane
4. Rotating the antenna to a horizontal plane

4-70. A corner reflector antenna is used for which of the following purposes?

1. To decrease frequency range
2. To increase frequency range
3. To produce a unidirectional pattern
4. To produce an omnidirectional pattern

4-71. If a corner-reflector antenna is horizontally polarized, its radiation pattern will take on what shape?

1. A narrow beam in the horizontal plane
2. A narrow beam in the vertical plane
3. A beam similar to a half-wave dipole in the horizontal plane
4. A beam similar to a half-wave dipole with a reflector in the vertical plane

4-72. When radio or radar antennas are energized by transmitters, you must not go aloft until which of the following requirements are met?

1. A safety harness has been issued to you
2. All transmitters are secured and tagged
3. A working aloft "chit" has been filled out and signed by proper authority
4. Each of the above

ANTENNA BASICS

YOU ARE HERE: HOME > ANTENNAS > ANTENNA BASICS

What are the basics of antennas?

Antennas, to quote a friend, are one of life's eternal mysteries. "All I'm totally certain of is that any antenna is better than no antenna and the antenna should preferably erected as high and be as long as is possible or desirable". Here we will discuss the very basics of antennas. Remember that thought: **these are just some introductory antenna basics**. Each type of antenna will eventually have its own page. In particular I would commend everyone to read my page on earth dangers. I think it ought to be compulsory reading.

The basic antenna

The most basic antenna is called "a quarter wave vertical", it is a quarter wavelength long and is a vertical radiator. Typical examples of this type would be seen installed on motor vehicles for two way communications. Technically the most basic antenna is an "isotropic radiator". This is a mythical antenna which radiates in all directions as does the light from a lamp bulb. It is the standard against which we sometimes compare other antennas.

This type of antenna relies upon an "artificial ground" of either drooping radials or a car body to act as ground. Sometimes the

antenna is worked against an actual ground - see later.

Antenna Polarisation

Depending upon how the antenna is orientated physically determines it's polarisation. An antenna erected vertically is said to be "vertically polarised" while an antenna erected horizontally is said (not so surprising) to be "horizontally polarised". Other specialised antennas exist with "cross polarisation", having both vertical and horizontal components and we can have "circular polarisation".

Note that when a signal is transmitted at one polarisation but received at a different polarisation there exists a great many decibels of loss.

This is quite significant and is often taken advantage of when TV channels and other services are allocated. If there is a chance of co-channel interference then the license will stipulate a different polarisation. Have you ever noticed vertical and horizontal TV antennas in some areas. Now you know why.

Antenna Impedance

Technically, antenna impedance is the ratio at any given point in the antenna of voltage to current at that point. Depending upon height above ground, the influence of surrounding objects and other factors, our quarter wave antenna with a near perfect ground exhibits a nominal input impedance of around 36 ohms. A half wave dipole antenna is nominally 75 ohms while a half wave folded dipole antenna is nominally 300 ohms. The two previous examples indicate why we have 75 ohm coaxial cable and 300 ohm ribbon line for TV antennas.

A quarter wave antenna with drooping quarter wave radials exhibits a nominal 50 ohms impedance, one reason for the existence of 50 ohm coaxial cable.

The quarter wave vertical antenna

The quarter wave vertical antenna is usually the simplest to construct and erect although I know a great many people who would dispute that statement. In this context I am speaking of people (the majority) who have limited space to erect an antenna.

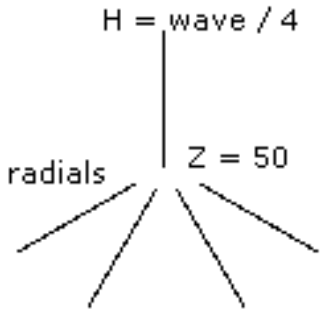

Figure 1. - a quarter wave vertical antenna with drooping radials

In figure 1 we have depicted a quarter wave vertical antenna with drooping radials which would be about 45 degrees from horizontal. These 45 degree drooping radials simulate an artificial ground and lead to an antenna impedance of about 50 ohms.

A quarter wave vertical antenna could also be erected directly on the ground and indeed many AM radio transmitting towers accomplish this especially where there is suitable marshy ground noted for good conductivity. An AM radio transmitting tower of a quarter wave length erected for say 810 Khz in the AM band would have a length of nearly 88 metres (288') in height.

The formula for quarter wave is L = 71.25 metres / freq (mhz) and in feet L = 234 / freq (mhz). Note the variance from the standard wavelength formula of 300 / freq. This is because we allow for "velocity factor" of 5% and our wavelength formula becomes 285 / freq.

When a quarter wave antenna is erected and "worked" against a good rf ground (called a Marconi Antenna) the earth provides a "mirror" image of the missing half of the desired half wave antenna.

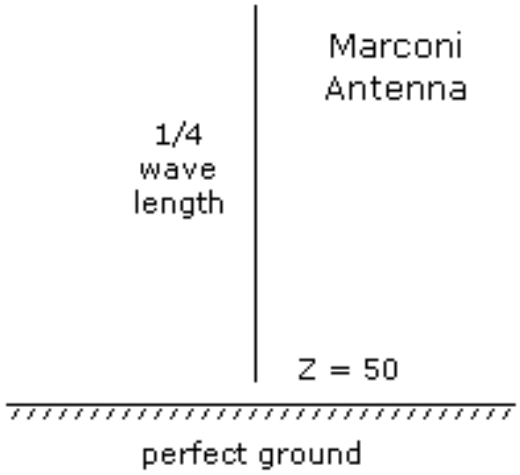

Figure 2. - a marconi antenna

In figure 2 above where I have depicted the Marconi Antenna imagine a duplicate of the quarter wave antenna being in existence from the top of the ground and extending down the page. This is the mirror image.

Half wave dipole antenna

The half wave dipole antenna becomes quite common where space permits. It can be erected vertically but is more often than not erected horizontally for practical reasons. I gave quite a good example of its use in my paper on radio telescopes from my original site. I have reproduced it in figure 3 below.

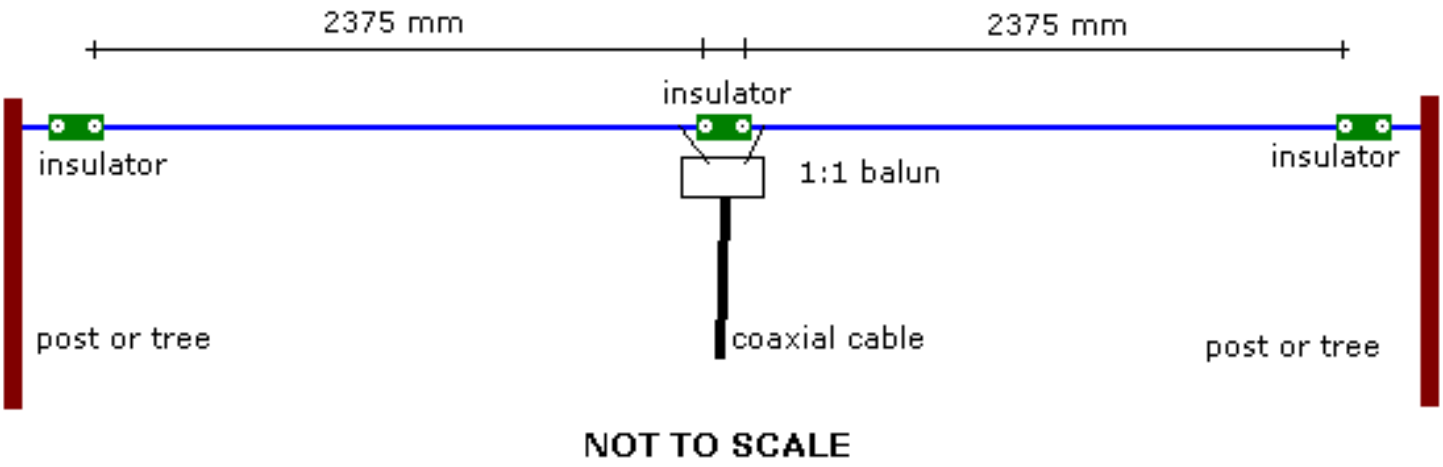

Figure 3. - half wave dipole antenna

This particular antenna was dimensioned for use at 30 Mhz. You will note that the left and right hand halves are merely quarter wave sections determined by the formula given earlier. The input impedance (affected by many factors) is nominally 50 ohms.

As with all antennas, the height above ground and proximity to other objects such as buildings, trees, guttering etc. play an important part. However, reality says we must live with what we can achieve in the real world notwithstanding what theory may say.

People erect half wave dipoles in attics constructed of fine gauge wire - far from ideal BUT they get reasonable results by living with less than the "ideal". A lesson in life we should always remember in more ways than one.

The folded dipole antenna

The folded dipole antenna is probably only ever seen as a TV antenna. It exhibits an impedance of 300 ohms whereas a half wave dipole is 75 ohms and I'm certain someone will be alert enough to ask "why 75 ohms, if figure 3 above is 50 ohms?".

Within the limits of my artistic skills I have depicted a folded dipole antenna below.

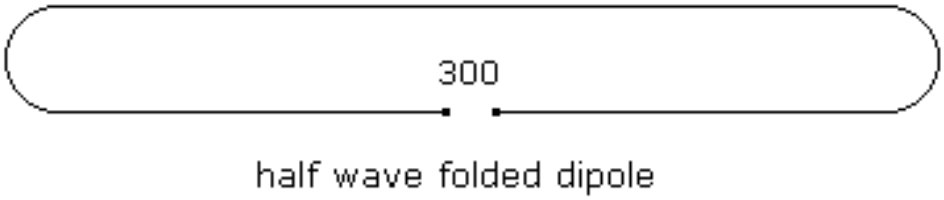

Figure 4. - half wave folded dipole

One powerful advantage of a folded dipole antenna is that is has a wide bandwidth, in fact a one octave bandwidth. This is the reason it was often used as a TV antenna for multi channel use. Folded dipole antennas were mainly used in conjuction with Yagi antennas.

The Yagi antenna

The Yagi antenna or more correctly, the Yagi - Uda antenna was developed by Japanese scientists in the 1930's. It consists of a half wave dipole (sometimes a folded one, sometimes not), a rear "reflector" and may or may not have one or more forward "directors". These are collectively referred to as the "elements".

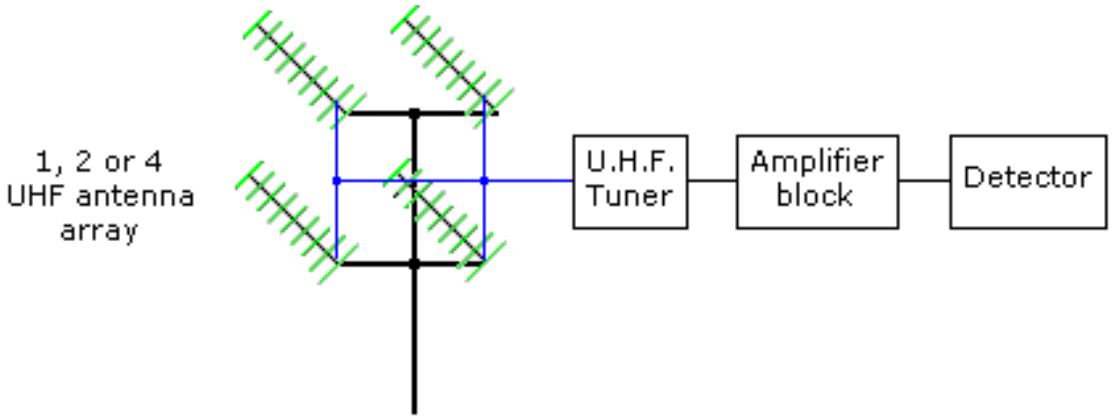

Figure 5. - the Yagi antenna

In figure 5 above I have reprinted a UHF Yagi antenna array from my radio telescopes page. You will note, not altogther clearly.

However in figure 6 below, which happens to be a photograph of a neighbour's TV antenna, I can clearly point out details of a practical Yagi antenna.

This particular antenna has been optimised for dual band operation. It is designed to pick up both VHF and UHF transmissions. Because I live in a regional of NSW in Australia, TV antennas tend to be single channel types designed either for higher gain or better directivity. Different examples will be presented later.

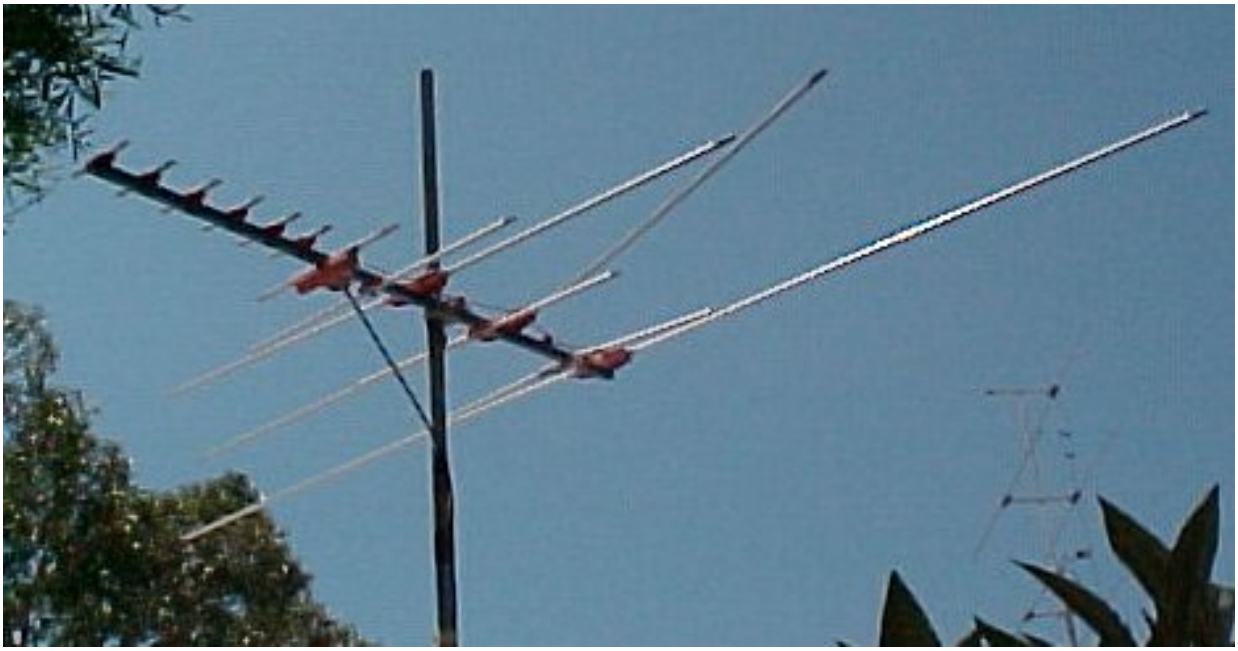

Figure 6. - a practical Yagi TV antenna

Looking from left to right on this dual band Yagi we have six UHF "director" elements which improve gain and directivity. Next is the UHF half wave dipole which could have easily been a folded dipole but is in fact a plain half wave dipole.

The next three much longer elements form a "phased array" for the

VHF band. I am unsure of the function of the three remaining smaller elements, information is quite scant here but one would certainly be a UHF "reflector". Likely the other two also fulfill this function also.

Note: This is a horizontally polarised antenna and is orientated roughly NNW, 315 degrees.

You will notice the effect of very strong storms from the sea have had in bending the second larger elements. In my locality storms are a problem but not as much as roosting parrots such as large sulphur crested cockatoos.

UHF Yagi antenna

In the photograph in figure 7 below you can see a classic UHF Yagi antenna. It has a total of nineteen "elements" comprising seventeen "directors", a fancy folded dipole with a "low-noise mast head amplifier" and a "reflector".

Figure 7. - a vertically polarised UHF Yagi antenna

This is a a vertically polarised UHF Yagi antenna and it is orientated WSW or 225 degrees. It does in fact pick up signals about 100 Km or 60 mile distant from Sydney.

This is the very same antenna I was suggesting to be used in the radio telescope array I depicted in figure 5 above.

Stacked half wave dipoles or a collinear array

The majority of TV antennas in my retirement village are stacked half wave dipoles. These consist of four sets of a half wave dipole and a reflector only, but mounted one above another. These antennas owe their origin to the days we only had VHF TV in the area. Surprising with the introduction of UHF they continued to function quite well in picking up UHF as well. This particular antenna is my one and I've never had the need to go to a UHF antenna. The top two elements normally are home to roosting "top knot" pidgeons, a pigeon native to Australia.

Figure 8. - four stacked half wave dipoles collinear antenna

To the left of the photograph are the "reflectors" and to the right are the four vertically stacked half wave dipoles. The wires connecting each half wave dipole are done in a "phased way". This comprises a collinear antenna array and is so arranged for improved gain.

Note this antenna is horizontally polarised.

Loop Antennas

The loop antenna comes in an amazing number of configurations. It is a "small space" antenna and although extremely inefficient is capable of surprising results. In receiving applications the loop antenna works on the principle of the **"differences"** in voltages induced by the current flowing in the sides of the antenna. As you might imagine these difference voltages can be extremely minute in amplitude and any loop antenna usually requires an associated amplifier capable of at least 25 dB power gain following it.

One example of a shielded loop antenna is taken from my tutorial on mobius winding techniques is shown in figure 9 below.

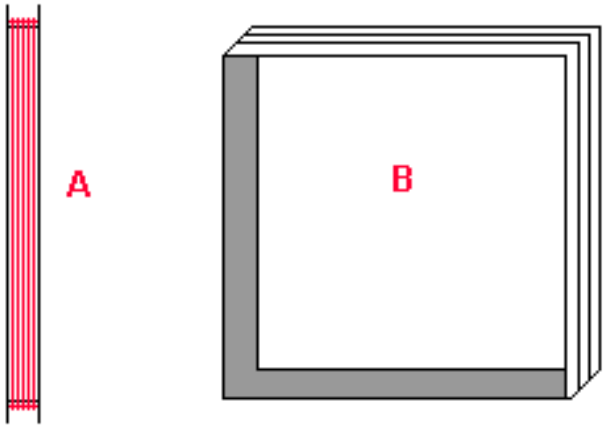

Figure 9. - mobius winding of a loop antenna

This is the general loop antenna which has one interesting characteristic. It responds well to signals arriving in one direction, either from the left hand side of your computer screen or the right hand side of your computer screen for the loop shown in figure 9 (b) above. Signals from either your face or from behind your monitor would produce equal signal currents from both sides of the loop and consequently produce no difference voltage output.

Technically speaking, a loop antenna responds to the magnetic field

rather than the electric field.

Rather than being omnidirectional (as a whip antenna would be) the loop antenna responds to the cosine of the angle between its face and the direction of arrival of the electromagnetic wave. This actually produces a figure eight pattern, which for receiving presents no probems. The addition of a small whip antenna in conjuction with proper phasing allows the direction ambiguity to be resolved and we have an antenna relatively ideal for direction finding.

The most common loop antenna you will encounter is the loopstick antenna [in the U.K. it is referred to as a "ferrite rod antenna"] built into portable receivers. In figure 10 below is the AM and shortwave loopstick antenna in a Sanyo model RP2127 MW / SW receiver (it's old).

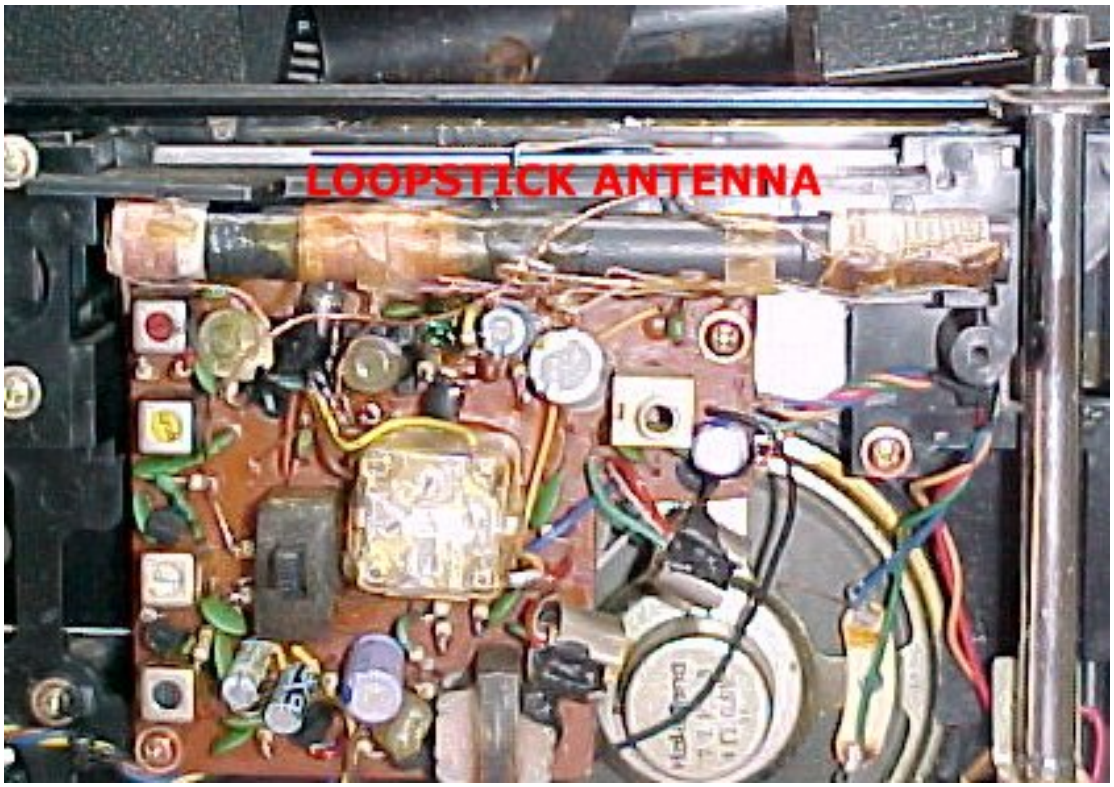

Figure 10. - AM and shortwave loopstick antenna

The AM and shortwave loopstick antenna is located in the upper half under the words "loopstick antenna". For greater efficiency and size reduction, a loopstick antenna is wound on a "ferrite" rod. This

particular one happens to be circular but you may encounter ones which are rectangular.

As an experiment you might, if you have a loopstick antenna radio available, tune to a weak station and rotate the radio around 360 degrees. You should notice two points 180 degrees apart where the signals seem to be the strongest and similarly notice two other points 180 degrees apart where the signals seem to be the weakest - these are called "nulls". This is the aid to "Radio Direction Finding - RDF"

Terminated Tilted Folded Dipole

Now here is a little gem. The terminated tilted folded dipole is bound to give a "rush of blood to the head" of any avid DX'er (that means long distance -dx- receive / transmit enthusiast).

The terminated tilted folded dipole is somewhat similar to the half wave folded dipole in figure 4 above yet the claims for its performance are quite astonishing. The terminated tilted folded dipole is claimed to have a bandwidth of something like 5 or 6 to one, been extensively tested and adopted by the US Navy, easy to construct from readily available materials and, has a feedpoint impedance of around 300 ohms.

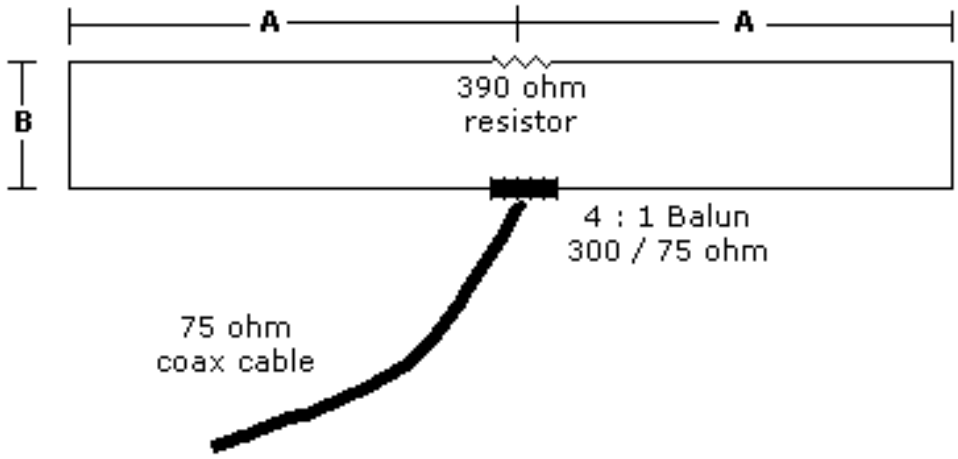

Figure 11. - Terminated Tilted Folded Dipole

The dimensions "A" and "B" for a terminated tilted folded dipole are as follows:

Each leg "A" = [2 X pi (15.25 / Fo)] and;

Distance "B" = [2 X pi (0.915 / Fo)]

where in both instances 2 X pi = 6.28 and Fo is in Mhz.

There seems to be some debate about the exact formula, my friend L. B. Cebik (see next) says:

"The "Wide-Long" version coincides with standard construction formulations, since the antenna is about 300/F(MHz) long and 10/F(MHz) wide. (Excessively fussy cutting formulas for this antenna are largely superfluous, since strict resonance is not in question)."

My friend L. B. Cebik (see later) has modeled this antenna. **Modeling the T2FD**

Further comprehensive details on the claims for the amazing terminated tilted folded dipole antenna and its construction can be found at:
http://www.hard-core-dx.com/nordicdx/antenna/wire/t2fd.html

Conclusion on antenna basics

The reason there has been emphasis on TV antennas is simply because nearly everyone can look at examples in their own locality for comparison. At TV frequencies the physical dimensions are such I can offer practical examples with photographs.

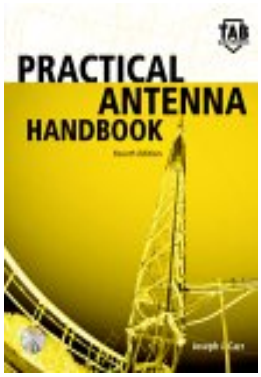
The same basic principles apply at HF and LF although physical sizes tend to be totally impractical.

As time permits I will flesh out more and more in depth articles on all these antennas and even more types not even mentioned here. This page alone comprises well over 2,000 words so you can imagine the job ahead with competing demands on my time. Meanwhile consider this important publication on antennas.

Meanwhile I would also suggest that you take a good look at L.B. Cebik 's W4RNL great web site. My good friend LB is "THE antenna guru".

PRACTICAL ANTENNA HANDBOOK

By Joseph Carr, from TAB Books



Designed for use by the novice as well as the professional, this book/CD- ROM combo gives the reader all kinds of projects with material that explains why they work.

A wide variety of antennae are covered: high frequency dipole, vertically polarized HF, multiband and tunable wire, hidden and limited space, directional phased vertical and directional beam, VHF/UHF transmitting and receiving, shortwave reception, microwave, mobile, marine and emergency.

This third edition has new material on wire antenna construction methods, antenna modeling software, antennas for radio astronomy and Radio Direction Finding, and antenna noise temperature.

BUY NEW FROM AMAZON

ORDER - U.S.A. - Practical Antenna Handbook

A WORTHWHILE PUBLICATION ON THE TOPIC OF ANTENNA BALUNS

ORDER - U.S.A. NOW Building and Using Baluns and Ununs : Practical Designs for the Experimenter - by Dr. Jerry Sevick, W2FMI.

Got a question on this topic?

If you are involved in electronics then consider joining our "electronics Questions and Answers" news group to ask your question there as well as sharing your thorny questions and answers. Help out your colleagues!.

The absolute fastest way to get your question answered and yes, I DO read most posts.

This is a mutual help group with a very professional air about it. I've learn't things. Not for absolute newcomers to ask questions BUT it is an excellent learning resource for lurkers.

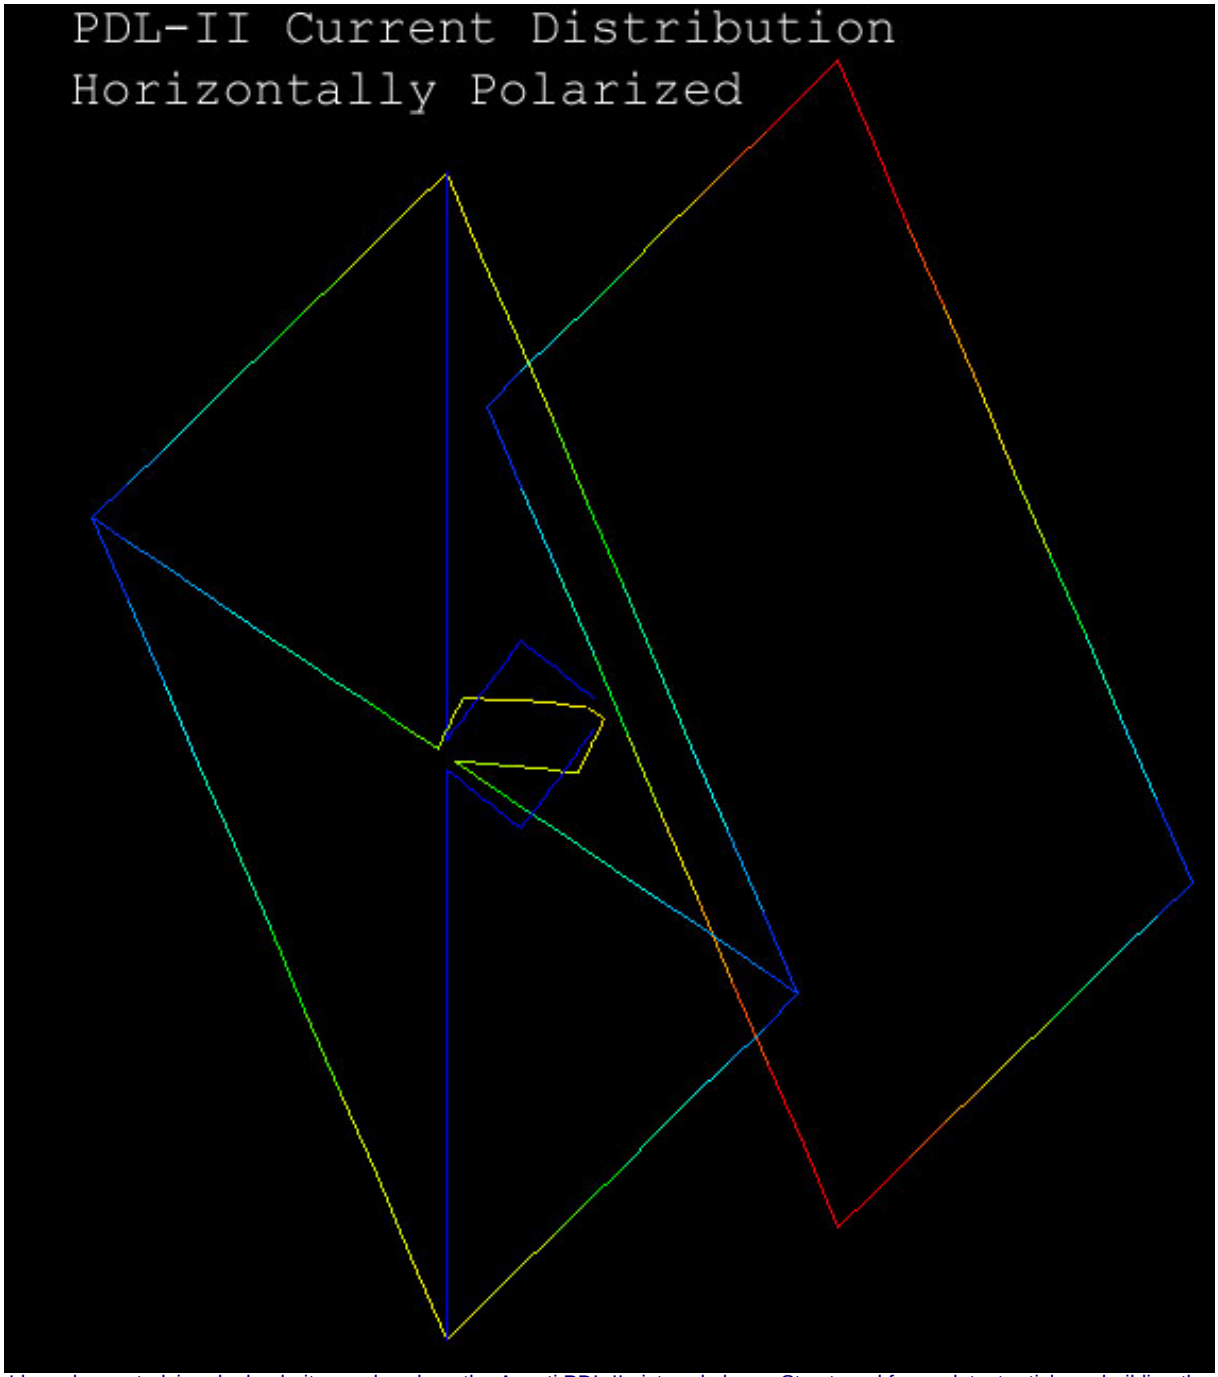
Get the true facts about different type of Citizen Band / 11 Meter antennas!



I have been studying dual polarity quad such as the Avanti PDL-II pictured above. Stay tuned for my latest article on building the ultimate dual polarity cubical quad!

Last update: Wednesday, 19-Nov-2003 23:40:43 EST Updated!

Hello, this site is dedicated to bringing true information about the different types of antennas you can use, buy and build for Citizen Band Radio and 11 Meter DXing. From concept to construction, I have set out to provide the most technically correct information possible. It contains information from antenna basics to advanced antenna theories such as the angle of radiation. I believe that it is not necessary to have great knowledge of electric fundamentals to understand how an antenna works. I have included tons of figures so that you can see what I am talking about! This site should be of interest to all CB users and 11 meter DXers because the station antenna provides the most improvement in station performance (even more so than an amplifier) when it is built correctly.

I decided to do this after all the info I read at antenna manufactures web sites. They all try to sell you their antenna. On one site I read says top loaded mobile antennas are the best, even better than base loaded. Then you read the web site of a company that makes base load mobiles only to find out base loaded are the best. Good thing is, I am not trying to sell you an antenna. Most of these web pages (and ad's in magazines) are done by the advertising department, not by the antenna engineers. And those advertised gain numbers are not regulated by any government agency! If you are looking for quick answers, frequently asked questions, this is not the place to start reading. I recommend reading it all, so that you get all the important concepts. Another reason I decided to this page is lack of good information on the web about antennas in general. Everyone has a "resource" site with a 1000 dead links to antennas manufacture pages....but no one has any *real* content. So here is my attempt at it! If there are any section that you would like to see added, let me know. For further reading see my BIBLIOGRAPHY

This page *has* to be viewed at a resolution *greater* than 800x600. I am sorry if you can not turn up the resolution any higher than 800x600, but I had to make the figures big enough to show detail clearly. You know your resolution is too small if you have to scroll out to read the end of each line in the sections (not this page, however). Click HERE for instructions on how to turn the resolution up in Windows 95/98/NT.

The Yagi building page is up!

Antenna Basics

Where to start reading if you are not really familiar with antenna basics such as radiation resistance, SWR, antenna bandwidth and polarization. Even if you have heard of these terms, read on to get a better understanding of all the essential fundamental antenna subjects. Discussion on the different type of antennas will use terminology explained here.

Coax Basics

Information about coaxial cable. Wonder why changing the your coax length changes the SWR of your antenna? Subjects such as impedance and velocity factor will be explained.

Antenna Types

Details the most common types of antennas used on 11 meters. Different types of omnidirectional and beams are covered and explains which design most common commercial CB antennas use. This is the section to read if you do not want to build your own antenna but figure out which commercial design best suites you. Make sure you read the "Hybrid" section if you own a Moonraker (or any beam with a quad reflector) for an important note.

Mobile Antennas

Explains mobile antenna basics.

Performance Tips

Four ways to improve your stations performance greatly.

- Co-Phase your antennas for 3db more gain
- Circular Polarize your dual polarity beam for solid DX contacts
- Angle of Radiation, Match the height of your antenna to the distance you are trying to communicate
- Really Ground that radio for improved receiver performance!

Antenna Building

Build your own optimized DX antenna. Not for the faint of heart. Now includes a JavaScript Calculator to fully automate designing the antenna for the frequency you talk on (Cubical Quad)!

- 4 Element Cubical Quad
- 4 Element Yagi NEW!

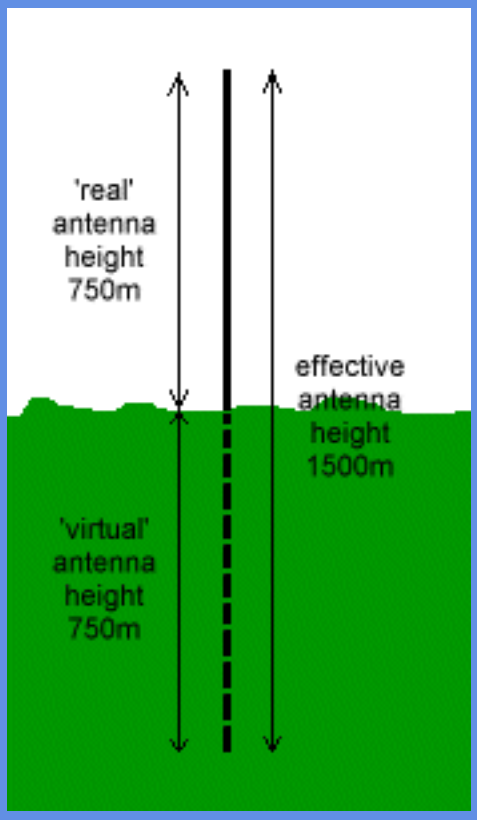
Basic Antenna Theory

Radio waves are generated by electrons accelerating in the antenna.

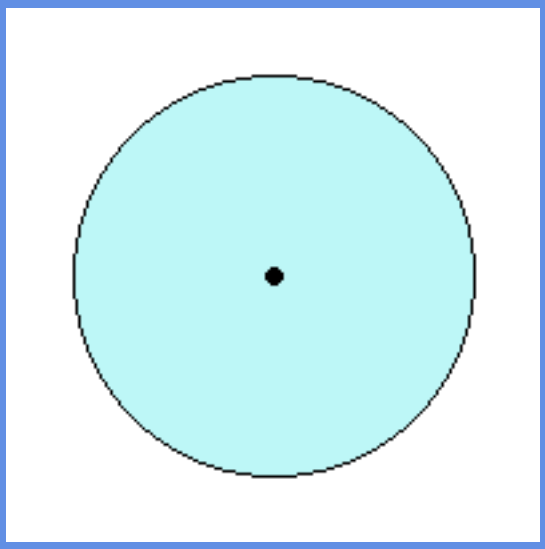
Consider a transmitter perpendicular to the ground. The electrons in the antenna, when a signal is applied, are changing their velocities continuously (i.e. moving up and down very quickly) in response to the applied signal.

For a station that broadcasts at a wavelength of 1500m, the antenna needs to be 750m long. This is because there is a 'virtual antenna' caused by the aerial being earthed in the ground:



The transmitting aerial (and the receiving aerial) need only be half-the-wavelength tall.

Now if this transmitter has no directional properties (i.e. it radiates in all directions equally), it has a coverage area, assuming completely flat ground, that is a perfect circle:



(View from above - antenna in centre; blue is coverage area)

Broadcasters rarely use a non-directional aerial though. It is possible to 'force' the energy radiated by the transmitter into particular directions - the aerial becomes directional. Directional aerials are used to great effect near the coasts of the UK, where the broadcasters do not want their signal to be easily picked up on the continent.

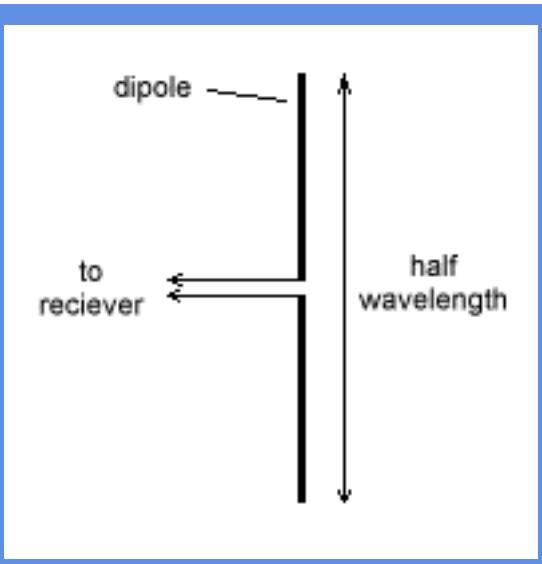
It is important that signal doesn't leak onto the continent since i) continental stations use the same frequencies and leaking signal would cause interference and ii) some programme broadcast rights apply to the UK only.

Under unusual weather conditions, despite the best efforts of broadcasters both in this country and abroad, signals travel much further than they normally would and interfere with reception of stations using the same channel, causing co-channel intereference.

Let's switch the emphasis from the transmitting aerial to the receiving aerial. Similar principles apply for receiving aerials as for transmitters as above.

The Half-Wave Dipole

There is only one part of a receiving aerial that is active, i.e. does the receiving and is connected to the TV/radio set. This active element is called the dipole. The simplest design of antenna would consist of a dipole only:

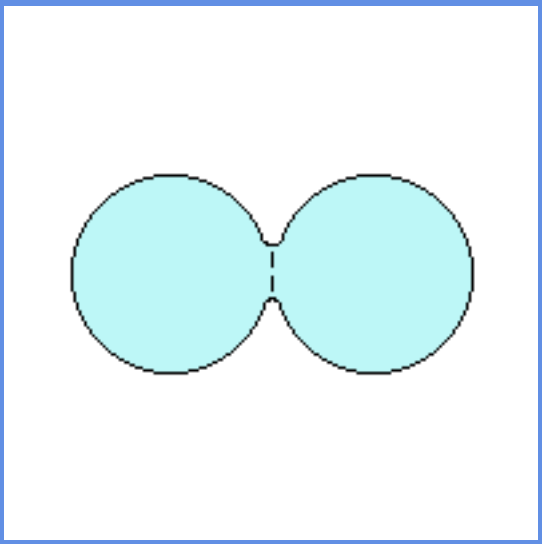


A half-wave dipole

In the diagram above, there are two wires marked 'to receiver.' For UHF and VHF, one wire will be the copper-core and the other the copper braiding of a co-axial cable.

Before we proceed, a quick word about gain. Although having a technical definition, for us 'gain' can mean "the effectiveness with which a receiving aerial receives a signal."

The diagram below shows the reception pattern of a half-wave dipole. The blue area is where the gain is higher than a certain value; the dipole is in the centre:



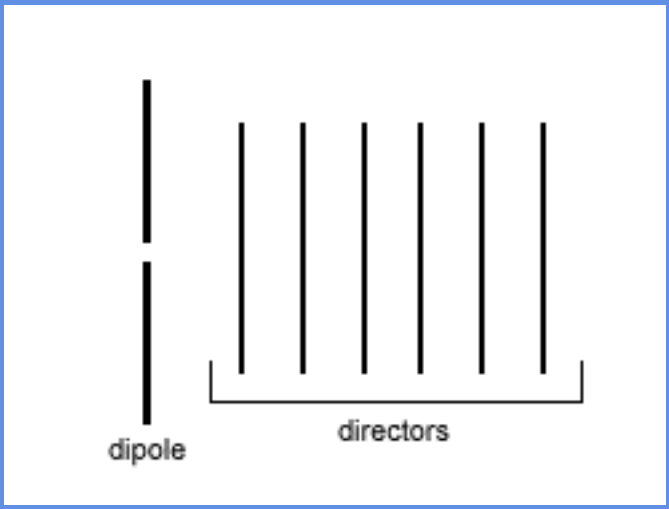
We can change the directivity of the aerial by adding other elements. Any other elements that we add to the basic half-wave dipole are called passive elements and are not connected electrically to the dipole.

There are two types of passive elements:

Directors

Directors alter the directivity of the aerial so that the aerial's gain is improved in front of the dipole. Most aerials have

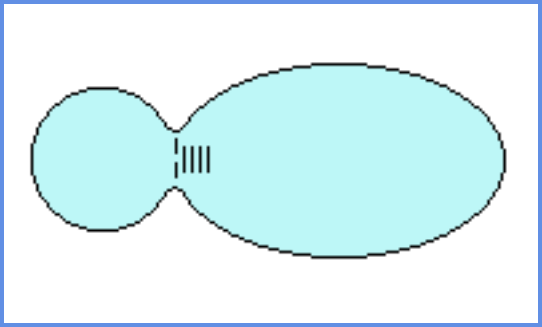
more than one director, and the more directors the aerial has the better the aerial is at picking out the signal from the required source and rejecting signals from other angles.



These diagrams do not show the cross-bar that holds all the elements in place as it does not much affect the characteristics of the aerial.

The spacing between the directors, diameter of the tubing used and the spacing between the first director and the dipole are important in practice but will be disregarded here. The length of the directors governs the bandwidth of the aerial (over which channels it is effective), but suffice it to say that it is about 75% the length of the dipole.

The gain of the dipole with directors in place looks like this:



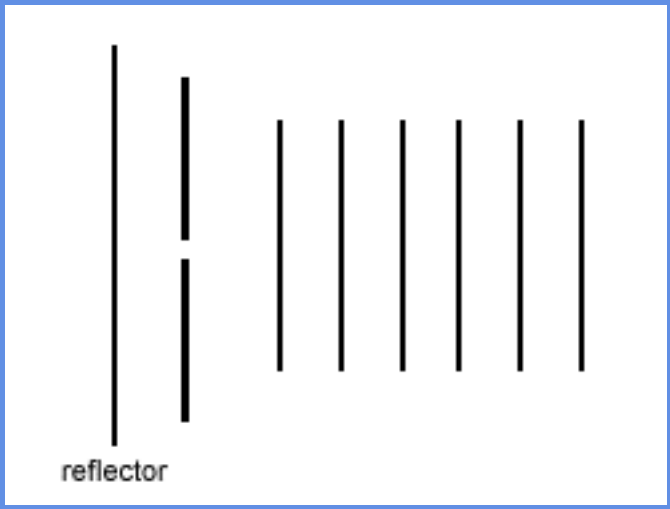
Notice how the gain is now more focused in the direction of the directors.

As stated earlier, the more directors an aerial has the more focused the gain is in the direction of the directors. Every new director added becomes less effective though, and in practice it is only worth adding 18-20 directors to the aerial, as any more than this wouldn't increase the gain very much.

On the diagram above, the aerial still has some gain at the rear - in other words, it can still receive signals from behind. This is known as a low front-to-back ratio.

The Reflector

To improve the front-to-back ratio we can add the second type of passive element, a reflector. The reflector reflects signal coming in from the back of the aerial whilst improving the forward gain.

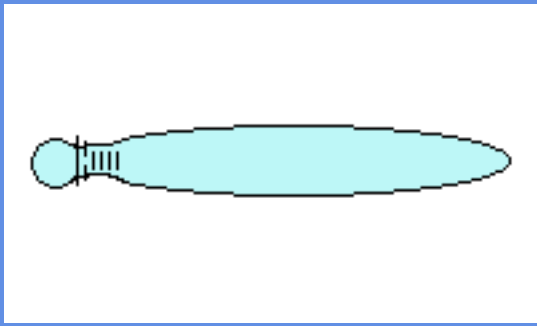


This design is called a Yagi-Uda array, after its creators.

Again, the length, size and position of the reflector affect the aerial's properties, but we won't go into that here.

The reflector can take the shape of a metal plate (with holes in it, making the aerial more impervious to wind) or several rods spaced equidistant from the centre of the dipole.

The result is that there is less gain behind the aerial and more, where we want it to be, in front:

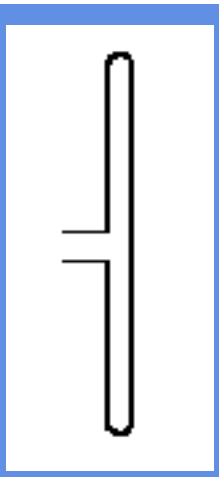


Folded Dipoles

In order to minimise signal loss it is important that the impedance (a sort of resistance for AC) of the dipole matches that of the feeder cable and the receiving set.

The impedance for the type of dipole discussed above is about 75 ohms. More often than not though the impedance needs to be altered to match the cable and receiving set characteristics.

This change of impedance is acheived by folding a rod over so that its folded length is still half-a-wavelength:



Now we know what each constituent part of an aerial is called and what its function is, let's look at some examples in the field.

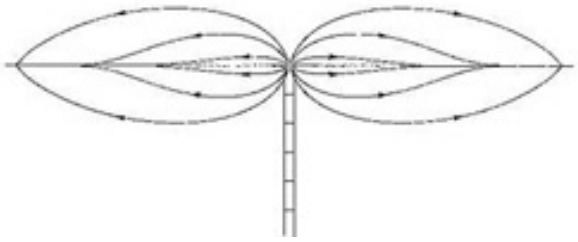
Why an Antenna Radiates

You don't have to know how an antenna works to use one, but getting a handle on this subject can deepen your understanding of radio. Here's a searching look at the mysterious process by which our antennas hurl energy from Here to There.



By Kenneth Macleish, W7TX
QST November 1992

If antennas didn't radiate, we might be well advised to dispose of our ham gear and take up another hobby. Fortunately, they *do* radiate. Our purpose here is to explore the basic principles underlying this wonderful and little-understood phenomenon.

Before starting, let's try a simple test to see how much you already know about antennas. Don't peek at the answers[1] until you have answered all the questions!

1. In a center-fed, half-wave dipole, electrons surge back and forth from one side of the antenna to the other.

True ___ False ___

2. It is possible for a perfect insulator to radiate.

True ___ False ___

3. Unlike ohmic resistance, "radiation resistance" has significance only at the feed point of an antenna or antenna system.

The ARRL World Grid Locator Atlas -- Containing all 32,400 Maidenhead Locator Squares.

True ___ False ___

ARRL Necktie -- Silk tie with ARRL diamond insignia.

4. The ground around a transmitting antenna radiates.

True ___ False ___

If you got all the answers right, you probably know more than the writer, and you have permission to skip the rest of this article.

An Imaginary Experiment

Take a pithball about the size of a marble between your thumb and forefinger. If you don't know what a pithball is, or can't find one, a hunk of plastic foam or a ping pong ball will be fine. For lack of a better name we will refer to any of these articles as a pithball. Rub the pithball on your carpet to give it a good electrical charge. Now wave the pithball back and forth in the air over a six-inch distance as fast as you can. The pithball is sending out electromagnetic waves! Let's say you are achieving a rate of 10 cycles of motion per second. If you have placed in the corner of the room a sufficiently sensitive megameter-wave receiver, it will detect a signal when tuned to a frequency of 10 hertz, or to a wavelength of 30 million meters. If you could vibrate your hand fast enough you might even be able to carry on radio communication in this fashion!

We will continue this experiment shortly. Meanwhile let's take a look at what goes on inside an antenna.

Put Your Antenna Under a Microscope

Now, admittedly the average antenna doesn't contain any pithballs. But it does contain hordes of minute, lightweight, electrically charged particles called *electrons.* Many of these are so-called *free* electrons that have broken loose from their parent copper or aluminum atoms and are able to travel more or less freely through the spaces between atoms, under the influence of any electric fields that may be present. The free electrons behave in many ways like tiny pithbalIs.

We know that an electric current in a conductor is simply a mass migration of free electrons. If the current is alternating, as in an antenna, the free electrons in a given locality move back and forth in unison. Evidently, then, any individual electron moves to and fro around an average position, like the pithball in our experiment. Let's see how far and how fast this electron might travel.

Consider an antenna made of #12 copper wire and operating at 14.1 MHz. Each free electron near the surface of the wire is executing 14.1 million cycles of motion per second. Knowing the number of free electrons per cubic inch of copper, the electric charge on each, and the depth of RF penetration into the wire (the *skin depth),* we can calculate the peak speed of an electron at a place where the RMS antenna current is, say, one ampere. The result comes out to be less than half an inch per second. At that rate the electron doesn't move very far during each half cycle of vibration: its peak-to-peak travel is no more than a hundred-millionth of an inch. In the eyes of an electron this distance is quite respectable, being tens of thousands of times its own diameter. The answer to question 1 above, though, is clearly "False." Not one electron makes it through the feed system from one side of the antenna to the other.

We can compute the electron's deceleration and acceleration, which are greatest when the electron is coming to a stop and then starting up in the other direction. At an antenna current of one ampere, these quantities reach more than 50,000 gs! And an accelerating or decelerating charged body, be it an electron or a pithball, is a source of

electromagnetic radiation.

A pithball is a pretty good insulator, and so, presumably, is an electron. So the answer to question 2 is "True": a perfect insulator *can* radiate.

Let's return to our imaginary experiment. This time, instead of waving a pithball at 10 hertz, we'll pretend to vibrate a single electron at radio frequency[2] and examine the resulting fields.

Fields of a Vibrating Electron

The detailed structure of an electron is unknown, but for our purposes it doesn't matter; we can assume that our electron is a little round ball with an electrical charge distributed uniformly over its surface. We determine the fields by solving Maxwell's equations[3] at all distances from the electron, right down to its surface. This analysis is not an exercise for the faint-hearted. We'll skip the details and concentrate here on the results.

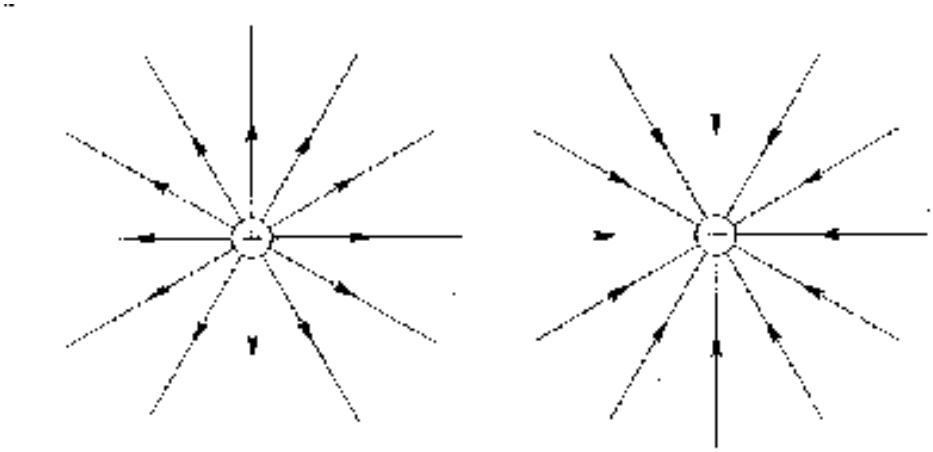

Fig 1 -- Always present around a charged particle, the coulomb field plays a vital role in energy radiation.

The Coulomb Field

Grasping the electron in, say, a tiny pair of tweezers, let's start by holding it still. After a while the only field present will be a stationary electric field that points outward[4] in all directions from the electron. The field lines take the form illustrated in Fig 1 for both positive and negative charges. This is called the *coulomb field.* It is always present, regardless of whether the electron is in motion. We'll find later that the coulomb field plays a vital role in the operation of antennas.

With vibratory motion, two new fields make their appearance.

The Magnetic Field

A moving electron constitutes a current, and a current is always surrounded by a *magnetic field.* As if hitchhiking, point the thumb of your right hand in the direction of the electron's motion; then your curled fingers represent the circular lines of the magnetic field around the electron. Point your thumb in the opposite direction and you see that the

magnetic field reverses, so a vibrating electron gives rise to an alternating magnetic field. At the electron's surface, the magnetic field is almost exactly in phase with the electron's speed, but as we move away, the phase of the magnetic field begins to lag. Out to a radius of 1/6 wavelength, the phase lag is small. Beyond this radius, the lag starts to increase at a more rapid rate and soon settles at 360 degrees per wavelength of distance.

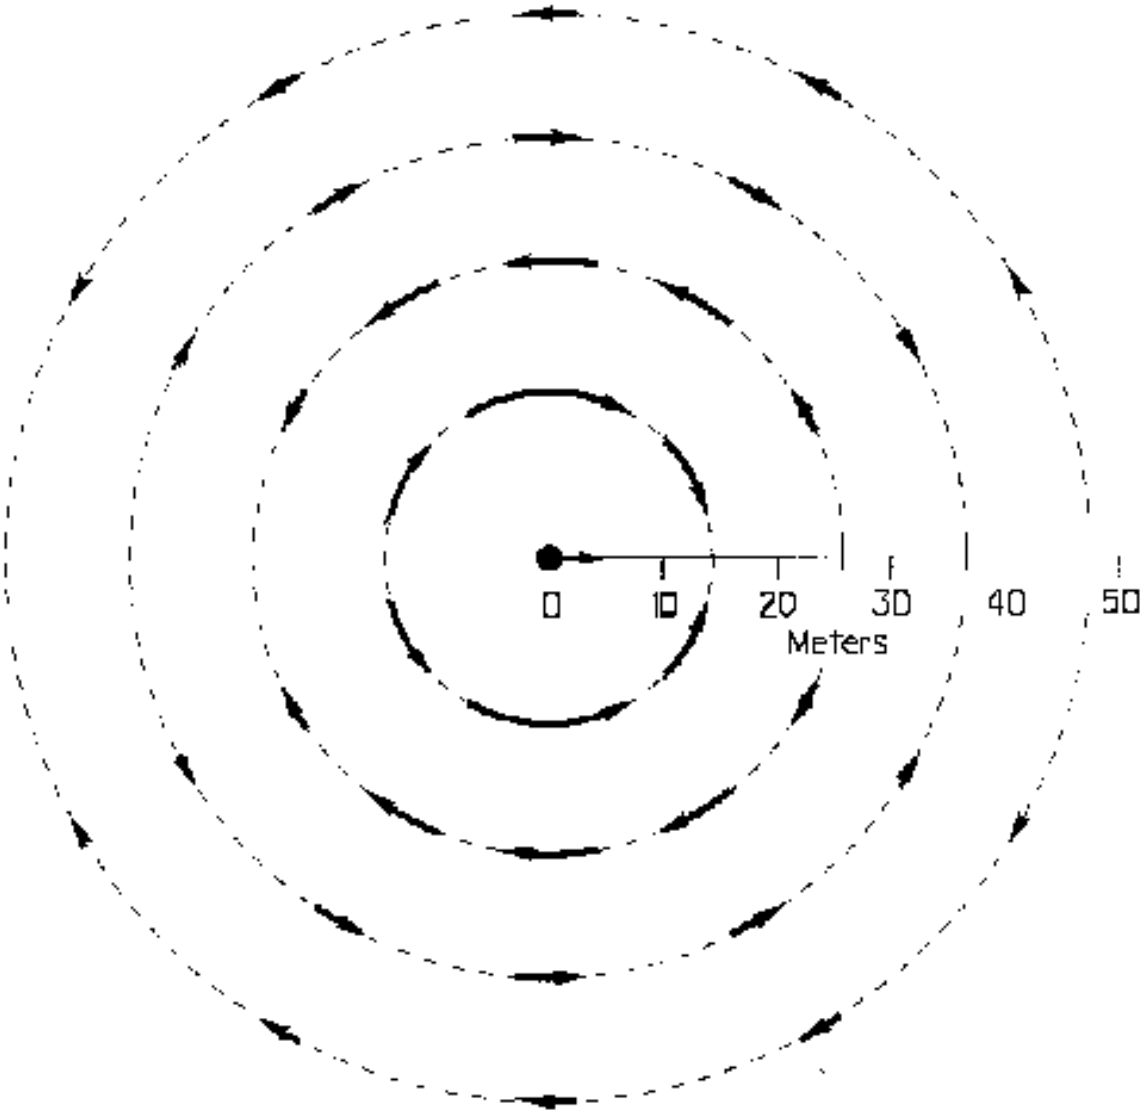

Fig 2 -- The radiation field of an electron vibrating as 14.1 MHz. Each broken line represents a wave crest.

The Dynamic Electric Field

The second new field is an electric field that results from the electron's acceleration. Because of its dynamic origin -- in contrast to the electrostatic nature of the coulomb field -- we'll call this field the *dynamic electric field.* It's useful to regard the dynamic electric field as the sum of two separate fields, one of which is in phase with the magnetic field and the other 90 degrees out of phase. We will call the in-phase component the *radiation field* and the out-of-phase component the *induction field.* It is the radiation field that carries energy from an antenna into the surrounding universe.

Fig 2 shows an area the size of a football field in which a lone electron, greatly magnified, is being vibrated at 14.1 MHz. The figure is a snapshot of the electron's radiation field taken at an instant when the electron is at the center of its travel and moving to the right, as indicated by an arrow. The curved arrows show the direction and strength of the radiation field. The dashed circles represent spherical wavecrests on which the field is at a local maximum. As we go outward from a wavecrest, the field decreases to zero, then reverses and rises again to the next wavecrest. Like ripples in a cosmic pond, these spherical waves are expanding outward at the speed of fight, 300 million meters per second.

At any one point, the radiation and induction fields vary as sine-wave functions of time. About 1/6 wavelength away from the electron (actually 1/[2p] wavelength), in a direction at right angles to the line of motion, the two fields are equal in amplitude. As we move farther away, the induction field falls off so much more rapidly than the radiation field that we soon have essentially nothing but the radiation field. Inside a vacuum-dielectric coaxial transmission line carrying power in one direction, the ratio of the electric to the magnetic field is equal to 377 ohms. In our pure radiation field, which carries power in the same manner even though there are no physical conductors present, this ratio is likewise equal to 377 ohms-a value that is sometimes called the characteristic impedance of space.

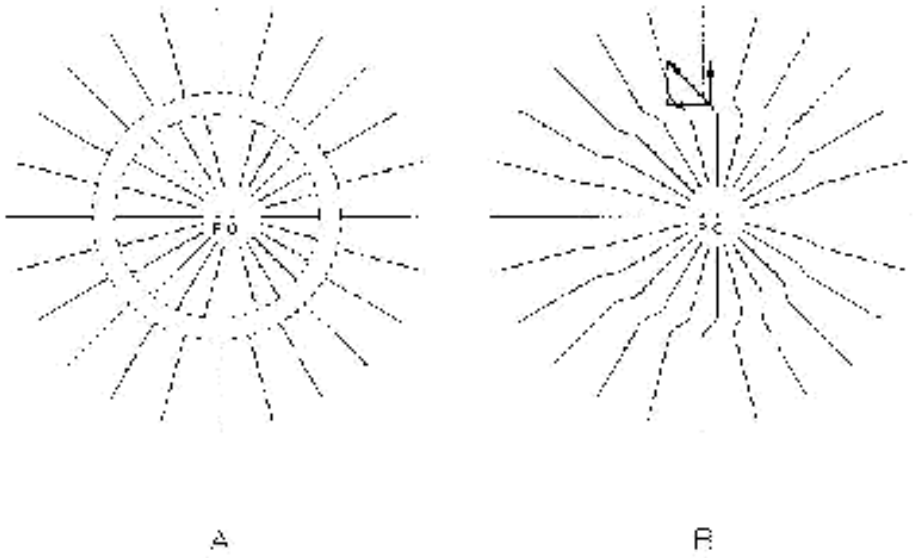

Fig 3 -- The electric field of an electron that was accelerated recently. The resulting disturbance in the field is traveling outward at the speed of light. The transverse component of the disturbed field is the radiation field.

Why an Accelerating Electron Radiates

We've described the radiation field of a vibrating electron, but we haven't yet explained why it happens. The answer is hidden in Fig 3A.

Suppose that, until a short while ago, an electron was held at rest at point P in Fig 3A. It was then accelerated briefly to the right by our tweezers and afterward was kept moving to the right at constant speed. At the present time (which we'll call time zero), the electron is passing point Q.

Fig 3A contains two circles. The larger circle (the outermost broken fine) is centered at P and has radius equal to the distance light would travel in the interval from the beginning of acceleration until time zero. The smaller circle is

centered at the spot occupied by the electron at the end of acceleration; its radius is equal to the distance light would travel between the *end* of acceleration and time zero. As time marches on, the circles evidently grow at the speed of light. The space between the circles is equal to the distance light would travel during the period of acceleration. If the electron moves slowly in comparison with light, as it does in an antenna, the distance it covers during acceleration is small compared to the size of the circles, so the circles are nearly concentric. For clarity we have greatly exaggerated the distance PQ; it too would be very small if drawn to scale. Now we can determine what the electric field must look like at time zero.

Outside the larger circle, the field at time zero is a stationary coulomb field centered on P, as if the electron had never started to move.[5] Inside the smaller circle, the field is a moving coulomb field centered on the electron's present position, point Q. Between the circles the field is intermediate between the fields in the other two regions.

Now connect the field lines across the space between the circles and erase the circles, making Fig 3B. You can see that the electron, while accelerating, gave birth to an expanding electromagnetic disturbance. In the disturbed region, as shown by the arrows, there is a transverse field component -- the radiation field -- in addition to the outward-pointing coulomb field.

The radiation field resulting from a *vibrating* electron, Fig 2, is simply a continuous series of such disturbances caused by successive intervals of changing acceleration and deceleration.

The Bootstrap Forces

The radiation and induction fields of a vibrating electron exist right down to the electron's surface. Since the electron's surface carries an electric charge, and since an electric charge is pulled by an electric field, it's fair to ask whether these fields are able to exert forces on the very electron that is producing them. In other words, can an electron "feel" its own dynamic electric field? The answer is yes. The electron is pulled by its own bootstraps! The tweezers that are providing the motive power must overcome the bootstrap forces.[6]

The bootstrap forces are responsible for two very important properties of a conductor: radiation resistance and inductance.

Radiation Resistance Versus Ohmic Resistance

By our definition, an alternating radiation field is in phase with the accompanying magnetic field. At the surface of a vibrating electron the magnetic field is essentially in phase with the electron's speed, so here the radiation field, and the bootstrap force exerted by it, are likewise in phase with this speed. The direction of the force is such as to resist the electron's motion. It is evident that the force feels to our tweezers like a drag proportional to speed, as if the electron were moving through a viscous fluid. This drag force is the cause of radiation resistance.

An electron moving in a conductor also feels a drag force that is due to frequent progress-impeding collisions between the electron and the atoms in its path. This drag is the cause of ohmic resistance, the familiar R in Ohm's Law.

Both kinds of resistance dissipate energy at a rate equal to the resistance times the square of the current. Of course, energy dissipated this way doesn't actually disappear. An alternating current, flowing against *radiation* resistance, turns electrical energy into radiant energy, which wings its way off into space. Current flowing against *ohmic* resistance transforms electrical energy into heat, which is mechanical vibration of the atoms of the conductor -- the atoms vibrate when they're hit by the moving free electrons.

Radiation resistance varies along the length of an antenna wire, but it is independent of the diameter and material of the conductor. The middle third of a half-wave, 14.1-MHz dipole has a radiation resistance of 3.7 ohms per foot. That's nearly 80 times the ohmic resistance of clean #12 copper wire at this frequency. Closer to the ends of the antenna, the radiation resistance is even higher.

Inductance

At the surface of a vibrating electron, the induction field, being 90 degrees out of phase with the magnetic field, is 90 degrees out of phase with the electron's speed (ie, the current). The bootstrap force of the induction field therefore opposes *the rate of change of current* rather than the current itself. Here we see the underlying cause of the property of inductance. In reacting to this bootstrap force our tweezers deliver energy *to* the electron during acceleration and receive back an equal amount of energy *from* the electron during deceleration. The delivered energy is stored in the magnetic field around the moving electron and is returned when the magnetic field collapses as the electron slows down.

Because the bootstrap force of the induction field is proportional to acceleration, it feels to the tweezers just like mechanical inertia. In consequence the electron has an *effective inertial mass* that greatly exceeds its gravitational mass.

Now let's step back and look at the fields in and around an entire antenna. You will recognize that the basic principles involved apply to any kind of antenna. Because of its simplicity, we will use an isolated, center-fed, half-wave dipole as an example.

The Big Picture

If our antenna doesn't contain any pithballs, it doesn't contain any tweezers either. What is it, then, that causes the free electrons to vibrate? In real life it takes an electric field to move an electron. Inside an isolated straight dipole, the motive power comes from the combined coulomb fields of all the charged particles, positive and negative, in the antenna. We'll refer to this combined field as the *antenna's* coulomb field.

In addition to the coulomb field, the antenna as a whole exhibits a magnetic field that is the sum of the magnetic fields of all the moving free electrons. It also sports a dynamic electric field that is the vector sum of the dynamic electric fields of all the free electrons. As we did with an individual electron, we can separate the dynamic electric field of the antenna at any point in space into two components, one in phase with the total magnetic field and the other 90 degrees out of phase. We will call the in-phase component the radiation field of the antenna and the out-of-phase component the induction field. Right at the antenna, both fields are parallel to the metal surface.

It happens that the coulomb field and the induction field fall off much more rapidly than the radiation field with increasing distance from the antenna. At distances greater than a few wavelengths from the antenna, in what is called the antenna's *far field*, the electric field is essentially pure radiation.[7] Closer to the antenna, we have the *near field*, which is a mixture of the radiation, induction and coulomb fields.

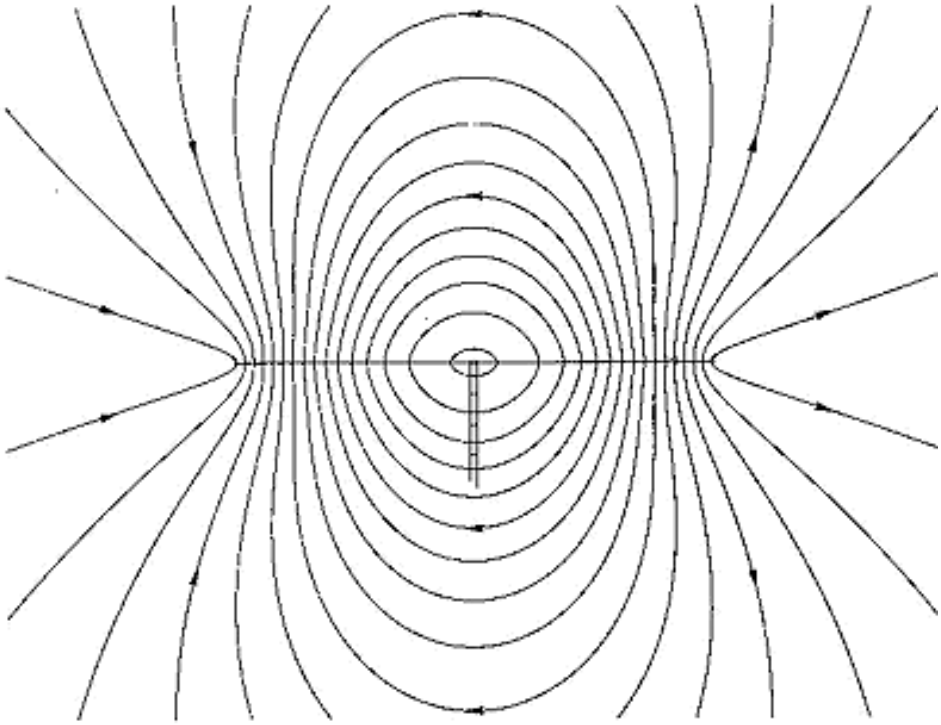

Fig 4 -- The coulomb field at an instant in time around a half-wave resonant dipole A half-cycle later, the polarity, and all the arrows, will be reversed. The spacing between the field lines indicates field strength.

Action of the Coulomb Field

We see in Fig 4 a snapshot of the coulomb field near the antenna. This picture shows an instant in time when the right-hand half of the antenna is positively charged and the left-hand half is negatively charged, as a result of a process that we'll examine in a moment. A half-cycle later, the polarity, and all the arrows, will be reversed. The spacing between the field lines indicates field strength. At the antenna wire or tubing, the field lines are nearly, but not exactly, perpendicular to the metal surface.

On alternating halves of the antenna, the perpendicular component of the coulomb field tries to pull electrons out of the surface. This effort is generally unsuccessful in amateur antennas because the "work function" for copper or aluminum -- the energy it takes to dislodge an electron from the surface -- is too great. If the transmitter power is very high, though, the field may be strong enough to pull electrons out into the air. The result is an exciting (but power-wasting) luminous display called *corona.* But because the coulomb field leans slightly away from the perpendicular at the antenna's surface, it can always pull free electrons *along* the surface.

At one point in the RF cycle, free electrons throughout the antenna are moving to the right at or near their maximum speed. The right-hand half of the antenna thereupon begins to accumulate an excess of electrons, even if no single electron will shift to the right by more than a hundred-millionth of an inch. In the left-hand half of the antenna the departure of free electrons leaves an equal excess of oppositely charged metal ions, which are stationary atoms that have lost an electron. The coulomb field produced by this increasing imbalance of charges now opposes the electrons' rightward motion. By virtue of their effective mechanical inertia (also known as the bootstrap force of their induction field), the electrons coast for a while against the rising force of the coulomb field, which eventually brings them to a

stop and then propels them back toward the left. After the electrons again reach maximum speed, now in the opposite direction, the foregoing scenario is repeated with left and right interchanged. The end result is the vibratory motion of free electrons that causes them to heat the metal and generate electromagnetic waves.

Newton's second law of motion tells us the relationship between the acceleration of an electron and the sum of the forces acting on it. In this case, one of the forces is the pull of the coulomb field parallel to the metal surface. The other two forces are the bootstrap force of the dynamic electric field and the drag of ohmic resistance. According to Sir Isaac, the sum of all three forces is equal to the gravitational mass of the electron times its acceleration. We will assume that an electron is so nearly weightless that its gravitational mass can be set to zero in this equation. Then the three forces must always add up to zero.

Turning this statement around another way, we can say that the dynamic electric field and the parallel component of the coulomb field partly cancel each other, the remaining field being just enough to overcome the drag of ohmic resistance. If the ohmic resistance is small enough to be ignored, the coulomb field is precisely equal and opposite to the dynamic electric field everywhere on the surface of an antenna.

This result leads to a procedure, which amounts to the construction and inversion of a matrix, for computing the current distribution on an antenna. Then, using the principles we've been discussing, we can compute the behavior of the system in detail.

Power Flow Through Space

Electrical engineers use the term *real power* for power that flows in one direction past a given point. They also speak of *reactive power*, which is power that flows back and forth in alternating directions with a net flow of zero in any one cycle. The radiation field of an antenna transmits only real power, which travels out toward distant localities without ever reversing direction. The induction field carries only reactive power, and the coulomb field carries both real and reactive power. Again we'll illustrate this with an isolated, center-fed, half-wave dipole.

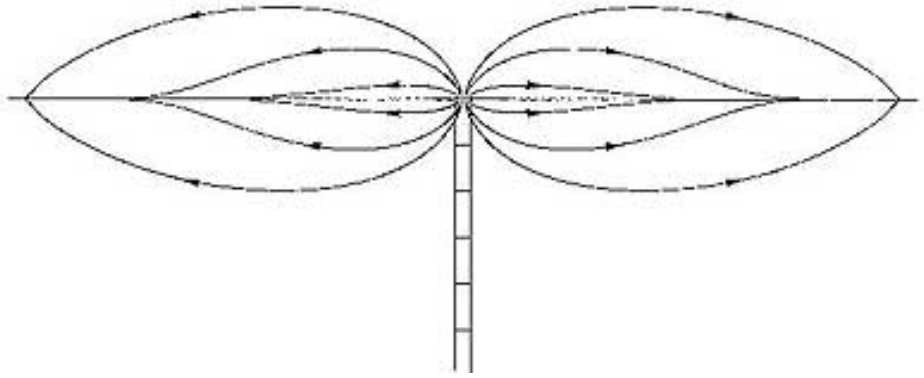

Fig 5 -- Flow of power from the feed point of a half-wave resonant dipole. The coulomb field around the antenna conductors carries power *through the space surrounding the conductors.*

Real Power Flow

How do you suppose your hard-earned RF power gets from the feed point to the rest of the antenna? You might think that it flows out through the wire or tubing of the dipole, but actually this real power is carried *through the*

surrounding space by the coulomb field. Some lines of power flow are plotted in Fig 5.

As you see in the figure, when power coming up the feed line reaches the antenna it spews out into the air in all directions. It then arches to the right and left on curved paths that eventually intersect the antenna. At the points of intersection the coulomb field donates its real power to the free electrons, making up for the energy they are losing to ohmic resistance and radiation resistance.

Reactive Power Flow

During one interval in the RF cycle, the charge on the antenna reaches a maximum, and the current and the magnetic field go through zero. A quarter of a cycle later, the reverse is true. In the first interval, the antenna is surrounded by a cloud of electrostatic energy stored in the coulomb field. In the second interval, the coulomb field has disappeared, and we find the same energy stored in the magnetic field. The energy stored in the coulomb field is used in accelerating the effective inertial mass of the free electrons, which by their motion create the rising magnetic field. Energy thus moves from the coulomb field, via the induction field, to the magnetic field, only to move back again during the next quarter cycle as the magnetic field collapses. This is reactive power flow, with a net of zero.

You can think of the cloud of electrostatic energy as energy stored in the distributed capacitance between the two halves of the antenna. Similarly, the stored magnetic field energy can be thought of as energy residing in the distributed inductance of the antenna wire. If power is suddenly cut off by short-circuiting the feed point, the antenna doesn't stop radiating right away. Instead, it oscillates with diminishing vigor at its resonant frequency until the energy stored in the fields has been dissipated in ohmic resistance and radiation resistance. Our antenna can be accurately described as a resonant circuit made up of distributed capacitance, distributed inductance, and two kinds of distributed resistance.

Antennas and Non-Antennas

What do the following items have in common: a dipole antenna, a radar dish, the ground around a transmitting antenna, a coil and capacitor in parallel, and a wire carrying music to a loudspeaker? One answer: to a greater or lesser degree, they all radiate!

This is true because in operation they all carry time-varying currents and, consequently, accelerating electrons. The dipole antenna is an example of a distributed circuit that owes its existence to the fact that it radiates well. It is designed for efficient conversion of electrical energy into radio waves. But any system of conductors that carries varying currents behaves in accordance with the principles described earlier. The same processes, including radiation, take place whether we call the system an antenna or something else. For example, what we generally refer to as reflection from a conducting surface (the radar dish, the ground) is actually radiation from free electrons set in motion by incident electric fields.

In Sum

Perhaps the foregoing intuitive introduction to classical electromagnetic theory will inspire further development and refinement of the ideas presented. In any event, I hope you'll be able to contemplate an antenna, or a non-antenna, with a warm feeling for all the interesting things going on in and around it!

Notes

[1]1--False. 2--True. 3--False. 4--True.

[2]The classical electromagnetic theory we use in this article is valid at frequencies from dc through microwaves. At still higher frequencies one must venture into the realm of quantum electrodynamics.

[3]For some pertinent theoretical background see Feynman, Leighton and Sands, *The Feynman Lectures on Physics*, Vol 11 (Addison-Wesley Publishing Co, 1964).

[4]To get an outward-pointing field we must take the charge on the electron to be positive instead of negative as is actually the case. I find it easier to visualize the interaction of electric fields and electrons by thinking of the electron charge as positive. In the end it doesn't make the slightest difference. After all, Ben Franklin, on rubbing an ebony rod with cat's fur, could just as well have defined the charge induced on the cat to be positive. Life might be simpler today if he had.

[5]If you were observing from anywhere outside the larger circle at time zero, the electron would appear to be at point P instead of its actual position, point Q. That's because, according to Einstein's theory of relativity, the news that the electron has started to move can't propagate faster than the speed of light. If you were anywhere inside the smaller circle, the electron would appear at time zero to be in its actual position.

[6]The electron is pulled by its own coulomb field too, but equally in all directions, so the net effect is zero.

[7]In summing the radiation fields at a given point in the far-field region from all the free electrons, we must take into account the differing phases of the source electrons and the varying propagation times. The resulting phase variations cause partial reinforcement or cancellation of the fields, to a degree that depends on direction from the antenna. This effect is the basis of the very extensive subject of antenna radiation patterns, which we will not discuss further here.

Ken Macleish received his first Amateur Radio license 60 years ago at age 12. He now has an Extra Class ticket and still enjoys ham radio, especially CW ragchewing.

He holds a BS in physics (1939) from Caltech and a PhD in physics (1943) from the University of California at Berkeley. He was with Tennessee Eastman Company at Oak Ridge, Tennessee, during World War II, then transferred to Eastman Kodak in Rochester, New York, where his most recent position was assistant director of research and engineering in the Kodak Apparatus Division. In 1962 he joined the Perkin-Elmer Corporation in Norwalk, Connecticut, as a vice president of engineering. He retired in 1970 to enjoy the climate and scenery of Arizona.

Ken has authored QST articles on frequency counters and frequency measurement. Also, over the years, he's had a nagging desire to understand why a radio antenna works. Combining this desire with a background in physics, a hobby of ham radio and an interest in computers, Ken has been working off and on for some time to help dispel some of the mystery surrounding this subject.

Construction Practices

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 2/25/2000)

Introduction

The construction of light weight structures that support wire antennas requires some definite insight into the behavior of the materials. I shall consider only constructions using fiberglass tubes that telescope and the guy lines that are required to stiffen the structures. In some cases, the guy lines are actually the antenna wires, to the mechanical properties of the wires is also important. To understand the structural properties of fiberglass tubing, you should read Properties of Fiberglass Rods and Tubes. This section should give you a first hand understanding of the mechanical properties of this material and a good feel for the amount of bending that can be expected for various diameters and lengths of tubing. The total bending of composite telescoping spreaders made from the standard sizes of tubing can be estimated by considering the loading of the outer most sections at the beginning of the next larger section and working inward so long as the total angle of bending remains small. Small for practical purposes is about 20 degrees. In the case of most light structures, the bending will be more than is desirable, and guy lines will be required to take some the load thus reducing the total bending moment along the beam or spreader. In the end, the maximum loading is controlled by the tendency of the spreader to buckle due to the total force of the guys along the axis of the tubing or rods. This limiting force is easily computed given the geometry and the modulus of elasticity of the material. The remainder of this section considers mostly construction practices that have been found to work well and save time in assembly and disassembly of the antennas. As most of the antennas considered in this web site can be considered as portable, assembly time is often an important factor.

Telescoping Spreaders

The standard tubing sizes available from Max Gain Systems begin at 1/4" OD and work

upward to about 2" in 1/4" increments. The walls are slightly less than 1/8" thick allowing the sections to telescope. In the case of the 3/4" tubing, the OD is slightly too large, and it is not possible to insert this size into the 1" material more than about a foot without getting it seriously stuck. This works fine as a fixed length spreader, but you can not vary the length. I shall focus on the construction of light weight antennas using only the 1/8", 1/4" and 1/2" sizes for the spreaders and the 3/4" and 1" sizes for boom and upper mast sections. These materials are sufficiently light that all antennas I have considered here can be easily constructed and erected by a single person.

The standard procedure used to assemble telescoping aluminum sections works equally well here. Six inches to one foot of overlap is always desired between sections. The sections are locked in place by using standard hose clamps to compress the tubing at the tip. For this to work, a slit must be cut at the tip of each section to be compressed, and the depth of the cut should be about twice the diameter of the tubing. So, for 1/2" material the cut should be about 1" and the hose clamp mounted exactly flush at the tip. The cut can be made most easily using a hack saw. you should be careful not to breath the dust from this operation, i.e., I suggest you use one of the paper filter masks while doing the sawing. You may find it difficult to find hose clamps smaller than 1/2" in most hardware stores, however, the 1/2" size will normally compress down to 1/4" but that is about the limit. The 1/8" solid rod can be used for micro extensions to the spreaders, but these are normally limited to about 6" in length. As a result, the maximum length of the spreader is limited to about 16' when using 8' sections of 1/4" and 1/2" materials. So the largest practical structure might support a full-size rotatable 20 meter dipole. A more useful limit for quads and planar wire beams is about 12'.

Supporting Spreaders

After considering many standard procedures for supporting spreaders, I decided that quick assembly was more important than cheap. There are several inexpensive ways to mount spreaders, for example, you can use a 1 or 2' section of 3/4" fiberglass rod in the center that can be U-bolted to a plate or hub. The plates and hubs are normally made of aluminum or hardwood. I experimented with both materials and found that neither suited me for this application. After discussing the problem with a good machinist, he suggested that we try PVC. We initially constructed four hubs from this material for testing, and found that it is sufficiently strong, light in weight, dark in color, easy to machine, and holds tolerances well. Currently, we are making these available in one size only, that is, for 1/2" spreaders with a 1" boom or mast. Stainless steel set screws are used to lock the spreaders into the sockets and to lock the hub to the most or boom. The initial hubs have been in use for two nearly years at this point and show no degradation of the material other than a slight change in color. See our Products Page for details and cost. These hubs permit rapid assembly and disassembly using a small Allen wrench. We have paid considerable attention to the accuracy of the machining. The spreaders

are held accurately at ninety degrees and the length from the center of the hub to the tip is exactly one inch longer than the spreader when the spreaders are fully inserted in the sockets. These tolerances are important to maintain so that the lengths of the guy lines can be accurately calculated when they are needed.

Guy Lines

We have experimented with and tested guy lines made of three materials at this point. The decision of which to use depends upon a number of considerations such as visual impact, the amount of stretch that can be tolerated, the degradation over time related to weather and ultraviolet, and the expense of the material. The following materials have been tested:

Material	Diameter	**#Test**	**E, Modulus of Elasticity**
Nylon Fishing Line	25/1000"	40	
Black Dacron Rope, DR33225	3/32", ~ 105/1000"	>600	
Bonded Kevlar, Size 207	25/1000"	>	

Table 1

Properties of Guy Line Materials

Of the three materials, the Black Dacron is most visible due to its greater diameter, the Kevlar is next due to its gold color, and the Nylon is least visible of the three if the material is clear or lightly tinted. Of the three materials, the Kevlar stretches the least for a given force and does not creep with time. In general, it is difficult to measure the tensile strength of these materials, as it depends upon how the materials are tied or bonded to the supports. These materials will always break at knots, so, that tells you that tying knots in the material is not the best way to form the tie-loops. After considerable testing we found that crimp fittings designed for fishing leaders worked well for the monofilament Nylon lines. These work less well for the multi-filament line, because the line flattens easily and requires the crimp to compress fully which is often doesn't. This results in slippage under tension. In the case of Kevlar, we found that most of the failures could be prevented by double crimping and tying a double half-hitch behind the crimp. The the larger diameter Dacron material can be handled with standard aluminum crimp fittings designed for wire cable. Again, the crimp fittings have to be compressed evenly across the tube. It is a good idea to do a few practice crimps and test them under tension just to be sure you have the technique under control. Once you are sure of this, it is time to make some

guy lines of specific length.

The easiest way to make guy lines of accurate length is to fabricate them on a wood board about 8' feet long using two finishing nails separated by the desired length if the lengths are less than 8'. Longer spans can be looped back one or more times, i.e., the nails are spaced at some sub-multiple of the required length. We have found that stainless steel leader clips are very useful for attaching guys to the eye-bolts. The leader clips permit easy assembly and disassembly-assembly of the structures and provide a simple method of attachment that is stronger than most other methods. The combination of the crimp fittings and the leader clips permits the guys to be assembled under tension. As shown in the figure below. The second figure shows

The computation of the length of guy lines is normally not very difficult in the case that the assembly consisting of a hub and spreaders is planar. However, even in that case, one must make allowance for the distance of the attachment points form the spreaders, guy posts, and any other attachment structure that changes the distance between the two points of attachment. If you use snap clips, you must include them in the length of the guy. As an example, consider calculating the length of a guy line that spans the distance from a central guy post to a point near the tip of an 8' spreader. The lines are to be secured with snap clips to eye-bolts that extend perpendicular to the center post and to the spreader. Suppose the guys are attached to the center post at a height of 36" above the plane of the antenna. The eye-bolt extends 1.5" from the center of the post. The attachment to the spreader is set at 93 inches form the center of the hub, and the eye-bolts extend 1.25" above the center of the spreader. The spreaders are to be planar (not bent). The offsets due to the eye-bolts define a slightly smaller right triangle whose length, L, and height, H, are as follows:

L = 93 - 1.50 inches

H = 36 - 1.25 inches

So, if S is the required length of the guy line, the required length is:

S = sqrt (L^2 + H^2) = 97.9"

In the case where the spreaders are bent out of the plane, the computation of the guy lengths is a little more complicated. This is because as the spreader is bent by pulling on the guy point near the tip, the length of the guy point moves up and out of the plane and closer to the center guy pole. If you choose the amount to bend upward out of the plane, you then must know how far that point moves toward the center as well as the angle of the bend at the guy point on the spreader. Calculating these quantities is possible but a bit complicated, so it may be simpler

just to bend the spreader and measure the length from the guy point to a point perpendicular to the guy pole or directly to the attachment point on the guy pole. However, the table below gives the approximate length of the tip of the spreader perpendicular to the center of the guy pole, the elevation of the tip above the plane of the hub, and the approximate force required to pull the spreader into this shape when guyed to a 3' guy pole.

All materials used for guy lines stretch, and the amount of tension in the line determines how much it stretches. Different materials of various weights stretch different amounts, so you may want to measure the amount of stretch. Nylon fish line stretches quite a lot while Kevlar thread hardly stretches at all. The stretched materials also grow in length under tension, for example, a Nylon line cut initially to 100" may creep to 104" when to about 3 kg or 6.6 lbs. It will also almost return to its original length when left un-tensioned. Because of this behavior, it is very difficult to measure the modulus of elasticity except by dynamic means. On the other hand, a similar length of Kevlar thread size #207 will stretch only about 3/8" when tensioned to 3kg and returns to the same length when the tension is removed. However, even the Kevlar deforms slightly over a period of weeks by about 3/8" to ½" for a 100" length. This means that you should provide for some room for adjustment when setting the locations of the guy points. You should assume that line lengths will grow a bit and provide space to extend the guy points. It is also possible to alleviate the stretching by pre-tensioning the material before cutting the lengths, and this is especially true for Nylon. In the case of Kevlar, the tension may take several days to weeks to stretch the material. Pre-tensioning also is commonly done with copper antenna wire, as it also grows in length in a similar manner. So, it is a good idea to pre-tension all materials before cutting. The only exception to this rule might be the Kevlar.

Fortunately, it is easy to compute the amount of stretch for a given material with simple tools. If you have a fishing scale, a pulley, a long board and a few nails, you have every thing you need. Or you can use the same materials that we use for which the numbers are known. (to be completed)

W2IK Presents:

"OVERLOOKED ANTENNA CONSTRUCTION TIPS"

==========

By Bob Hejl - W2IK c2004

Many ham radio operators enjoy the triumph of constructing or repairing their own antennas. As guidelines, they often use one or more of the many antenna designs which are available in both books and on the Internet. Sometimes they might even take a basic design and adapt it to increase it's efficiency or to make the antenna fit within the physical limitations of their property. It is unfortunate that in these designs little thought is ever given regarding material selection beyond it's cost, weight and strength. There is another important detail that must be taken into consideration during selection and before construction is to begin. The best antenna design using the strongest materials available may be a fruitless effort if you expect your antenna to perform for an extended period of time. One of the most overlooked antenna construction considerations involves the action that usually occurs when two dissimilar metals are brought into physical contact (mated) during the assembly process and exposed to the weather. There can be a serious onset of a type of corrosion at their respective contact points.

This corrosion, also called "galvanic corrosion", can create havoc in as little as three months. Galvanic corrosion is a process that occurs when certain metals are connected to each other and moisture, such as rain, condensation or even high humidity, is introduced. When all of this is present, electrons flow between the two metals (also called "ionic flow"), which causes the most chemically active metal to change. When galvanic corrosion occurs, it can usually be identified by characteristic surface blistering or white powder corrosion around dissimilar metal points.

If left on its own, the corrosion process will continue, eventually pitting of the metal will occur and electrical or RF conductivity will fail. It's problems can be magnified when an antenna is used in humid, windy, intense heat or cold (thermo-galvanic corrosion) or other harsh conditions. Even an antenna encased in a fiberglass shell, such as a vhf or uhf repeater antenna, can suffer from the effects of this corrosion.

There is a direct relationship between various types of dissimilar metals when they are mated. Some dissimliar metals, such as copper and brass, when mated cause very little corrosion. There are other metals, however, that react most harshly when matched. Zinc and brass, for example, will cause corrosion with the zinc metal quickly breaking down. If you wish to prevent galvanic corrosion the best means, of course, is to use the same metal throughout your construction. If this is not possible your next course of action would be to assemble materials that have a close relationship on a galvanic metals table. Here is a descending list of metals and their associated relationships in order of the most "noble" or least active.

least active ***gold***

silver

silver solder

bronze

copper

brass

nickel (plating)

tin
lead
lead-tin solder
stainless steel
iron/steel
aluminum alloys
aluminum
zinc-galvanized steel

most active ***zinc***

When choosing materials you should try to pick a metal part made from the type closest to the other metal parts you will be using as charted on the above list. It is very important to consider EVERY part of your antenna including clamps and washers. For example, if brass screws are used to hold aluminum tubing in place they will cause a headache when corrosion takes hold. The better choices would be either stainless-steel screws to secure aluminum tubing or brass screws to hold copper tubing.

Remember that if you are refurbishing an antenna system you might be locked into using a hard to find piece of hardware based upon the original construction materials. Some antenna companies skimp by using the cheapest, but improper mating metals. For example, if you are servicing a tall two-meter base or repeater antenna and you notice that the antenna company used stainless steel couplers and set screws to link two sections of brass or copper rods it would be wise to replace the couplers and the set screws with brass components. If you don't, you might find that the antenna will exhibit intermittent high swr when unseen corrosion takes place between the set screws and the rods. If any wind flexes the antenna the flexing will cause the corrosive joint to change the swr and it will not only effect your signal but will also stress your transmitter as the load it sees will constantly change with the wind. You don't want to "lose" a set of repeater output transistors because of antenna joint corrosion that could have been prevented. It's worth the extra time to locate hardware made of either the same metal or one closest to the antenna metal as outlined on my chart. In doing so you will avoid having to re-fix the problems caused by improper repair.

If you need to clean off a metal surface it is important to use a "like metal" brush to do so. Using steel wool to clean a brass rod that might be part of a vhf/uhf repeater antenna will embed small particles of steel into the rod and create a corrosive atmosphere. Use a small brass brush instead. Be aware that even when you solder, the type of solder used (silver solder or tin-lead solder) needs to be considered based upon what you are bonding. When you construct an antenna also be aware that the surface area of each contact point is very important. Making one small point of contact, using one set-screw for example, will increase the possibility of galvanic corrosion creating problems. This is compounded by the fact that any RF energy will have to pass through a smaller contact point causing additional resistance. If you must assemble two pieces of your antenna either design a larger overlap or use two or MORE flat tipped set-screws to hold the joint. Do not use plated set-screws because as soon as they are tightened they will lose some of their plating at the contact point possibly exposing the metal below the plating. This may cause a corrosion problem unseen to the naked eye. Multiple set-screws within the same collar are a must. This not only reduces the problem but also makes a better physical connection that won't be as easily loosened due to winds or vibrations.

Whenever you are inspecting an antenna for refurbishing, the tiny corrosion on the contact point of a set-screw may go un-noticed. Many problems can arise due to galvanic corrosion including high swr, lowered output power, reduced receive capability, introduction of intermod in vhf and uhf operations, induced static in receive, an increase in "stray current corrosion", "telluric effect corrosion" and harmonic interference being generated. If you find it necessary to combine metals not closely linked on the above list, use an intermediate metal, such as if you must attach a copper wire to aluminum tubing, use stainless steel or nickel washers and a stainless steel screw or a tinned solder lug with a stainless steel screw. This isn't the best solution, but it will reduce the chance of corrosion. The best answer is to always use "like metals" where possible.

In every case of bonding or connection, in order to reduce the galvanic corrosion, coat all of your antenna's joints and connections. This can be done with a joint sealing compound, but it is important that the compound is non-hygroscopic (not waterbased) and does not contain any aggressive ions that can be leached during service. Spray or paint on coatings that contain zinc or aluminum powder should be avoided. Epoxy-based coatings are much better. If possible, use a clear type as this will aid in joint inspections. If, during any inspection, you see a peeling of the sealer, remove it completely and re-apply. These epoxy coatings can be obtained at most marine supply companies as they are made for both marine and atmospheric applications. Make sure that the surface you wish to protect (the joint) is clean and dry. The spray type allows you a quick seal coating "in the field". In humid conditions, use a hair dryer to remove any mositure. You do NOT want any moisture trapped under the coating. If you are working with tubing, remember that moisture can be introduced through the ends of the tubing into the interior of the joint so make sure the tubing ends are also sealed. The less moisture the better the joint will be protected. BEFORE YOU COAT: Make sure that no corrosion has taken place at the joint. If it has, the corrosion that has started will continue. Take the time... inspect, clean and re-assemble any questionable joint. Also be aware that even when bolting your antenna to a tower you need to use the right hardware. Refrain from using stainless steel "U" bolts to connect an antenna to

an aluminum tower even though the two metals are close on the list. Use aluminum hardware or galvanized "U" bolts. So the next time you plan on building or repairing that antenna, consider your material selections accordingly.

BEFORE YOU LEAVE:

While I have your ear there is something else you should also know. This same principle also should be applied when repairing or installing a grounding system for your shack. Don't use copper grounding braid and attach it to steel (or even copper-clad steel) ground rods!! This creates a wonderful corrosion point that not only affects your system from a safety standpoint, but also RF may be reintroduced back into your shack and give you a nasty RF burn. Ouch ! Your best bet: Use several 1/2 inch copper tubing sections to act as ground rods, then attach your copper ground wire or braid using copper or brass clamps or wrap it around the tubing and solder it using silver solder. Another reason for doing this is that the copper tubing has more surface area exposure to the ground and is, of course, a better conductor. Use more than one and stagger them so they are not in a straight line and space them differently and not a fractional wavelength such as 1/4 wavelength from each other.

Formulas To Design Your Own Dipoles And Inverted Vees

Most hams are familar with the center fed, half wave dipoles and inverted vees that are very popular and easy to build. This formula will give you a starting point to make these antennas. There are several factors that affect the resonant frequency of any antenna. Some of these factors are: the height above ground, the diameter of the wire, nearby structures, the affects of other antennas in the area and even the conductivity of the soil.

If you've ever used some of the other antenna design programs you may realize that the formula for these types of antennas vary from about 476/f Mhz to 490/f MHz depending on the band and the height above ground!

Fortunately there is a **standard** formula that can be used as a starting point in your design. For a center fed, wire dipole, this formula is 468 / frequency in megahertz. I've always cut the antenna a few inches longer which would allow me to trim the antenna in order to obtain a 1:1 match.

The inverted vee has always been about 3 - 5% shorter than a dipole at the same frequency. I used 4% as a constant in the calculation. You may change this value to any number that you like to use.

This page uses the standard formula, 468 / f MHz to calculate dipole lengths. You may change this number if you know of a better number to use as your starting point.

AMANDX PRESENTS

DIPOLE ANTENNA

INTRODUCTION-The longwire antenna is a very effective antenna for the listener who wants to cover all of the shortwave bands from 530 KHZ to 30 MHZ. However if you have some favourite frequencies that you listen to on a regular basis you may wish to consider a dipole antenna. This antenna is a fairly easy to construct antenna and will give you better reception on the frequency it is cut for. Think of a dipole as a longwire that has a insulator in the middle.

FREQUENCY-A dipole antenna will not only work well on the frequency it is cut for, but also for the multiples of that frequency. For example if you cut a dipole for 7.0 Mhz will also work well on 14 Mhz, 21 Mhz and 28 Mhz. This way if you can pick and choose your frequency you can make one antenna work on two or three bands.

LENGTH- To find out how long the antenna should be all you have to do is fill in a simple formula:

FREQUENCY IN MHZ divide by 468 = LENGTH IN FEET

That is the only formula you need ever know to build a dipole antenna.

Formulas To Design Your Own Dipoles And Inverted Vees

This page uses the standard formula, 468 / f MHz to calculate dipole lengths. You may change this number if you know of a better number to use as your starting point.

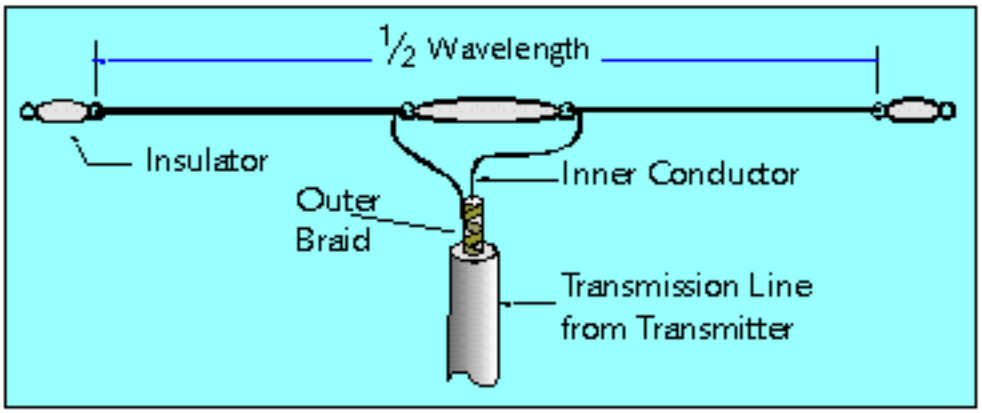
Your Inverted Vee's total length is feet
Each leg of the Inverted Vee is feet



dipole antenna

CONSTRUCTION- Once you have selected a frequency and calculated the length of wire you need add two feet to this length. This is done so you will have six (6) inches of wire at each end to wrap around the insulators. Once you have this extended length of wire cut it in half. This will give you both sides of the dipole.

Attach an end insulator to one end of each piece of wire. You can use the egg shaped insulators sold by many radio supply stores or make your own out of a piece of plastic. This can be done by cutting a piece of heavy plastic or plexi-glass to a size of about six (6) inches in length and about 2-3 inches wide. Drill a small hole one to one and a half inches from each end of the plastic to wrap the wire around. It is best to solder these connections and wrap them in a sealant tape to keep the effects of the weather from harming them.

The other free ends are attached to a centre connector which you can buy with a built in coaxial cable connecter, or make your own. This will look similar to the end connectors but you will have to find a way to secure the coax lead wire to the insulator. If you build your own when you attach the coax to the ends of the wires, insure that you solder and wrap the connections. One wire will go to the centre of the coax, while the other wire will go to the shielded braid of the coax. This will give you a perfect half wave dipole. You should also wrap the coax fitting of the commercially available centre insulator to keep water and other moisture out. Moisture will ruin the connections on any type of insulator and make the antenna less effective or at worst useless.

MULTI-BAND DIPOLES- As was stated above you can use the dipole on the harmonics or multiples of the frequency it is cut for. However if you are short on space you can build a multi-band dipole. This way you will get an antenna that will operate on several frequencies. Instead of using a single strand of wire you can use wire that has several insulated wires in it. These MUST be insulated wires to insure that they do not touch each other. You then cut the top wire to be the longest, the second wire to be the second longest, the third wire to be the third longest etc.. Only the longest wire is attached to the end insulators and all wires are fed to the centre insulator to attach to the coax feed line.

INSTALLATION- Once you have the antenna cut all you have to do in put it between two masts. Make sure that you use the free side of the end insulators to attach some rope. Tie this rope from the end insulators to the masts. Leave some slack on the antenna. If you pull too tight the antenna will break in the wind or if snow and or ice should coat the antenna. KEEP AWAY FROM OVERHEAD WIRES!! Keep away from these as should the antenna ever come into contact with an overhead wire you will do permanent damage to your radio if not yourself. All you have to do is feed the coax to your radio and listen to the stations come in. It would be best to install a lightening arrester in the coax feed line to help protect your receiver. These are available from many radio supply stores. Follow the instructions carefully! In areas where thunder storms or snow storms are common a lightening arrester is a must for safety.

You can install them flat or at an angle. If at an angle they will be more directional the direction taht they are sloped. You can also istall them as an inverted V shape. This dipole has a higher center with lower ends to save on space in smaller back yards. All three versions work well.
FURTHER INFORMATION- If you want more information on dipole antennas and for that matter all types of shortwave antennas look for these books:

Easy-up Antennas for Radio Listeners and Hams by Edward M. Noll

Joe Carr's Receiving Antenna Handbook by Joe Carr

The Easy Wire Antenna Handbook by Dave Ingram

Practical Wire Antennas by J. Heys

These books are orientated towards the Shortwave Listener more so than the Ham operator. The first two above are probably the best for the beginner and the more advanced, but not technically minded. They put forward a lot of information in a manner everyone can understand. Ed Noll's Easy-up Antennas for Radio Listeners and Hams even comes with tables giving you pre-calculated lengths for many types of antennas. There is lots of tips on making antenna construction simple but effective. It does not come any easier than this.

Why I use dBi---Mostly

L. B. Cebik, W4RNL

Although current commercial practice is to specify antenna gain in dBd, I tend in my modeling work to use dBi. It is reasonable to ask why, if for no other reaosn than to understand better the other entries in this collection of notes. So I shall explain why. My object is not to get anyone to change their preferred ways, but only to make a little clearer my preference for specifying gain in dBi.

dBi

Every measure in decibels, or dB, is ultimately a relative power measurement (with some defined relative voltage and current measures having been derived from the basic power measure). Decibels are defined this way:

Relative power in dB = 10 log (base 10) P1 / P2,

where P1 and P2 are two power levels measured in the same units (e.g., watts).

Since we may pick any two powers for P1 and P2, power gain or loss is strictly relative.

However, we have found it useful to select--for specific purposes--certain baseline power levels. One such level is whatever power there might be in the radiation far field of an isotropic radiator. An isotropic radiator is a lossless dimensionless point in free space that radiates equally well in all directions. Although some say this is a absolutely theoretic concept only, Brian Beezley, K6STI, has established that a pretty good appoximation of an isotropic radiator can actually be constructed.

Using this radiator as the baseline and taking measurements at the same far field distance from the antenna, the power received from the antenna will have a certain relative level in comparison to what would have been received from the isotropic radiator. What that level is depends on the characteristics of the test antenna and the direction in which we choose to take the readings, using a full 3-dimensional sphere as the possible directions for readings. In some directions we may get more power; in others we may receive less.

One of the chief advantages of the isotropic radiator is that its field never changes, so that it functions as

an agreed upon constant against which every antenna may be measured in every direction.

Every antenna measurement referenced to a P2 that is the far field power from an isotropic radiator has a positive or negative gain in dBi.

Gain

When we casually refer to antenna gain, we do not normally mean the gain in any haphazard direction from the test antenna. Nor do we mean all the possible gain numbers we might gather from a systemmatic tour around the surface of our far field globe surrounding the antenna. Gain in every direction is important, for it defines the antenna pattern and tells us where the far field is strongest and weakest and in the middle--and by how much.

However, when we casually mention gain, we are usually interested in the direction(s) of maximum gain from a given test antenna. Then we rotate the antenna to present that antenna direction to the receiving station. For satellites, we may rotate in 3 dimensions, but for HF, 2-dimensional rotation usually suffices (unless we must somehow compensate for a bit of tricky terrain and have the wherewithal to do so).

We can specify maximum antenna gain in terms of dBi. Then we can compare maximum antenna gains from 2 or more antennas by citing their gains in dBi and merely comparing numbers.

This practice is perfectly reasonable so long as we do not make it a fetish; that is, so long as we do not use this number exclusively in our gain considerations. Horizontal beamwidth is also important and is usually defined in terms of the number of degrees between half-power or -3 dB points where the direction of maximum gain is the center. Vertical beamwidth is also important in estimating the success of a potential path. We also want to know, in conjunction with vertical beamwidth, the elevation angle of maximum radiation. Together, these numbers give a more complete picture of antenna performance in a desired direction than raw gain alone.

I have modeled an array with a 21 dBi gain figure. However, the horizntal beamwidth is only about 17 or 18 degrees wide, making it unsuited for general amatuer operation. However, we often assume that competing antennas have the same beamwidth and that all we need to know in making our selection is the maximum gain. Good practice calls for making no such assumption. Rather, before we focus on maximum gain, we should establish that all other factors are equal.

dBd: a warm but fuzzy concept

The concept of dBd was formed to capture the gain of an antenna relative to a dipole. A dipole is considered the standard basic horizontal antenna, and comparisons to it seemed to some folks to be more meaningful than comparisons to the isotropic radiator.

Unfortunately, the concept of dBd has become a cluster of concepts. Here are some of them. The notation is my own, since few folks are anxious to distinguish the individuals in the cluster.

1. dBd-I: dBd ideal compares the gain of an antenna to an ideal dipole in free space. An ideal dipole uses infinitely thin lossless wire and is resonant at the frequency of interest. In this application, the ideal dipole has a gain of about 2.15 dBi, that is, 2.15 dB over an isotropic radiator. All measurements are thus arithmetically transportable between dBi and dBd-I by adding or subtracting 2.15, as appropriate.

dBd-I is of limited utility, since my backyard dipole may have a gain of 7.15 dBi and 5 dBd. Some folks become confused by the idea that a dipole has gain over a dipole. We then have to explain that the real wire dipole has gain over the perfect dipole in free space. That rarely helps a lot. And it does not tell us until we do some arithmetic how much gain some other antenna has over a real dipole.

2. dBd-RM: dBd can be expressed as the gain over a real dipole modeled at the same height as the test antenna. For studies that are strictly modeling investigations, this measure is sometimes useful. However, it requires that we further specify the construction of the dipole in terms of element diameter and element material. Using the same material, dipole gain will vary with element diameter. It will also vary inversely with the loss of the material used for the dipole.

Both these constraints apply within the further rule of keeping the dipole resonant. If we make measurements across a ham band, we shall find that the dipole gain varies with frequency unless we reresonate it for each readout frequency. Actually, we are usually more careless than this and take one resonant reading and apply it across the band without checking. And we tend to use fairly loose standards of resonance rather than converging the results. We may more precisely say that an antenna is resonant when the reduction of feedpoint reactance results in no further changes in gain to the number of significant digits that apply to the test.

As one more qualification, we should note that dipoles and other antrennas may have different elevation angles of maximum radiation over the same type of ground. When we cite dBd-RM, we must also say whether we are giving the figure for the dipole at its angle of maximum radiation or at the angle chosen for the test antenna. To avoid confusion, it is usually better to give details about the differing elevation patterns.

3. dBd-RR: dBd can be expressed as the gain over a real dipole set in the same position as the test antenna, where both antennas are oriented for maximum gain relative to the far field receiving site of the test range. For fairness, one should specify the construction of the dipole to ensure that the materials are comparable to those of the test antenna.

However, there are a number of variables that occur within this way of handling dBd. First, range conditions vary considerably from one site to another. Second, some testers take the average of a number of readings in various directions, while others take readings along a single line defined as the best test line. Third, different ranges may use different test heights. The importance of this factor stems from the

fact that many antennas that might be tested have different elevation angles of maximum radiation than a dipole, and this variance may introduce differences in readings as we change test antennas and as we move from range to range with different test antenna heights.

Good testing and modeling protocols would specify all of the relevant factors applying to the comparisons involved. We sometimes do find these specifications. Unfortunately, we often don't. Without the specifications, comparisons in dBd-R (either M or R) are quite difficult to make. If we could only bring all antennas to a single test range with a single (large) set of dipoles and standardized conditions, we could likely establish the gain of each antenna over its standard dipole and then have truly precise comparisons among antennas. Someone has noted to me that the odds of the earth being struck by a meteor like the one which ended the reign of the dinosours are higher than the odds of the emergence of a universal test range. I really wish I could have disagreed with this individual.

For additional pitfalls of careless dBd-ing, see the next item on the Index.

Why I tend to stick to dBi

My antenna work includes the building of test models of antennas that are feasible to construct, but is devoted predominantly to modeling all sorts of antennas for all sorts of purposes. This factor alone suggests the use of a single standard for all comparisons, such as dBi. However, there are a number of reasons I tend not to use dBd except in special circumstances.

1. The relevant comparisons are not with a dipole. Very often, antenna comparisons are among antennas that do not include dipoles. In such cases, simply comparing gain figures in dBi tells us all we need to know and can know about the relative maximum gains of the antennas. For example, in comparing the gains of self-contained 1 wl wire-loop antennas, the best designs for a given purpose are the ones that are best within the group, and the group does not include a horizontal dipole.

Likewise, when contemplating whether it is worthwhile to increase the size of a Yagi for 20 meters from 3 to 4 elements, the dipole is not relevant. Rather, the relevant gain comparison is between both models and real antennas of 3 and 4 element design. The gain advantage is derived as easily from dBi as from any other system of gain numbers.

2. The relevant comparisons have only passing reference to maximum gain. Additional factors, such as elevation angle, beamwidth, etc., may be far more important than gain itself. For some applications, good antennas do not need gain relative to a dipole. But thay may require close specification of other antenna properties. Gain becomes a secondary specification for which dBi suffices nicely.

Range tests are another matter

If my work were primarily with real antennas, then dBi would become a problematical term. A test range

approximation of an isotropic radiator is an unlikely event anytime soon. Hence, antennas on test ranges must be compared to some standard, and the dipole is the most likely simple horizontally polarized candidate. If we accept this premise, then it is unreasonable to expect range testers to then correlate their results to a scheme of modeling in which the gain is converted to a value in dBi.

However, this situation makes it imperative that range testers specify a test protocol and comparison antenna for the evaluation of the procedure against good engineering practice. In many instances, the comparison antenna will not be a dipole (although amateurs often think only in terms of Yagi tests). Verticals require specification of a vertical standard of the appropriate class. Nothing substitutes for the revelation of detailed test protocols where range testing is at stake.

Conversion of the test situation to models--like any other case of modeling--is at best the most reasonable approximation we can develop. Absolute precision is unlikely in most instances. Hence, the conversion of range test results to modeling results--with the accompanying conversion of dBd-RR (with a clear specification of the standard dipole used) to dBi--is not an automatic process and is subject to varying degrees of adequacy.

Modeling of detailed test protocols, on the other hand, can yield some correlation factors among different test protocols. A model may substitute one standard dipole for another, may insert or remove test range objects affecting results, may change antenna heights with ease, etc. As a simple example, if Smith tests his antenna at 60' up and Jones tests his at 85' up, the differences in test results (all other facors being equal or equalized) can be at least tentatively resolved with effective modeling.

Whatever the prospects for such work in the future (for we have just begun to scratch the surface of effective modeling in antenna work), those who predominantly model will likely stick to dBi as the basic measure of maximum gain. Range testers will likely stick to dBd-RR, where the range test is a comparison to a dipole or other relevant standard.

Since I am mostly a modeler, I use dBi---mostly.

How High should my Dipole be?

Dipole Antennas - the Effect of Height Above Ground

I frequently hear the question: how high should my dipole be? Or alternatively, will my dipole work well at this or that height? Unfortunately, these questions can not be answered without first stating what you want the dipole to actually DO, i.e. how you plan to operate with it. Some possible goals for a dipole might be:

1. DX work.
2. Local work: nets and rag chewing.
3. Directionality: gain in one direction, or nulls in some other direction
4. Omni-directionality.
5. Feed point impedance of 50 ohms.

As you may surmise, many of these potential goals are mutually exclusive, or at least tradeoffs.
However, once you define what you want to do with your dipole, then you can look at the radiation patterns to see if it will accomplish those goals.

I make the assumption that anyone reading this understands that DX work requires a low angle of radiation, with gain in the favored direction being desirable. Nets and rag chewing require a much higher angle of radiation and an omni-directional pattern. A null aimed in some direction may be desirable in various situations. Something close to 50 ohms impedance will aide matching and power transfer to/from coax cable.

There are many other potential goals for a dipole, but the ones I have listed are those that are most dependent on it's height above ground. Thus this discussion will not touch upon the issues of multi - banded operation, tuned open wire feeders, and the like. So, lets limit the issue at hand to: how the character of a dipole varies with its height above ground.

To investigate this problem, I have modeled a hypothetical wire dipole using the EZNEC program (from W7EL). This model is well within the verified capability of EZNEC.

For those interested in the modeling details, this dipole, named D40M, has the following specifications:
Material: #12 copper wire.
Length: 69.057 feet.
Ground Type: good (.005,13) NEC Sommerfield.
Frequency: 7.00 MHz nominal, but the comparative patterns were computed by adjusting the frequency slightly for resonance at each height.

The dipole was modeled at various heights from .05 wavelengths (7 feet) to 4 wavelengths (560 feet) above

good ground. One may argue that 560 feet is ridiculous for a 40 meter dipole, but keep in mind that the data can be scaled down to a 10 meter dipole with similar results.

The table below tabulates the results. In the first two columns, the antenna's height above ground is given in wavelengths and in feet. The next two columns show the maximum gain in the favored direction (i.e. broadside to the wire), followed by the launch angle and the -3 dB vertical beam width. The next two columns once again present the gain and launch angle / beam width, but for the axial direction (off the ends of the wire). Finally, the last 2 columns list the complex impedance at the feed point, and the actual resonance frequency at that specific height.

Height	**Height**	**Fav Dir**	**Fav Dir**	**End Dir**	**End Dir**

***** Elevation plots shown below

Analysis, Favored Direction:

The first thing to notice is that the gain in the favored (broadside) direction varies very little with height. The important change in the broadside pattern occurs in the launch angle of the primary lobe. As the antenna

moves closer to the ground, the launch angle of radiation gets higher and the -3 dB vertical beam width becomes broader. Note that below the benchmark height of ½ wavelength, the launch angle increases rapidly. Once the dipole is lowered to 0.3 wavelengths, most of the radiation goes in a vertical direction. This explains the frequently heard "rule" that a dipole must be at least ½ wavelength high to work. The seeming anomaly with the beam width below 0.4 wavelengths is easier to understand by viewing the plots shown below.

Analysis, End-Fire Direction:

One frequently sees a dipole azimuth pattern depicting a very sharp null off of the ends of a dipole. While technically accurate, this can be very misleading as the table above shows, and is a result of trying to depict a 3 dimensional pattern in 2 dimensions. This often seen null is only evident at the same launch angle as the maximum broadside gain. Of major significance is the large amount of gain off the ends at higher launch angles. Due to multiple lobes forming above ½ wavelength, this is not easily shown in tabular form. I have arbitrarily chosen to list gain and launch angle for the secondary lobe with the lowest launch angle, but recognize that there is frequently a stronger primary lobe at higher angles. Consult the plots below for a better visualization.

Analysis, Feed Point Impedance:

The reference antenna length was chosen to resonate at the ½ wavelength height. As expected, the feed point impedance oscillates significantly as the height changes from our reference point. Thus we verify the old adage that you must trim the dipole to fit your particular QTH (height being very important). The corresponding resonant frequency for each height is shown in the last column for reference, since complex impedance's may be of less practical importance to some.

So, How High should the dipole be to work well?

Now we are back to looking at what we want the dipole to achieve.

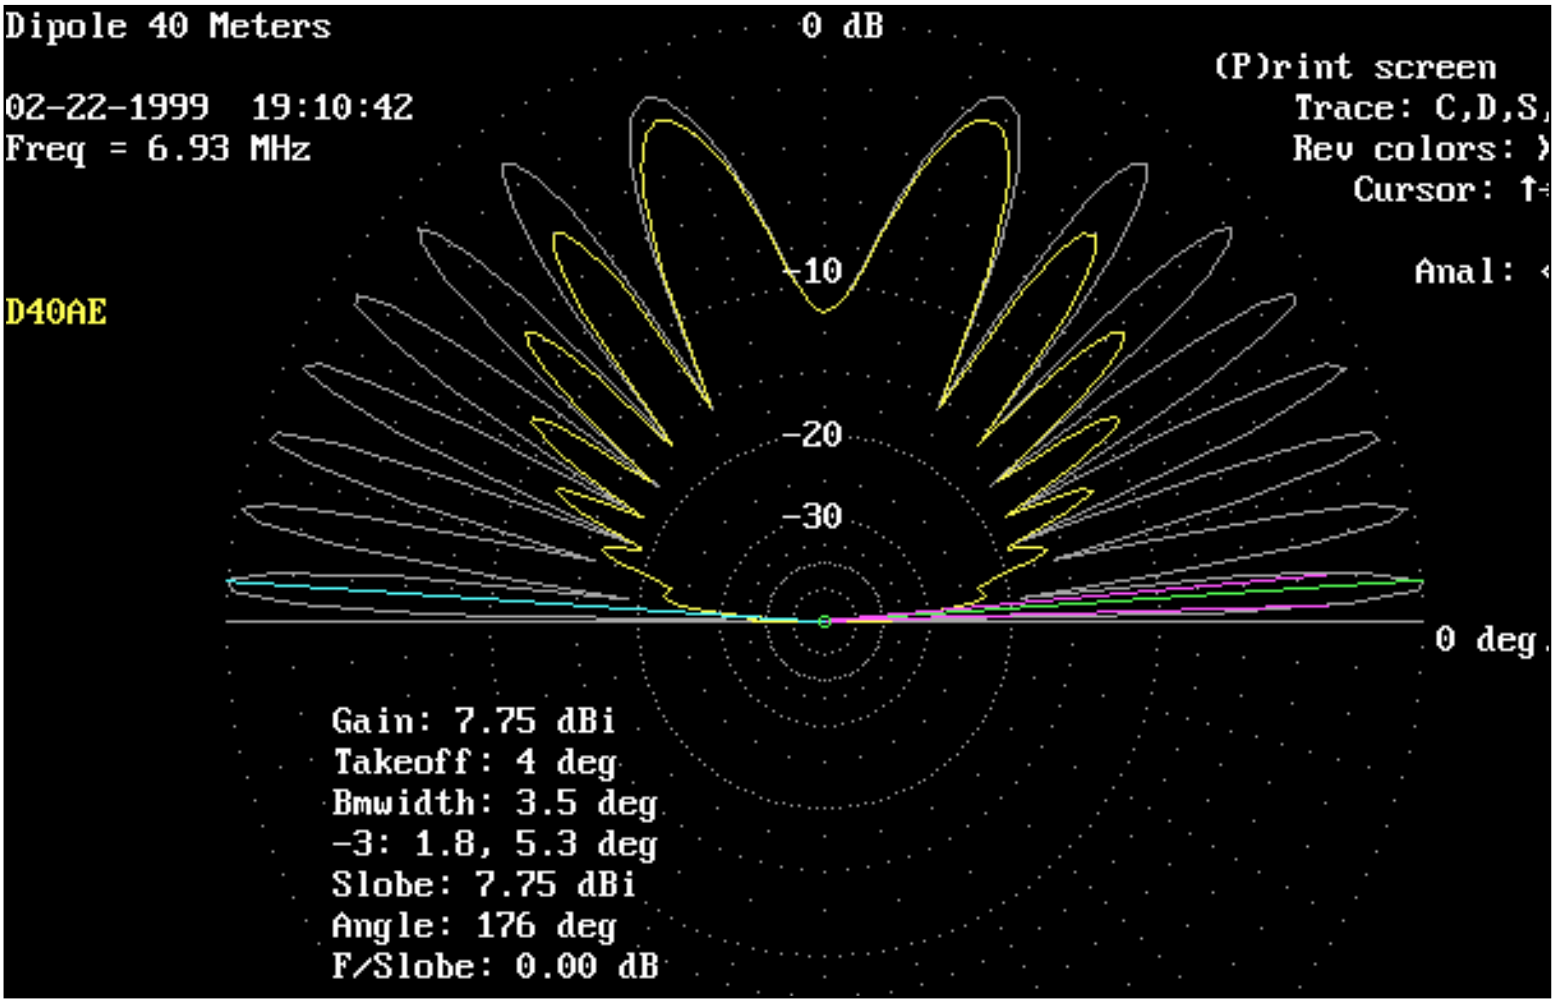
For DX work, higher placement is warranted, since more power concentrated between 5 and 15 degrees is reported to be of major benefit. Heights around one wavelength are necessary to get the broadside lobe to launch in this range. However, higher may not always be better. Pay careful attention to the magnitude of secondary lobes in the broadside direction, as well as high angle radiation off the ends. Some heights would appear better than others due to concerns with nulling out local QRM. A complete discussion of of this aspect is beyond the scope of this article, but may be investigated at a later date.

For local work, lower heights appear to be more beneficial. Note especially how omni-directional our dipole becomes at lower heights. Below 0.4 wavelengths, there is less than 1 dB of attenuation in the end fire direction, which suggests a height between 0.4 and 0.3 might be an ideal compromise for local nets and rag chewing.

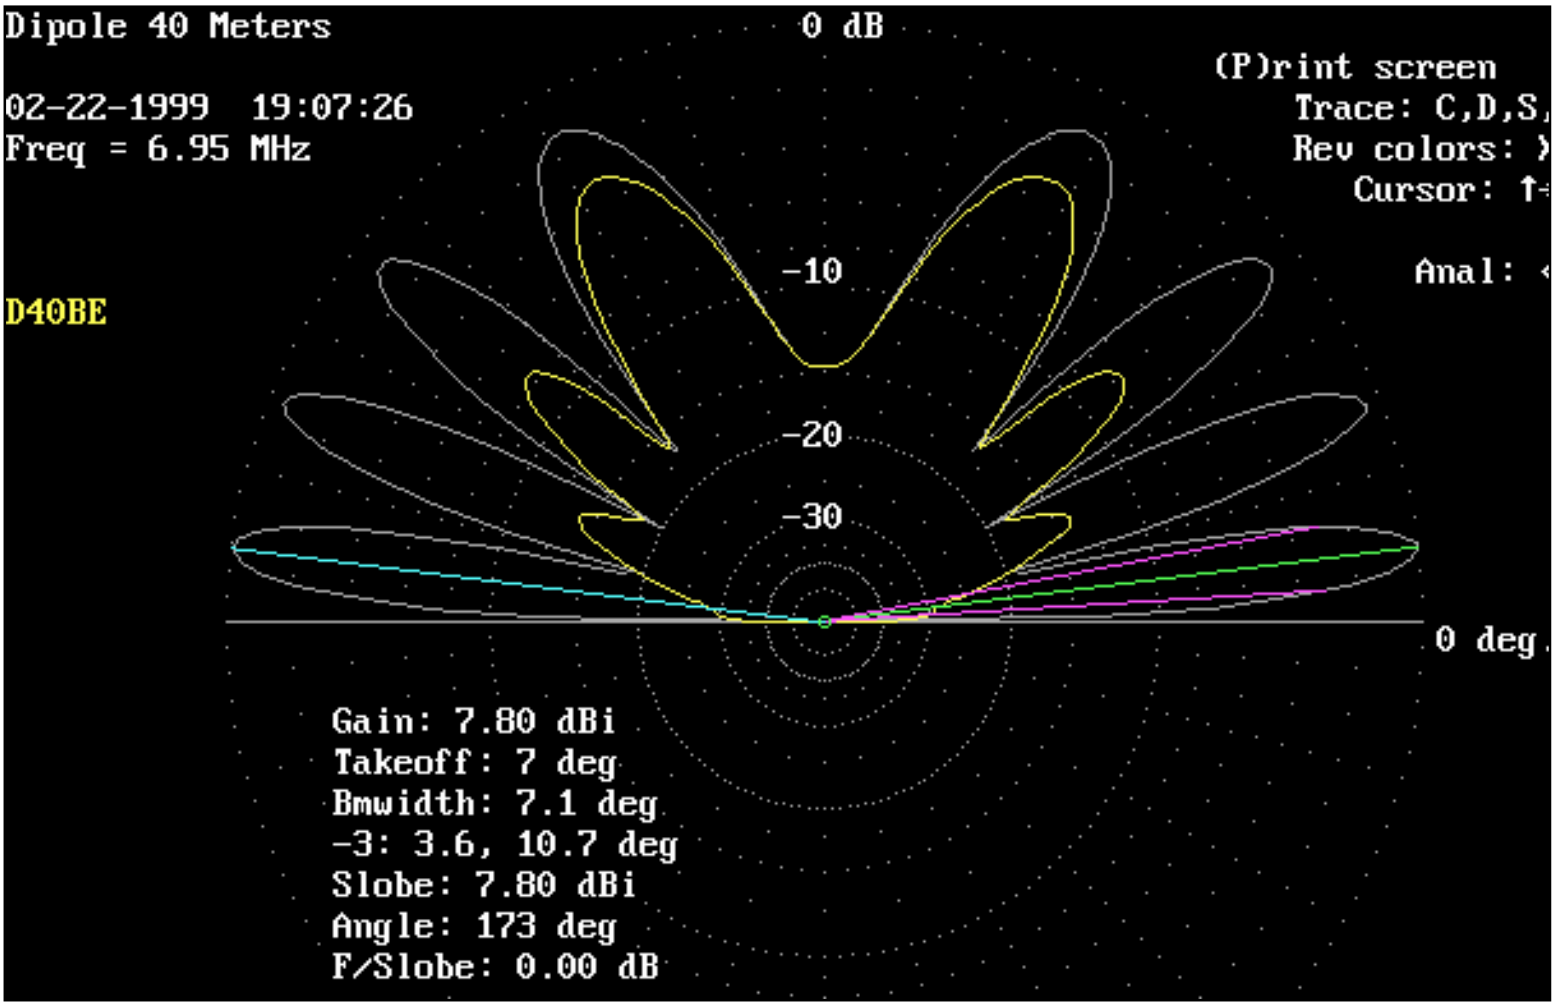
Feed point impedance and matching does not seem to be of major concern except at very low heights. The effect of height on 2:1 SWR bandwidth was not investigated.

Radiation Plots

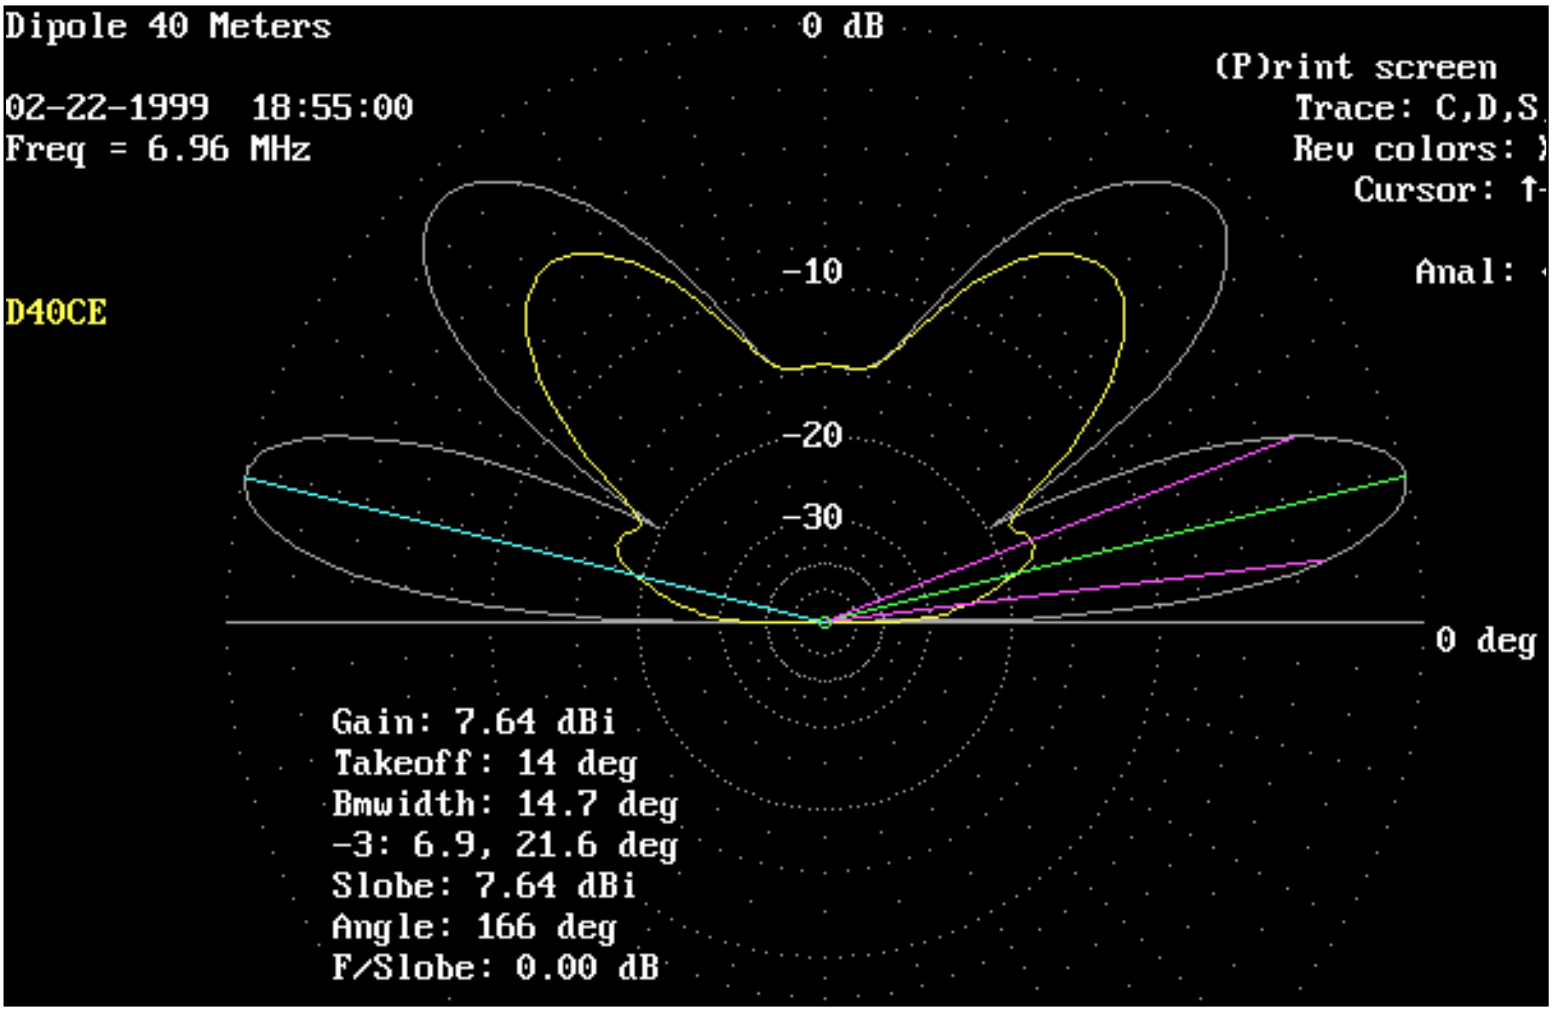
Our first plot shows the elevation pattern in both the broadside (white trace) and end fire (yellow trace) directions for a height of 4 wavelengths, or 560 feet. Note the substantial high angle radiation in all directions, in addition to the excellent low angle lobes.



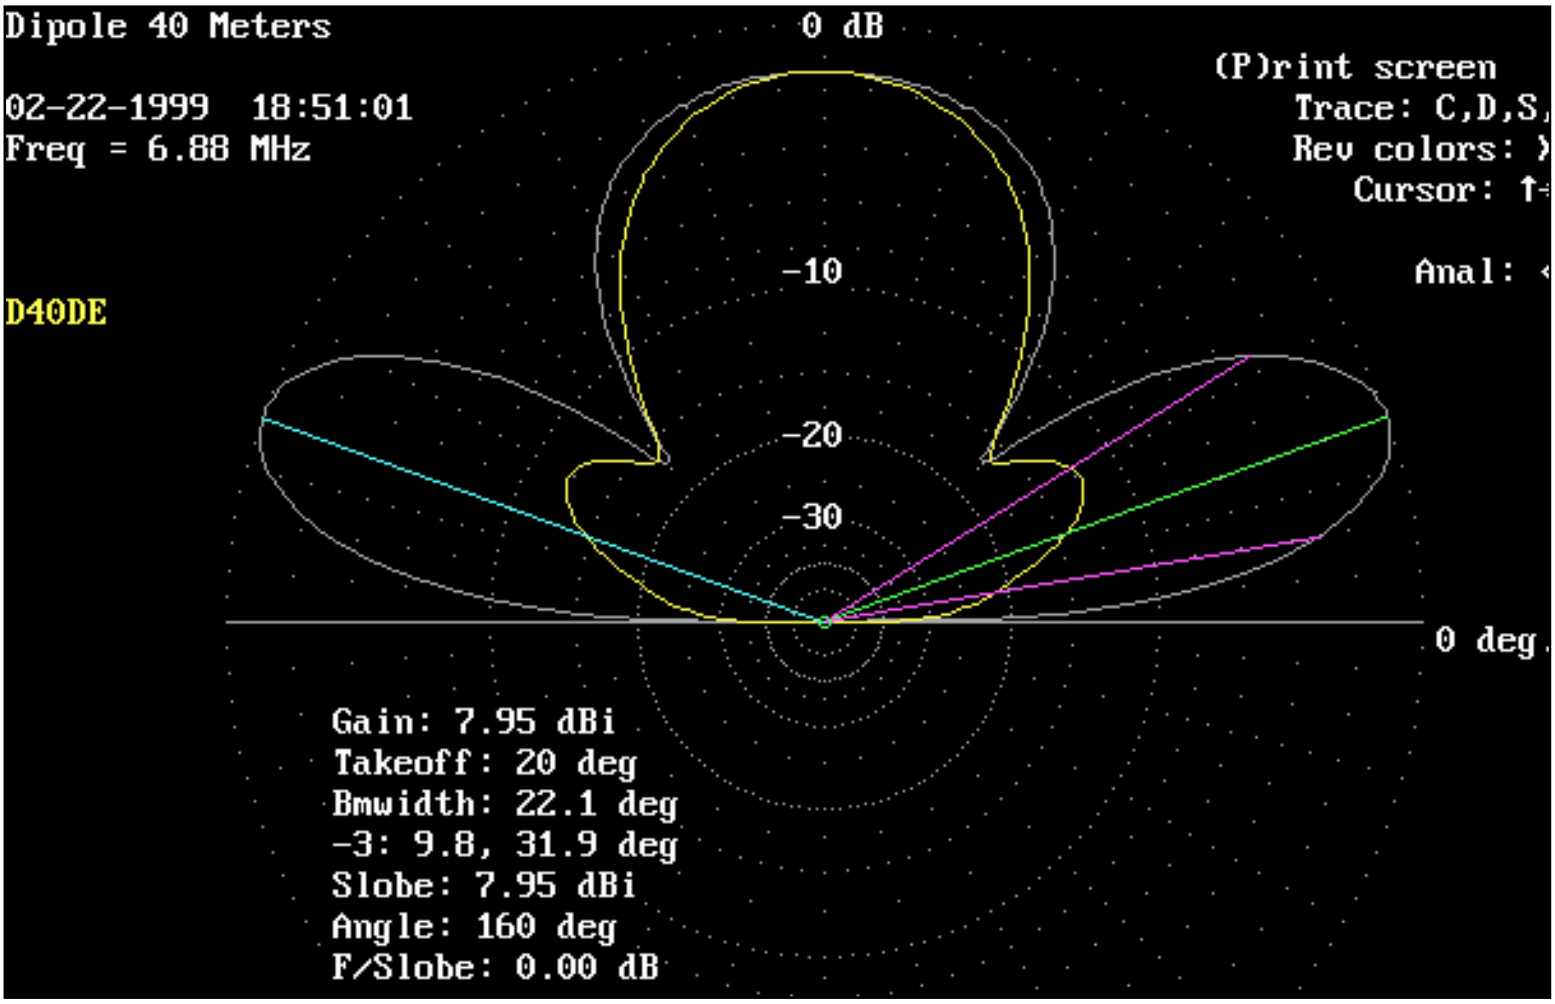
This plot shows the elevation patterns at a height of 2 wavelengths, or 280 feet.
White trace is broadside. Yellow trace is axial (off the ends).
Still Lots of high angle radiation.



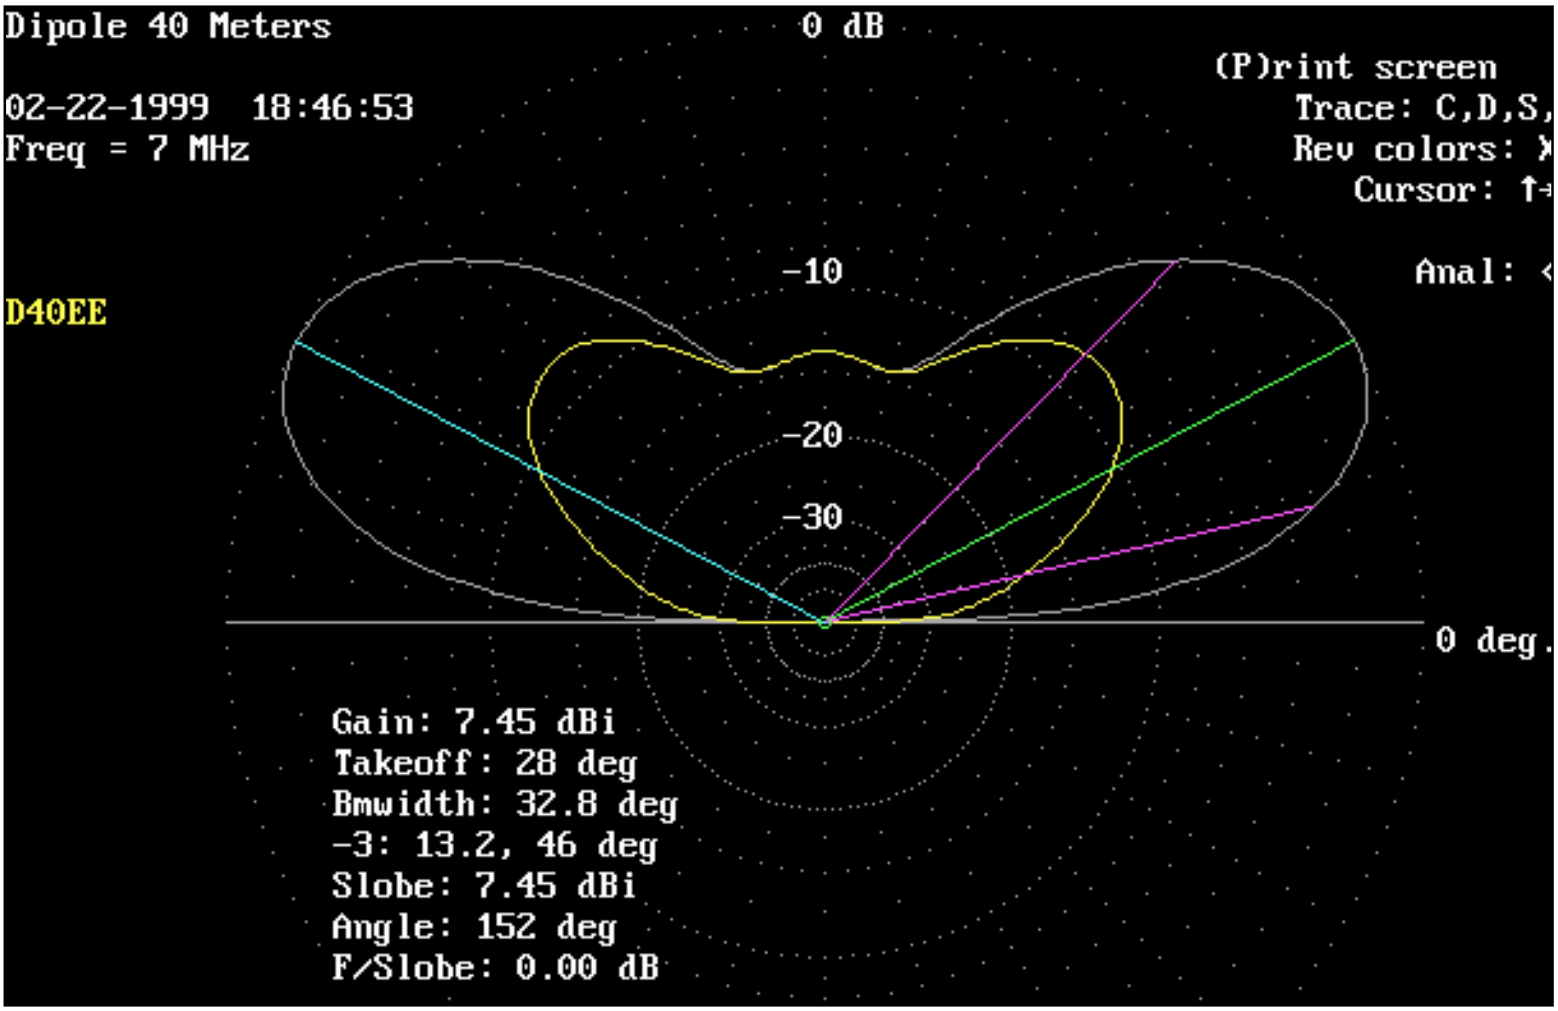
This plot shows the elevation patterns at a height of 1 wavelength, or 140 feet.
White trace is broadside. Yellow trace is axial (off the ends).
The secondary lobe is down to 47 degrees, but the primary lobe is up to 14 degrees.



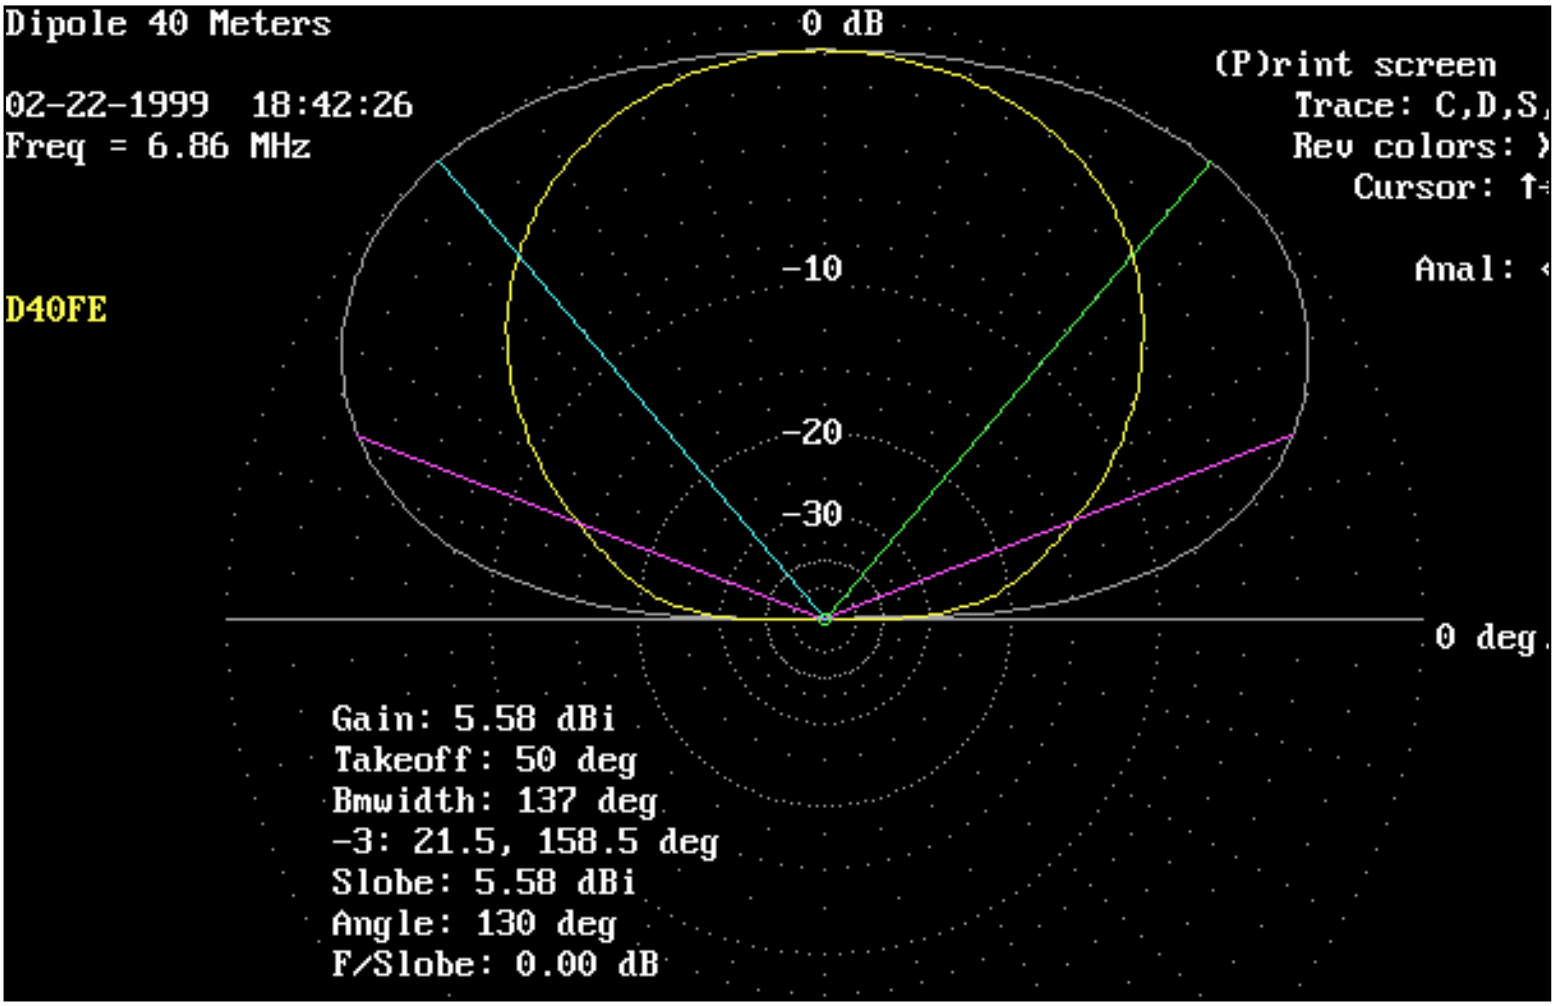
This plot shows the elevation patterns at a height of 0.7 wavelength, or 98 feet.
White trace is broadside. Yellow trace is axial (off the ends).
The primary lobe is up to 20 degrees.
Note the large vertical lobe which has appeared!



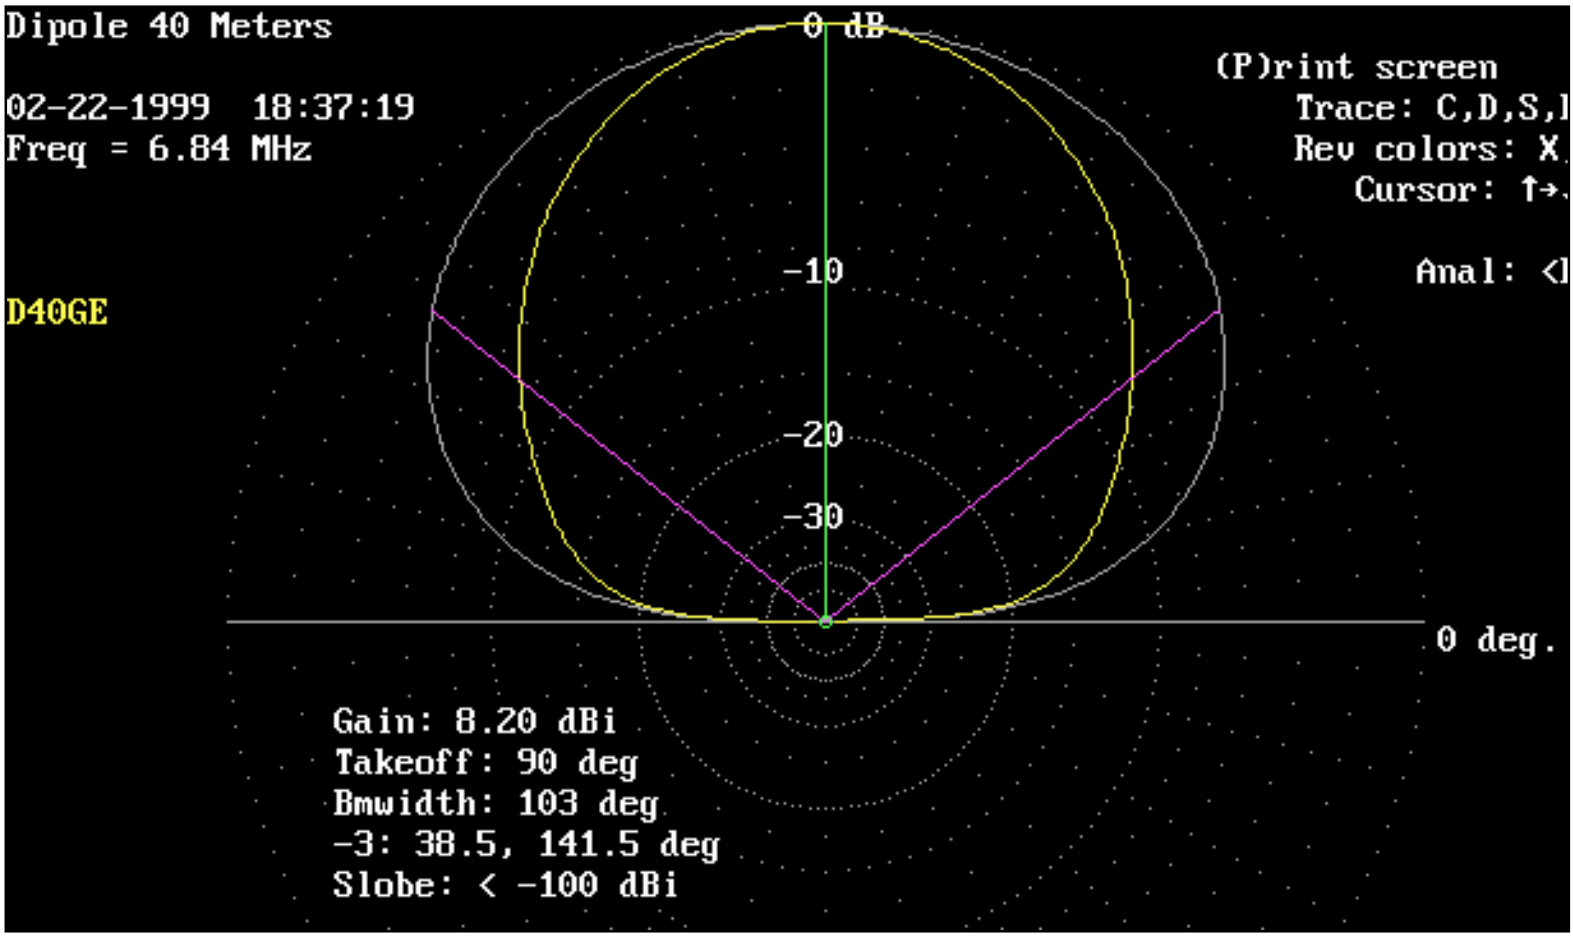
This plot shows the elevation patterns at a height of 1/2 wavelength, or 70 feet.
White trace is broadside. Yellow trace is axial (off the ends).
Now that's a classical dipole pattern!



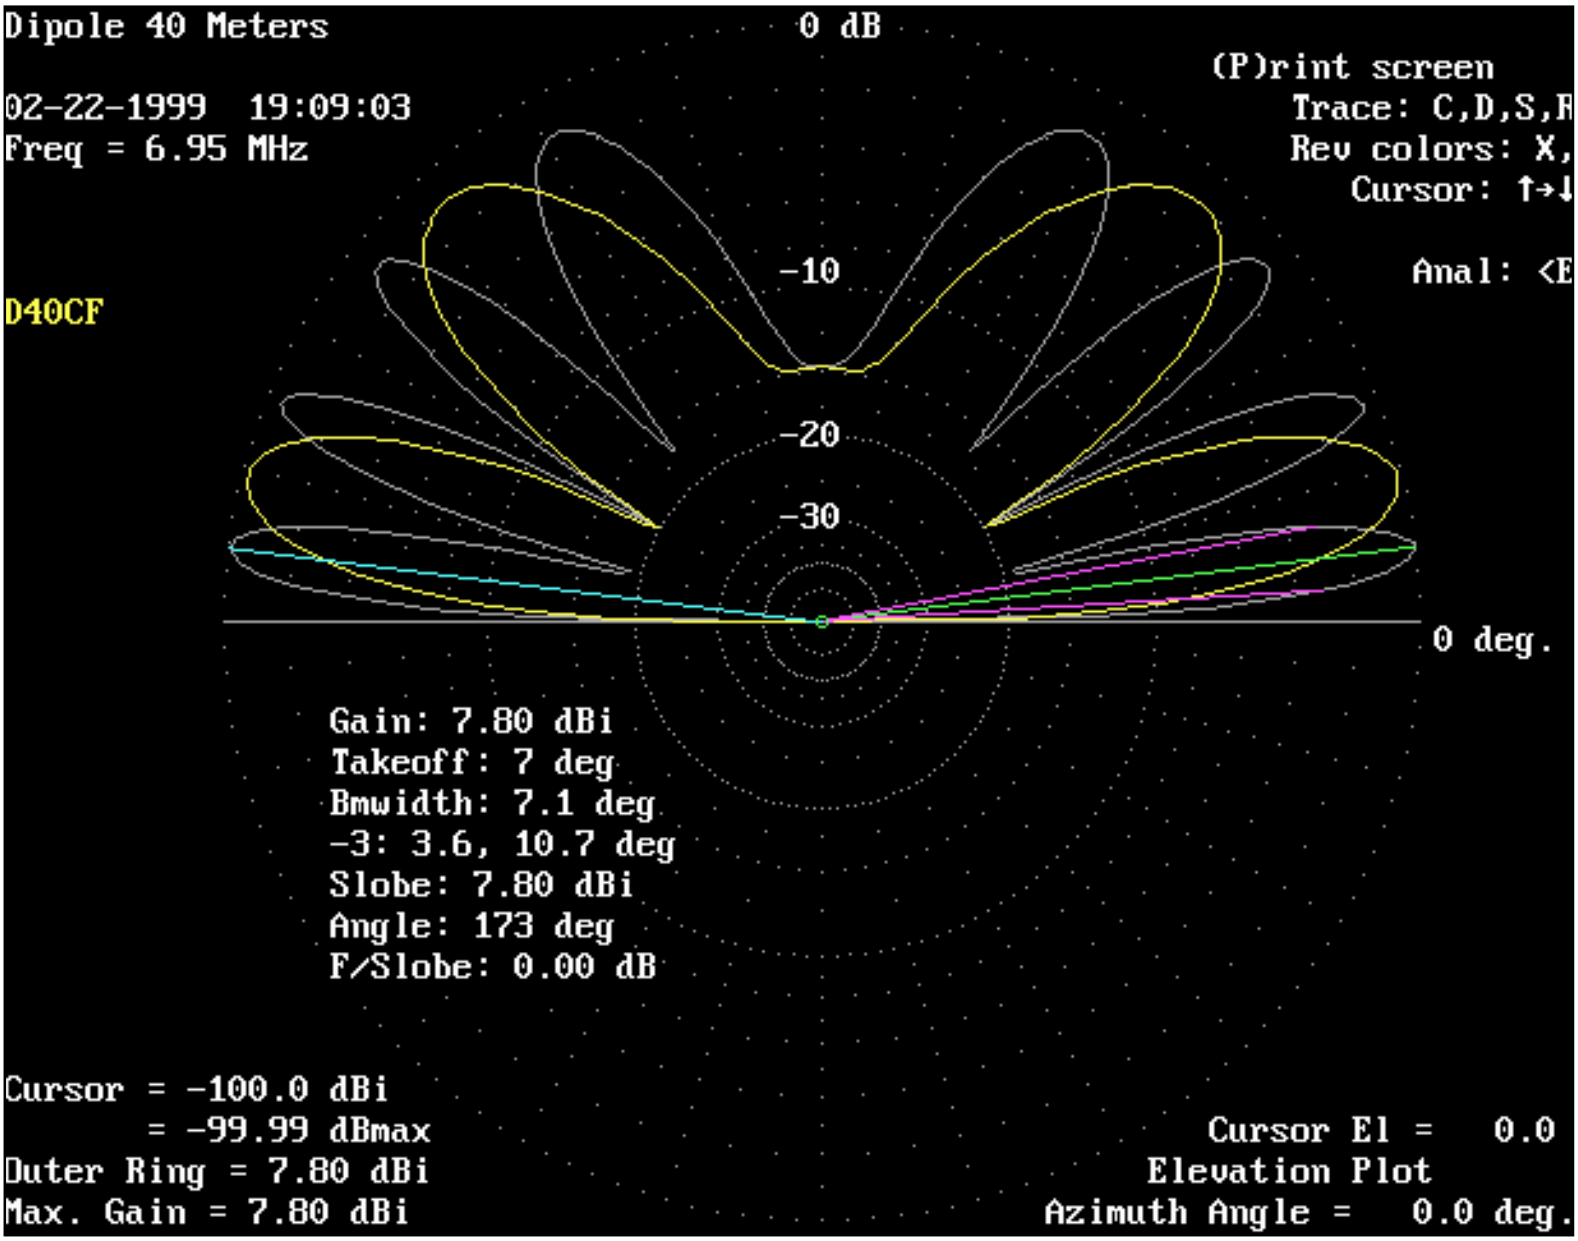
This plot shows the elevation patterns at a height of 0.3 wavelength, or 42 feet.
White trace is broadside. Yellow trace is axial (off the ends).
We are entering the "skywarmer" mode here.



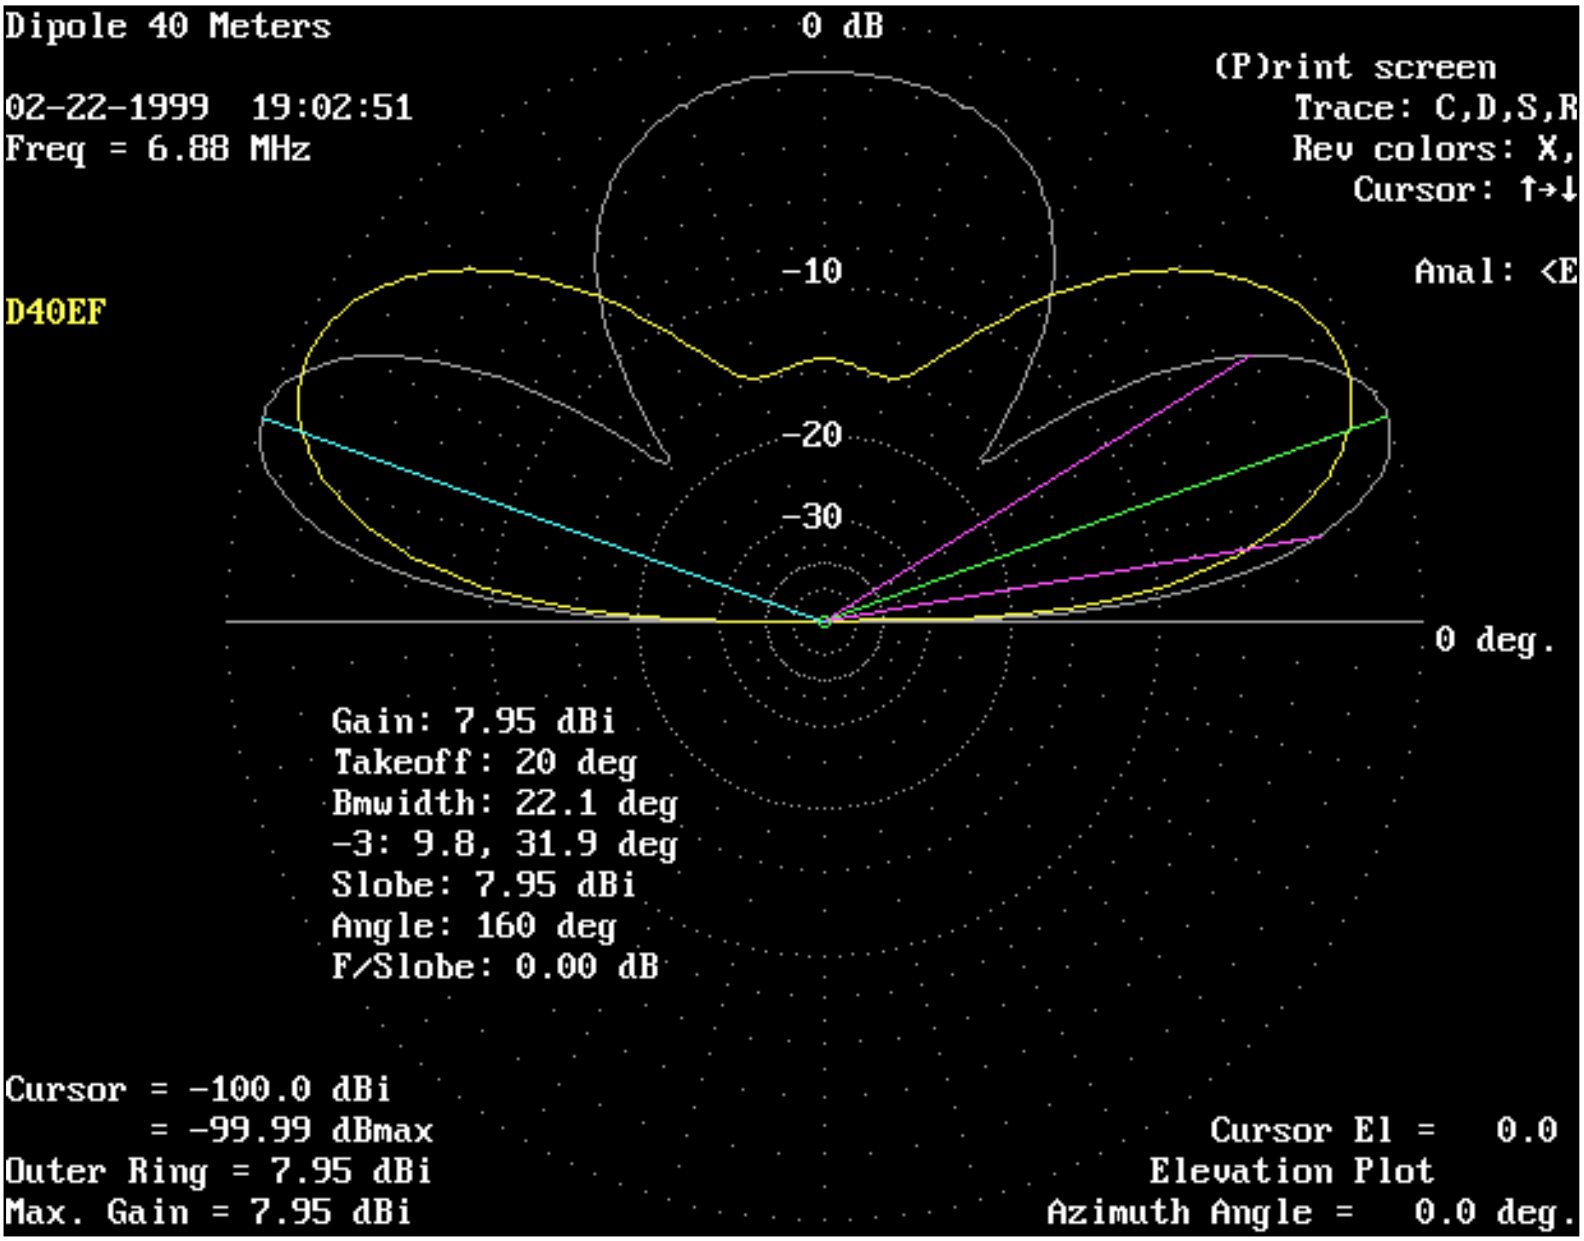
This plot shows the elevation patterns at a height of 0.1 wavelength, or 14 feet.
White trace is broadside. Yellow trace is axial (off the ends).



This plot shows comparative elevation patterns, in the broadside direction only,
White trace is for 2 wavelengths, 280 feet.
Yellow trace is for 1 wavelengths, 140 feet.



This plot shows comparative elevation patterns, in the broadside direction only.
White trace is for 0.7 wavelengths, 98 feet.
Yellow trace is for 0.5 wavelengths, 70 feet.



This plot shows comparative elevation patterns, in the broadside direction only.
White trace is for 0.5 wavelengths, 70 feet.
Yellow trace is for 0.3 wavelengths, 42 feet.
Pink trace is for 0.1 wavelengths, 14 feet.

Antenna Tuner Operation

I'm a little confused about how antenna tuners function in terms of reducing antenna system SWR. Is it true that an antenna tuner does not really 'tune' the antenna? And if an antenna is cut to resonance already, what good is a tuner?

Yes, it's true-an antenna tuner doesn't really tune your antenna in the strict sense of the word. It does not, for example, adjust the lengths of your antenna elements, their heights above ground and so on. What an antenna tuner or transmatch does do, however, is transform the impedance at the feed line input to a value that your transceiver can handle (typically 50 Ohm-see Figure 1). When thinking about antenna tuners and SWR, it's important to remember that the tuner has no effect whatsoever on the SWR between itself and the antenna. It's the SWR between the tuner and the transceiver that changes.

In practical terms, all a tuner does is act as a kind of adjustable impedance transformer between the antenna system and the radio. It takes whatever impedance the antenna system presents and attempts to convert it to 50 Ohm--or something reasonably close to that value--for the transceiver. When the transceiver "sees" a 50 Ohm impedance, it is able to load its maximum RF output into the system. That power is transferred through the antenna tuner, to the feed line and, ultimately, to the antenna--minus any losses incurred along the way.

These losses are the reason that the highest efficiency feed-line for each individual case is desirable and why some amateurs use ladder line.

What is the correct way to tune an antenna tuner?

Most antenna tuners have an inductance rotary switch and two capacitors. The capacitors are often labeled ANTENNA and

TRANSMITTER. In some antenna tuners the inductance switch is replaced with a continuously variable inductance, popularly known as a roller inductor.

Let's assume you're using a tuner with an inductance switch, because they are the most common. Place both capacitor controls at their mid-range positions. Don't trust the knob markers if this is your first experience with the tuner; remove the cover and turn the knobs until the moving capacitor plates are only half meshed with the stationary plates. If the knobs are pointing to half scale, consider yourself lucky. If not, loosen their Allen nuts and rotate the knobs so that they point to mid scale. Replace the tuner cover and you're ready to go.

Turn the radio on and, with the ANTENNA and TRANSMITTER controls at mid scale, crank the inductance switch until you hear the loudest noise or signals coming into your radio. Then, rotate the ANTENNA and TRANSMITTER controls until you get to the absolutely loudest noise or signal level on the radio. This should be close to your best tuning spot.

With your rig set to low power, send an ID then transmit a continuous carrier while you tweak the ANTENNA and TRANSMITTER controls for the lowest reflected power reading with the highest output power as read on the SWR meter. You may find that you have to vary the position of the inductance switch a position or two to get your best match. Be gentle to your radio; keep the key-down periods as short as possible.

Depending on the impedance at the antenna input (and the overall design of the tuner) you may not be able to obtain a flat 1:1 SWR on all frequencies and bands.

Plus, a Morse code course. Instructor lesson modules, for use with *Now You're Talking!*

Do You Need an Antenna Tuner?

Maybe yes, maybe no. It all depends on the type of antenna and feed line you're using.

By Steve Ford, WB8IMY
Assistant Technical Editor

There is a great cloud of mythology surrounding antenna tuners, particularly when the conversation turns to what they can and cannot do. Make no mistake, they are useful devices in the right applications. The trick is deciding whether you need one!

When Rigs and Antenna Systems Disagree

Every antenna has an *impedance* expressed in *ohms*. The same is true of the feed line you use to connect your transceiver to the antenna. Impedance sounds like a complicated beast and, to a certain extent, it is. In simplest terms, it is a combination of *inductive reactance*, *capacitive reactance* and garden-variety *resistance*.

It's probably best to avoid a long discussion about the meaning of reactance. This is "New Ham Companion," not the *Proceedings of the IEEE*. If I had several more pages to devote to this article, I'd be more than happy to bore you to tears with reactance theory. For our purposes, think of reactance as opposition to the flow of an ac signal in a circuit. In this case, the ac is the RF generated by your transceiver and the circuit is your antenna system. File this idea away for the moment. We'll come back to it later.

Meanwhile, back at the radio ranch....

The impedance of the antenna depends on a number of factors, including the length, operating frequency, height above ground, proximity of metal objects and even weather conditions (such as ice on the antenna). The impedance of the feed line depends on how the cable is constructed.

Your feed line does more than simply connect your radio to your antenna. It acts as an impedance *transformer*. That is, the impedance of your antenna is transformed by the feed line into the value your radio "sees" when you connect it to the cable. This *system impedance* acts as a *load* for the energy created by your radio—just like a light bulb is a load for the energy supplied by a battery.

Most amateur transceivers are designed to work with a load impedance of 50 ohms. When your radio sees an impedance of 50 ohms, or something close to it, you're on easy street. You press the mike switch, close the CW key or type on your keyboard and all is right with the world.

But what happens when the impedance *isn't* 50 ohms? Now you have a situation known as a *mismatch*.

When a mismatch exists, a certain portion of the power generated by your radio is *reflected*—like light is reflected by a mirror. This reflected power comes shooting back down the cable to your radio. When it reaches the radio, it is reflected back toward the antenna. The reflected power combines with the *forward* power being generated at the radio to create *standing waves* in the feed line.

By using a *standing-wave-ratio* (SWR) meter, you can measure both the forward and reflected power. A 1:1 SWR reading indicates that no power is being reflected back to your radio. This is good. On the other hand, an SWR of 3:1 or more means that a substantial amount of power is being reflected. This is usually bad. (Don't you love these simple concepts?)

A high SWR can cause considerable RF voltages to develop in the feed line and in the output circuits of your radio. This is a dangerous condition for your rig—especially if it is a modern solid-state transceiver. To prevent this, many radios manufactured within the past 10 years include SWR protection circuits. When the SWR gets too high, these circuits automatically reduce the output power or, in some cases, shut down the transceiver altogether (see Fig 1). Older tube radios are much more forgiving, but even they can be damaged when operated under high SWR conditions.

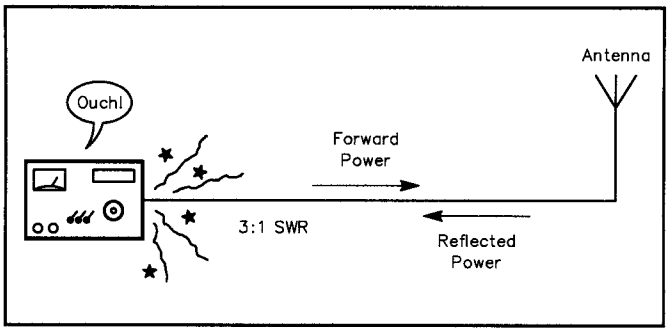

Fig 1—Most transceivers are designed to expect an antenna system impedance of 50 ohms. When the antenna impedance is something other than 50 ohms, a transmission line mismatch occurs and a portion of the RF power is reflected back to the radio. *Standing waves* are created in the feed line and high RF voltages can develop. When the *standing-wave ratio* becomes higher than 3:1, your transceiver may be damaged.

If your antenna system presents a serious mismatch to your radio, what can you do? If you connect your transceiver directly, the protection circuitry will drop your output like a rock. Worse yet, you may find yourself on the receiving end of an expensive repair bill. You need to provide a 50-ohm load for your transceiver—regardless of what is really present. One way to accomplish this is by using an antenna tuner.

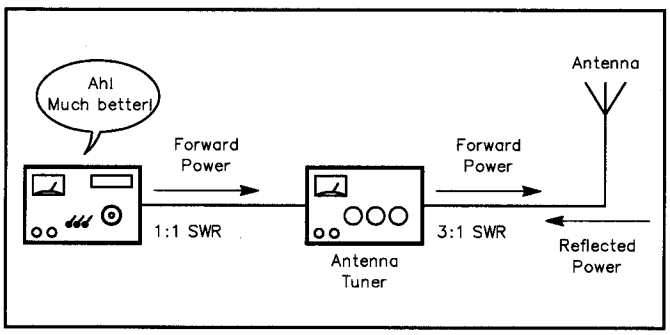

Fig 2—By using an antenna tuner, you can adjust the impedance your transceiver "sees" to a hospitable 50 ohms. The antenna mismatch to the line still exists, but the tuner protects your radio from the RF voltages while allowing it to develop its maximum output.

How Does an Antenna Tuner Work?

In its most basic form, an antenna tuner is simply a network of variable inductors (coils) and capacitors. By adjusting the coils and capacitors, you counterbalance and cancel the effects of the inductive and capacitive reactance at the *transceiver* end of the feed line. (*Now* you know why I bothered bringing up the subject of reactance in the first place!) As the reactances are canceled, the impedance at the transceiver is transformed to 50 ohms (see Fig 2).

As far as your transceiver is concerned, the load impedance is matched and it's free to dump all of its power into the antenna system.

I bet a number of you are saying to yourselves, "*Wait a minute!* The impedance at the transceiver side of the tuner is 50 ohms, but it's still some other value at the antenna side. All you've done is shift the mismatch problem from the transceiver to the tuner!"

You're right. The mismatch still exists, but now it's at the output of the antenna tuner instead of the transceiver. By using the tuner, we're protecting the radio while still allowing it to develop maximum output. If the tuner is well designed, it should be able to handle the RF voltages and currents caused by the high SWR.

Of course, the reflected power is still bouncing back and forth between the antenna tuner and the antenna. Some of this power is lost in the feed line. If you're using low-loss feed line, however, most of it is radiated at your antenna. In the meantime, your transceiver is happy and you're happy. Who could ask for more?

Use an Antenna Tuner if...

...you want to feed your antenna with open-wire line.

Open-wire line (or *ladder line*) offers extremely low loss at HF frequencies (much better than coaxial cable). One problem is that open-wire line is *balanced* while your transceiver output is *unbalanced*. You need to use an antenna tuner with a built-in *balun* to form a bridge between the balanced line and the unbalanced output of your radio. A balun is a type of transformer that converts balanced feed lines to unbalanced, or vice versa. (***BAL***anced to ***UN***balanced. Get it?) Most antenna tuners use 4:1 baluns that also convert the impedance of open-wire feed lines to a value that the tuner can handle.

...you want to operate your antenna on bands other than those it was designed for.

When you attempt to use, say, a 40-meter dipole on 10 meters, a big mismatch will develop, along with a high SWR. By using an antenna tuner, you may be able to create a 1:1 SWR at your transceiver. (I say "may" because the mismatch can sometimes be so great that it is beyond the capability of your tuner to handle.) The high SWR may cause substantial loss in a coaxial feed line, but at least you'll radiate *some* power at the antenna.

...your antenna has a narrow *SWR bandwidth* on some bands.

Some types of multiband antennas do not offer low SWRs from one end of each band to the other. There is usually a range—expressed in kilohertz—where an SWR below 2:1 can be achieved. For example, a multiband trap dipole may offer an SWR of 2:1 or less from 3600 to 3800 kHz. That's an SWR bandwidth of 200 kHz. If you try to operate above 3800 kHz or below 3600 kHz, you'll encounter an SWR higher than 2:1 and your radio may become displeased. With an antenna tuner, you can operate outside the SWR bandwidth and still load the full output of your radio into the antenna system.

Don't Bother with an Antenna Tuner if...

...your SWR is 1.5:1 or less at the frequencies you operate most often.

An SWR of 1.5:1 or less is not serious and does not require the assistance of an antenna tuner. Most modern rigs will tolerate a 1.5:1 SWR just fine. In fact, many will be happy at an SWR of 2:1. If you are using a good-quality feed line, the loss caused by an SWR of 1.5:1 or even 2:1 isn't enough to worry about at HF frequencies. Many hams are obsessed with providing an absolute 1:1 SWR for their radios at all times. Apparently they also have money to burn!

...you have a high SWR at VHF or UHF frequencies.

VHF/UHF antenna tuners are available, but my advice is to save your money. Remember that an antenna tuner massages the antenna system impedance *at the transceiver*. The mismatch still exists and the SWR is still high at the antenna side of the tuner. Even the best coaxial cables have significant losses at VHF and UHF when the SWR is high. A VHF/UHF antenna tuner will make your radio happy, but most of its power will never make it to the antenna. The best approach is to correct the mismatch at the antenna by adjusting whatever tuning mechanism it provides. If the antenna cannot be tuned, check the cable for defects and make sure you've installed the antenna properly.

...you're interfering with TVs, telephones and other appliances in your neighborhood.

Despite what you may have heard, an antenna tuner will not necessarily cure your interference problems. It's true that most antenna tuners will reduce the level of *harmonic radiation* (signals your radio generates in addition to the ones you want), and if the interference is being caused by harmonics, a tuner may help. Most interference, however, is caused by RF energy that's picked up indirectly by cables or wires, or directly by the device itself. By using an antenna tuner, you'll probably radiate more energy at the antenna than you did before. That may make your interference problem worse!

Looking for Mr Goodtuner

So, you've decided that you need an antenna tuner after all. Antenna tuners come in all shapes and sizes. What features should you consider?

❑ **A built-in SWR meter**—An SWR meter of some type is a must if you want to use an antenna tuner. When adjusting your tuner, you need to keep your eye on the *reflected power* indicator. Your goal is to reduce the reflected power to zero—or at least as close as you can get. When the reflected power is zero, the SWR is 1:1 at your transceiver.

Many tuners feature built-in meters. If not, you can purchase one separately. Your radio may even have its own SWR meter.

❑ **A roller or tapped inductor**—More expensive tuners feature a variable coil called a *roller inductor*. As you turn the front-panel inductor knob, the coil inside the tuner rotates. A metal wheel rolls along the coil like a train on a railroad track. As the wheel moves along the coil, the inductance increases or decreases.

Less expensive tuners do not use roller inductors. Instead, there is a coil with wires attached at various points. On the front panel, a rotary switch selects the wires. According to how the inductor is wired in the circuit, selecting one *tap* or another

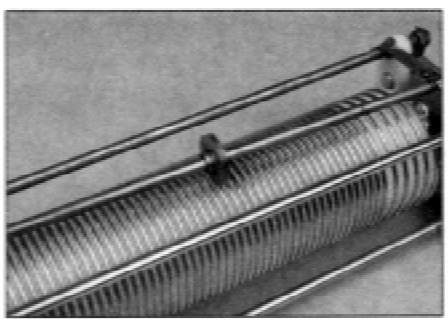

Fig 3—This is a typical roller inductor. Notice the wheel that rolls along the coil windings. As the wheel moves, the inductance changes.

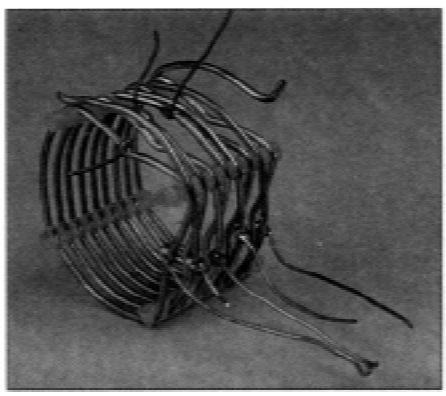

Fig 4—Tapped inductors have wires attached at various points. By selecting a particular wire, you get a fixed amount of inductance.

varies the inductance. This is known as a *tapped inductor.*

There are advantages and disadvantages to both approaches. Roller inductors offer the best tuning performance, but they are subject to the woes of mechanical wear and tear. For example, if corrosion builds up on the wheel or the coil windings, the electrical quality of the connection will deteriorate. Roller inductors are also cumbersome to use. You may have to twist the control many times when moving from one band to another.

Tapped inductors are easy to use and free of mechanical problems (unless the switches get dirty). However, you may find that they restrict the operating range of your tuner. When you turn the switch, you select a *fixed* amount of inductance. You can't easily change it to tune a particularly difficult mismatch situation.

❑ **A built-in balun**—If you intend to use an open-wire feed line, buy a tuner with a built-in 4:1 balun. These baluns often dissipate quite a bit of heat, so always choose a large balun over a small one.

❑ **Multiple antenna capability and dummy loads**—Some tuners offer the ability to connect more than one antenna. This is handy in all sorts of applications. Let's say you have a vertical antenna for 40-10 meters and a wire dipole for 80 meters. You can connect both feed lines to your tuner and easily switch between them.

Built-in dummy loads are convenient, but not necessary. A dummy load is a resistor (or group of resistors) that absorbs the output of your transceiver while allowing very little energy to radiate. It's used for making transmitter adjustments and other tests. If your tuner lacks a dummy load, you can purchase one separately.

❑ **Automatic operation**—Most transceiver manufacturers offer *automatic* antenna tuners. These tuners are usually built in the radio itself, or they're offered separately. Automatic tuners are convenient when you need to change bands or frequencies quickly. You simply push a button and your tuner adjusts its coils and capacitors to achieve the lowest SWR. Some automatic tuners sense when you've changed frequency and will readjust immediately! (You don't have to lift a finger.)

Automatic antenna tuners are expensive and their tuning range is limited. If your operating style requires you to jump from band to band rapidly (contesting is one scenario), consider an automatic tuner. Otherwise, conserve your cash and invest in a manual tuner.

A Word About Power Ratings

If your transceiver produces only 50 or 100 watts of power, a 200- or 300-watt tuner should do the trick, right? Well...yes and no. Remember what we said about mismatches causing high RF voltages in the tuner? If you're trying to use your tuner in a high-SWR situation, the RF voltages at the tuner may cause an unpleasant phenomenon known as *arcing*. That's when the RF energy literally jumps the gaps between the capacitor plates or coil windings. When your tuner arcs, you'll usually hear a snapping or buzzing noise. The reflected power meter will fluctuate wildly. Interference to your TV and other devices will increase dramatically. You may even see brilliant flashes of light inside your tuner!

Arcing is obviously bad news for your tuner. It's your tuner's way of saying, "Stop! I can't handle this mismatch!" There are two cures for arcing: reduce your output until it stops, or get a tuner with a higher power rating.

High-power tuners use large capacitors and coils. The gaps between the plates and windings are greater, making it more difficult for an arc to occur. If you can afford it, you're always better off buying a tuner with a 1.5 kW rating or better. (The exception is QRP operating where you're running low power levels.) A hefty tuner costs more, but it will serve you well in the long run.

Buy or Build?

As you comb through the advertising pages of *QST*, you'll see many new antenna tuners for sale. The prices are often reasonable and the quality is usually good. Keep your eyes open for used tuners, too. If an old tuner is in decent condition, it's every bit as usable as a new one.

If you like to build things, however, consider an antenna tuner as your next project. Antenna tuners are relatively easy to construct. You can find capacitors and coils at hamfest flea markets at low prices. Even roller inductors—the most expensive part of a roller-inductor tuner—can be found for less than $40 if you look carefully.

Your chances of success with an antenna tuner project are excellent. You have to try pretty hard to build one poorly! Best of all, you'll have the satisfaction of using a piece of equipment that you've put together yourself. The *ARRL Handbook* offers several tuner designs you can try. Heat up your soldering iron and go to it! QST

Radio Tips:

Log it or Lose it

Back in the old days (not all *that* long ago!), the FCC required every amateur to keep a detailed station log. (In addition to regular QSOs, hams even had to log unfruitful CQ calls.) And although we're not required to keep a log nowadays, an accurate station log is useful not only today, but tomorrow, too.

We all have things we like to keep track of: states and countries worked and confirmed; information for awards; or the names and addresses of our on-the-air friends. A well-kept station log is invaluable in your quest for the Worked All States or the DX Century Club (DXCC) awards. In addition to keeping a running list of states and countries, your logbook is the perfect place to keep detailed information on a wide range of subjects.

Your logbook is also a good place to keep notes on modifications to your equipment. Not only will the information be easy to find for future reference, it will be easier to note the effects of such changes by referencing contacts before and after.

How does your new loop antenna compare with your old trap vertical? Check out the signal reports in your logbook and you'll have a good idea!

DXers often refer to their logs when trying to work into specific parts of the world. When is the best time to work Africa in the winter? A quick check of last year's log entries will probably turn up the required information.

While you're at it, why not keep other changes in your log? When you upgrade, note it in your log. When you get a new rig or put up that long-awaited tribander, write it down. Ten years down the road, your log entries will bring back a flood of memories!

Speaking of memories, poring through your old logbooks can be a lot of fun. You'll come across your first QSO and remember how nervous you were, or you'll come across rare DX stations you've worked, pileups you've busted or the first time you worked someone special. Reliving those events is almost as much fun as it was when it happened!

Computers have become quite popular in ham shacks across the country—especially those belonging to contesters and DXers. If you have a PC in your shack, you might want to consider keeping your station log on your computer. A number of suitable programs are available. Check the ads in *QST*. Logging programs may also be available through your local club or computer user's group. If you're into programming, consider writing your own logging software.

If you do go the computer route, remember to keep regular backups and a hard copy of your log information—otherwise, the benefits of having instant access may be lost if your data disks are lost or damaged.

If computerized logging isn't your thing, *The ARRL Logbook* is just what you've been looking for. Used by thousands (millions?) of hams over the years, the latest version is available from the ARRL for $3.50. It has room for nearly 1000 QSOs and includes useful information such as Q signals, a time-conversion chart, the ITU phonetic alphabet, an RST chart, international call sign prefixes and more.—*NTØZ*

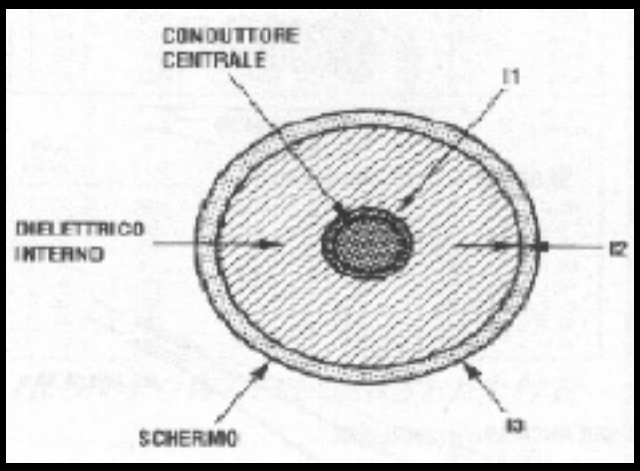
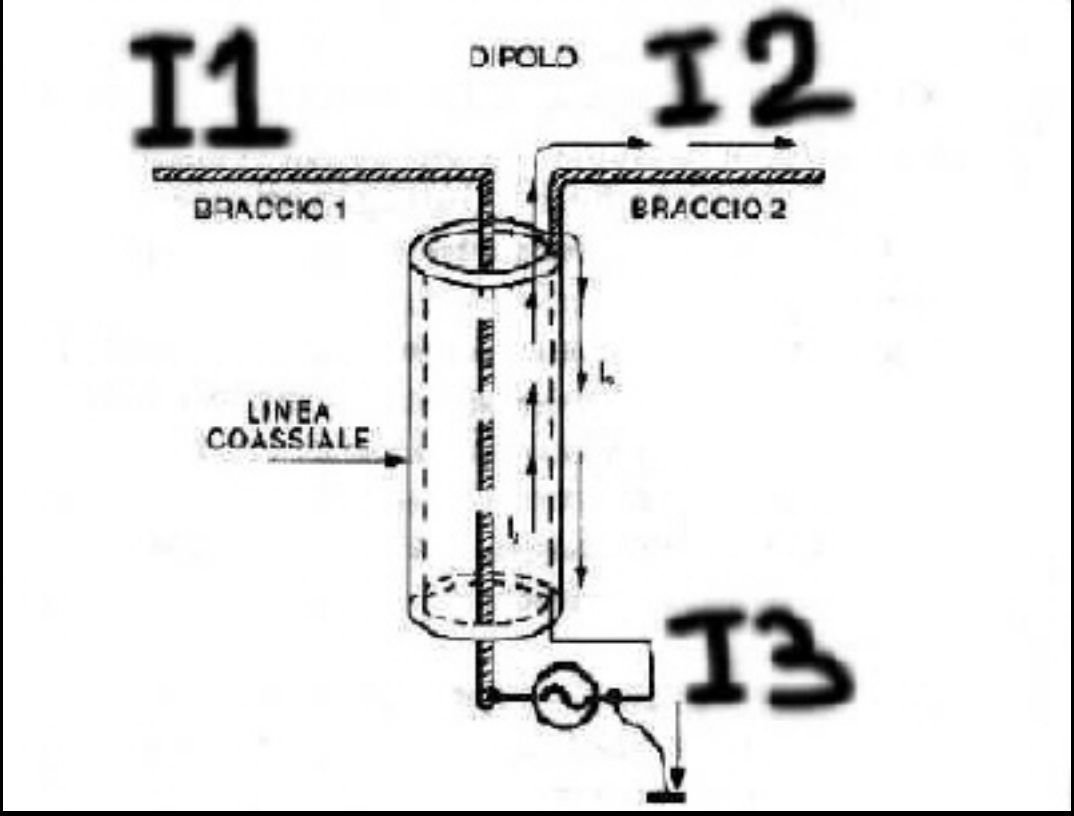
Teory Practice My Balun

ABOUT BALUN



May be baluns are still a mystery for hams; the only way to understand it is learning what it is and how to use it.
The word balun means balanced-unbalanced: it's used to adapt a balanced device to an unbalanced one; in a balanced device (as larger type of antennas) we have on both terminal the same voltage respect to the ground (if not so it's an unbalanced device);
a dipole with direct feed is balanced, a coaxial cable is unbalanced.
So, when we connect a balanced device to an unbalanced one the following occurs:

we have a dipole with coaxial cable direct fed (i.e. RG213); normally, transmitting, there are 2 currents on the cable:



1. **I1, which flows trough the central wire of coaxial cable and from transmitter goes up to the dipole;**

2. **I2, which flows (for the skin effect) on the inside part of the copper shield;**

The two currents, equal and opposite, humble itself and we have no radiation from coaxial cable.
The two currents cames on the dipole to be irradiated; part of it cames back; the one on the shield cames back trough the external side of the shield (no more the inside: so we have 2 current on the shield, I2 and I3); the value of this current (which we'll call I3) depends to the impedance value of the external side of coaxial cable respect to the ground (in a word if it will find high or low resistance);
if impedance will be high, I3 will find high resistance and its value will be low; if impedance will be low, resistance will be low and I3 value will be high; in this way I3 will radiate RF and the external side of the coaxial cable will radiate as a third wire of dipole: it's as we have a dipole with 3 wire (see picture 1); as consequence the radiation pattern will be distorced (see picture

2);
the big problem is that this new wire is often near TV and telephon cables irrading directly on those: so we have more probabilities to cause TVI.
This new wire, when its impedance is low, change the dipole impedance so we can have high S.W.R; this is the reason why (without balun) varying the coaxial cable length the S.W.R. changes.
Let's see now why use a balun; to delete this current I3, we need an high impedance for RF on the external side of coaxial cable; so we have high impedance casually for some cable length (odd multiple of 1/4 lamda) or using a balun: so the first reason to use a balun is TO AVOID THAT ON THE EXTERNAL SIDE OF COAXIAL CABLE FLOWS A CURRENT I3.
The simpler balun is a coil with some coaxial cable turns just belowe the antenna feed point: this inductance make the cable impedance (we mean the external side of cable shield) higher so that the RF current will find an high resistance and its value will be very low (that will not disturb I2 and I1 which flow inside the coaxial cable).

CHOKE BALUN

YOU ARE HERE: HOME > ANTENNAS > CHOKE BALUN

WHAT IS A CHOKE BALUN?

My friend Jim Duffy once said "Whatever antenna you chose, if it is fed with coaxial cable you should use a choke balun. This will prevent the feed line from becoming part of the antenna which can cause all sorts of problems. There are many designs to chose from. My favourite is an air core balun wound from coax".

Essentially, a choke balun is designed to "divorce" your antenna from the feed line. If your feed line is coaxial cable then you don't want it to be part of your antenna. You want to be able to deliver all your power to the radiator itself, i.e. "the antenna". A choke balun does this admirably.

Got a question on this topic?

If you are involved in electronics then consider joining our "electronics Questions and Answers" news group to ask your question

there as well as sharing your thorny questions and answers. Help out your colleagues!.

The absolute fastest way to get your question answered and yes, I **DO** read most posts.

This is a mutual help group with a very professional air about it. I've learn't things. Not for absolute newcomers to ask questions BUT it is an excellent learning resource for lurkers.

AMANDX PRESENTS

CHOOSING WIRE FOR AN ANTENNA

One of the most asked questions when it comes to antennas is what kind of wire should I use. The answer is as varied as the people who put them up. Over the last 28 years I have used or have seen used every kind of wire used to make an antenna. Just one disclaimer the information below is referring to antennas used for listening and NOT transmitting.

Stranded or Solid

I have seen both used with great success. Stranded wire is as a rule (and we all know rules are made to be broken) easier to work with and can at times be stronger. Stranded wire is usually more flexible so if you are not putting out a straight wire or bringing it into a house or apartment it may be superior to solid core wire. Solid wire is at times (especially with thinner wire) easier to break.

Coated or Bare

Wire with a coating is called insulated while bare wire in uninsulated. For antennas I do prefer the coated or insulated wire. The reason for this is that coated wire can be easier to work with as if it touches something conductive such as metal it is OK. Bare wire must be kept away from anything conductive to work properly. If bare wire comes into contact with anything conductive that material becomes part of the antenna. This can ruin an antenna's pattern or worse yet a ground system. This latter matter can cause an antenna to short out or worse yet cause damage to a radio due to static discharges. The choice would be yours as the coating or insulation will NOT decrease the signals received. If radio signals can go through your brick wall the tiny amount of plastic or rubber used to coat the wire will not bother your reception.

Thickness

The thickness of wire is measured by its gauge. The higher the gauge number the thinner the wire. I have used wire any where from 24 to 16 gauge over the years. Now the very thin high gauge 24 or 22 wire was used in pairs to give it some strength. No use putting out an antenna and have the first gust of wind tear it up. Wire of 18 or 16 gauge is quite good. I often use lamp cord or light indoor extension cord wire. This is insulated and cheap to buy at any hardware store. Hey you can be frugal and buy half the wire you need and split the wires to give you the length you need on a heavier gauge wire that is twinned like the lamp cord. If you live in areas that are subject to bad weather especially high winds or ice storms heavier gauge wire should be used so it can with stand the elements if the antenna is up in the air.

Copper vs Everything Else

In my humble opinion it matters not which you use. I have used everything from copper to aluminum to mystery metal over the years. I have never noticed any difference in the signal strength obtained from different types of wire. Go with the price on this topic depending on what you can obtain at your location.

Simple rules to follow:

Once you pick the wire you want make sure you have thought these points out:

If a wire is going to be left on the ground coated/insulated wire is a must.

If a wire is on snow you can use either as snow in an insulator.

If a wire is up in the air and away from anything conductive you can use either type.

If up in the air and near or touching anything conductive you must use coated/insulated wire.

If you live in areas that are subject to bad weather especially high winds or ice storms heavier gauge wire should be used so it can with stand the elements.

OK now go out and put up something. Experimenting is half the fun in this hobby.

Life span of an antenna...one man's joking opinion:

Well, generally it depends on hours spent listening.

The antenna converts electro-magnetic energy into electrical energy, which is basically electrons moving into your radio.
There are only so many electrons in each inch of copper wire, so when they've been sent downstream into your radio, the wire will become "ionized" and deteriorate and probably fall down. This explains why, when you come home one day, your antenna is on the ground (see below).

What happens to all those electrons, you ask. Well, they migrate into your radio and accumulate. In older tube radios, there was a "grid leak" resistor circuit which allowed the electrons to fall on the ground. Now you can't see them, but they're there. As more pile up, they slide into your back yard.

Tube radios, because of the "grid leak" last a lot longer than solid state radios, which stop working when enough electrons have piled up inside to short it out.

Now those electrons in your back yard want to get back into the copper wire, so they "pull" the antenna down to be re-united with it. Since the antenna is high, and they're on the ground, this attraction is not strong, but on a windy day, the electrons get lifted from the ground towards the antenna, pulling it down again. The wind oftens brings in free electrons from your neighbor's homes (from TVs, etc), so there may be a lot of these things around. If too many electrons get lifted up all at once, they overload the antenna, causing a heat mark, or worse getting back into the radio. Now this is why your antenna usually falls down on windy days.

At least, that's how I understand it.

You can extend the life of your antenna by disconnecting it from your radio when you're not listening. But overall, 500 to 1000 hours spent listening will do in a longwire antenna.

It a joke OK!!!

Ground/Radial Systems

GROUND MOUNTING

A vertical antenna in its simplest form, is electrically equivalent to one-half of a dipole antenna stood on end. When the antenna is mounted close to the ground, the earth below takes the place of the "missing" half of the dipole. If ground conductivity is fair to good, a short metal stake or rod may provide a sufficiently good ground connection for resonant and low SWR operation on the bands for which the antenna is designed. This basic arrangement is shown in figure 1.

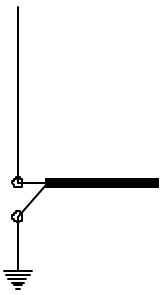

Figure 1

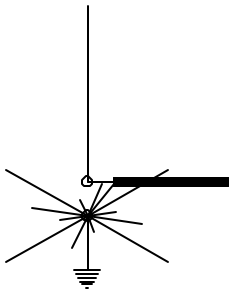

Figure 2

The way it works is that the capacitance between the vertical radiator and the ground causes *return* currents to flow along the earths surface back to the transmitter. If they have to come back along untreated lossy earth thy get back to the source greatly attenuated. This *return* loss is like a resistor in series with the antenna radiation resistance and will therefore affect the feed point impedance.

In almost every case the efficiency of a vertical antenna will be greater if radial wires are used to improve ground conductivity as in figure 2. It's important to note that there's no point in cutting radials to any particular length when ground mounting because the earth will detune them anyway. All you want to do is make the surface of the earth around the antenna more conductive than it is ordinarily.

If you can't copper-plate the backyard, the best approach is to run out as many radials as possible, each as long as possible around the antenna in all directions. Radials may be left on top of the ground however they should be buried for the sake of pedestrians and lawnmowers.

How long should radials be? A good rule is no shorter than the antenna is tall because 50% of your losses will occur in the first 1/4 8 out from the antenna. If you have more than a dozen radials, they must be longer to get the most out of them which is why the FCC specifies 113 wires each .4 8 for AM broadcast stations—the equivalent of a zero-loss ground plane. Obviously, for most ham work this would be overkill.

In some cases wire mesh (i.e. chicken wire) may be used as a substitute for radial wires and/or a ground connection, the mesh or screen acting as one plate of a capacitor to provide coupling to the earth beneath the antenna.

It should be noted that a ground rod is useful only as a d.c. ground or as a tie point for radials. It does little or nothing to reduce ground losses at r.f. regardless of how far it goes into the ground.

Bare wire, insulated, any gauge, it doesn't matter. The current coming back along any one wire won't amount to that much.

EFFICIENCY

The importance of reducing losses in the ground system can be seen from an examination of a vertical antenna's feedpoint impedance which at resonance consists of three components: antenna radiation resistance; conductor loss resistance; and earth loss resistance. An unloaded quarter-wave vertical antenna has a radiation resistance of about 35 ohms with negligible ohmic or conductor loss, but ground loss resistance may be very great if no measures are taken to reduce it, and in some cases ground loss R may even exceed the antenna radiation resistance. These three components may be added together to arrive at the feedpoint **impedance** of a **resonant** (no reactance) antenna. For the sake of illustration, assume that the ground loss beneath a quarter wavelength vertical antenna is 15 ohms, that conductor

loss resistance is zero, and that the radiation resistance is the textbook figure of 35 ohms. The feedpoint impedance would then be 15 + 0 + 35 = 50 ohms, and the antenna would be perfectly matched to a 50 ohm coaxial line. Since the radiation resistance is an index of the amount of applied power that is consumed as useful radiation rather than simply lost as heat in the earth or in the conductor, the radiation resistance must be kept as high as possible in relation to the total feedpoint impedance for maximum efficiency. Efficiency, expressed as a percentage, may be found by dividing the radiation resistance by the total feedpoint impedance of a resonant antenna, so under the conditions assumed above our vertical antenna would show an efficiency of 35/50 = 70%. As a vertical antenna is made progressively shorter than one-quarter wavelength the radiation resistance drops rapidly and conductor losses from the required loading inductors increase. A one-eighth wave inductively loaded vertical would have a radiation resistance of something like 15 ohms and coil losses (or trap losses for multiband antennas) would be in the range of 5 ohms. Assuming the same value of ground loss resistance (15 ohms), the feedpoint impedance would become 15 + 5 + 15 = 35 ohms and the efficiency would be 15/35 = 43%. From the above calculations it is clear that the shorter a vertical antenna must be the less efficient it also must be for a given ground loss resistance. Or to state the matter another way, more elaborate ground or radial systems must be used with shorter verticals for reasonable efficiency. If the ground loss of resistance of 15 ohms from the preceding example could be reduced to zero ohms, it is easy to show that the efficiency of our one-eighth wavelength loaded vertical would increase to 75%. Unfortunately, more than 100 radials each one-half wavelength long would be required for zero ground loss, so lower efficiencies with shorter radials must usually be accepted for the sake of convenience. In spite of their limitations, short vertical antennas over less than ideal ground systems are often more effective DX performers than horizontal dipoles which must be placed well above the earth (especially on the lower bands) to produce any significant radiation at the lower elevation angles. Verticals, on the other hand, are primarily low-angle radiators on all bands.

ABOVE GROUND (ELEVATED) INSTALLATIONS (rooftop, tower, mast. etc.)

The problem of ground loss resistance may be avoided to some extent by mounting a vertical antenna some distance above the earth over an artificial ground plane consisting of resonant (usually 1/4 8) radial wires. Four resonant radials are considered to provide a very low-loss ground plane system for vertical antennas at base heights of 1/2 8 or more. This arrangement contrasts favorably with the more than 100 radials for zero ohms loss resistance at ground level, and since 1/2 8 is only about thirty-five feet at 20 meters, very worthwhile improvement in vertical antenna performance can be realized, at least on the higher bands, with moderate pole or tower heights. At base heights below 1/2 8 more than four radials will be required to provide a ground plane of significantly greater conductivity than the lossy earth immediately below the antenna: even so, a slightly elevated vertical with relatively few radials may be more effective than a ground-level vertical operating over a larger number of radials if only because the former is apt to be more in the clear. Resonant radial lengths for any band may be calculated from the formula:

$$Length\ (ft) = \frac{240}{Frequency\ (MHz)}$$

Figure 3 shows the basic ground plane system for elevated verticals. Radials may slope downward as much as 45 degrees without any significant effect on operation or performance. Radials for different bands should be separated as much as possible and the far end of each radial insulated from supporting wires. Figure 4 shows a ground plane system that uses four resonant radials for 40 meters, another set of four for 20 meters, and a third set for 10 meters. A separate set for 15 meters is not ordinarily required because the 40 meter radials operate as resonant 3/4 8 radials on that band. At the lower heights the separate wires of this system may provide enough capacitance to ground to permit low SWR operation on 80/75 meters as well, but it is probable that at least one resonant radial will be required for low SWR on that band. It's important to note that cutting each conductor of rotator cable to a specific frequency will not work unless you separate it, angling each conductor away for most of its length because the longer ones will detune the shorter ones.

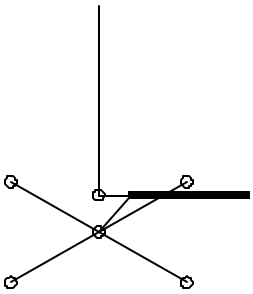

Figure 3

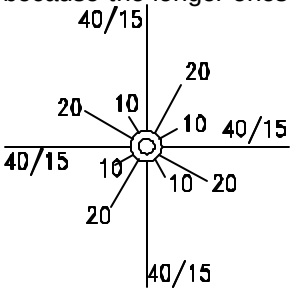

Figure 4

The 12-radial system of Figure 4 is a very good one, but it requires at least 12 tie-off points. Butternut has developed a multiband radial made of 300-ohm ribbon that resonates simultaneously on 40, 20, 15 and 10 meters. Four such radials offer essentially the same ground plane performance as the system of Figure 4 but require only 4 supports. These multiband radials plus additional wire for an 80 meter radial are available separately (our STR-II kit) or as part of the Butternut roof mounting kit (RMK-II).

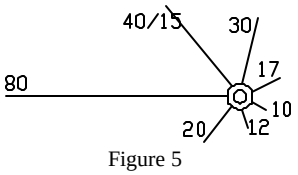

Figure 5

There are times when physical restrictions will dictate the use of fewer than four radials, and at least one

manufacturer recommends 2 radials per band, the radials for each band running 180 degrees away from each other. A simpler (and no doubt less effective) system is shown in Figure 5. Since only one resonant radial is used per band the antenna will radiate both vertically and horizontally polarized energy, and the pattern will not be completely omnidirectional. For true ground plane action and predominantly vertical polarization no fewer than three equally-spaced radials should be used.

Figure 6 illustrates the construction of a multi-band radial which is resonant on 40, 20, 15 and 10 meters. Good quality 300 ohm TV ribbon lead should be used (velocity factor is critical), and the conductors should employ at least one strand of steel wire to support the weight of the radial. Four such radials will be the practical equivalent of the system shown in figure four for operation on 40 through 10 meters.

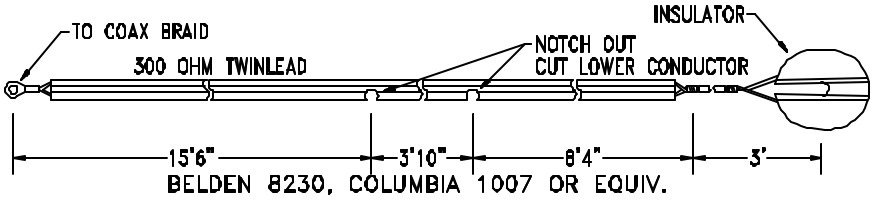

Figure 6

Regardless of the number of radials used in either elevated or ground level systems, all radials should be attached to the ground connection at the antenna feedpoint by the shortest possible leads. An elaborate radial system at ground level, for example, cannot be used with a vertical antenna on a rooftop or on a tall tower, for the length of the ground lead would effectively become part of the antenna, thus detuning the system on most or all bands.

METAL TOWERS AND MASTS

If a metal mast or tower is used to support a vertical antenna all radials should be connected to the mast or tower at the ground connection of the antenna feedline. This is because one of the functions of a resonant radial is to detune a supporting metal structure for antenna currents that might otherwise flow on the structure and thus turn the vertical antenna system into a vertical long wire with unwanted high-angle radiation.

OTHER MOUNTING SCHEMES

In cases where a resonant vertical antenna may neither be ground mounted nor used with an elevated ground plane, operation may still be possible if connection can be made to a large mass of metal that is directly connected or capacitively coupled to the ground, e.g., central air conditioning systems or structural steel frames of apartment buildings. Some amateurs have reported good results with vertical antennas extended horizontally or semi-vertically from metal terraces which serve as the ground connection. Alternatively, a quarterwave vertical may be window mounted if a short ground lead to a cold water pipe or radiator can be used. If a long lead must be used, tuned radials may be required for resonance on one or more bands. Great care should be exercised in such installations to avoid power lines and to keep the antenna from falling onto persons or property.

MOBILE HOME AND RV INSTALLATION

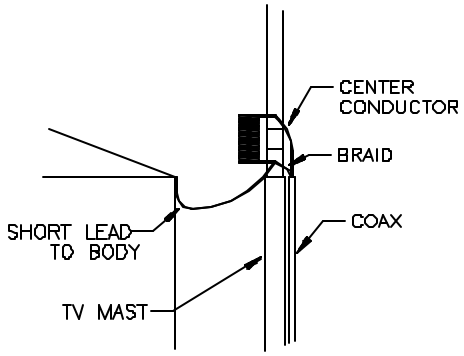
The principles of vertical antenna installations for use on mobile homes or RV's are the same as for other installations, and they all boil down to two main considerations. The first is that of erecting the vertical in the clearest possible spot, away from obstacles (including the MH or RV) that can interfere with radiation from the antenna. The second is that of installing the beat possible ground system beneath the antenna in order to minimize losses from r.f. currents flowing in the earth below the antenna. Fortunately, the metal bodies of both MHz and RVs can be used as highly conducting ground planes for vertical antennas in exactly the same way that automobile bodies, etc., provide the ground system for shorter vertical antennas for mobile operation. The metal body of an automobile, MH or RV may be viewed as one plate of a capacitor. Since the surface area of even a small automobile is quite large and in close proximity to the earth, its body is tightly coupled to the earth below and may be considered simply as an extension of the earth itself—a kind of hill as far as radio frequencies are concerned, but one having higher conductivity than the earth itself. RVs and especially MHz, having much greater surface area, will therefore provide a more extensive and effective ground system than a large number of radial wires occupying the same space as the MH or RV.

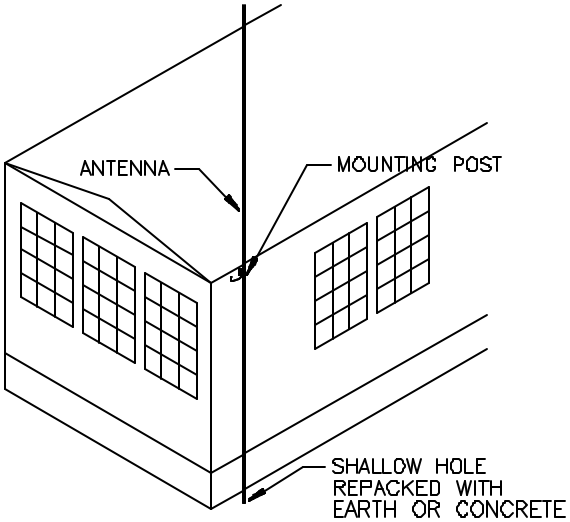
As in mobile installations, a vertical antenna may be mounted almost anywhere on the body of the vehicle or MH and made to operate with reasonably low VSWR, but it is generally considered that the best possible location for a mobile antenna is in the middle of the roof of the vehicle, i.e., at the center of the vehicle's ground plane and at a point where the antenna will not be in the "shadow" of any part of the vehicle. It is not usually convenient, or even practical to install a relatively tall vertical on the roof of an RV or MH for any number of reasons, so the next best procedure would be to install a vertical antenna with its base at the same level as the roof, preferably near the middle of one of the longer sides.

The exact way in which this may be done is a matter of convenience, but a short mast extending from ground level to the roof of the MH and RV and placed alongside the building or RV would provide a stable and sturdy support with a minimum of mounting brackets and other modifications to the RV or MH. For portable operation such a mast could simply be lashed alongside the RV with the base in a shallow hole in the ground for additional support, and there would be no harm in extending the mast a few inches above the roof level to permit attachment of ropes which could be used to hold the mast firmly against the side of the vehicle and to prevent side sway.

This system has been used successfully with various types of RVs, travel trailers and even passenger automobiles during portable operation. For "L" shaped mobile homes a vertical antenna should be placed in the corner of the "L" so that the metal roof will provide groundplane coverage over 270 degrees.

In all cases the base of the vertical antenna should not be more than a few inches away from the MH or RV so that the shortest possible lead may be run from the ground connection of the antenna to the metal body, as the length of this ground lead will effectively lengthen the antenna itself on all bands, and detuning can occur in some cases. A good electrical connection between the body of the RV or MH and the antenna is important, and in the case of mobile homes it would be a good idea to make sure that good electrical contact exists between the different parts of the metal body. Discontinuities can often lead to the production of harmonic radiation and TVI. The essential circuit connections are shown in the diagram above.





For permanent installations the bottom of the mast may be set deeper in the ground, and concrete may be used for greater strength and stability. The upper portion of the mast should be securely attached to the side of the building. Steel TV mast sections are readily available in lengths of ten feet and the mounting posts of Butternut HF verticals will slide into those which have an outside diameter of 1 1/4 inches and a wall thickness of .058 inches. Other vertical antennas may use different mounting techniques and requirements, so be sure to select a mast that will be suited to the particular situation. The main point to keep in mind is that the mast should not extend more than a few inches above the level of the roof so that the ground lead may be kept short.

LIGHTNING PROTECTION

Modern solid state amateur equipment is particularly vulnerable to damage from lightning or static induced transients that may appear on transmission lines, and conventional air-gap lightning protectors may provide no real protection at all for solid state gear. A line of very effective lightning and static protectors has been developed by ALPHA DELTA COMMUNICATIONS, P.O. Box 571, Centerville, Ohio 45459, for use with solid state equipment, and since these devices feature much faster transient discharge times than earlier designs, they should be investigated for possible use with all vertical and other antenna systems.

Many of the comments from below were removed from context and quoted to mean something else in another internet article. It is important to read everything ***IN CONTEXT****.*

How Does an Inductor or Loading Coil Work?

The most basic answers are:

What does the coil do? A loading coil does not replace a missing fraction of a wavelength. The coil simply inserts a series inductive reactance that cancels capacitive antenna reactance. When a 150 ohm reactance inductor is inserted in series with a 150 ohm capacitive load (like an antenna), only the resistive parts remain.

What determines current distribution in a loading coil? The capacitance to the outside world and the impedance above the loading coil. The current in any inductor would be equal at each end except for displacement currents, which are "imaginary currents" that flow through capacitance.

How much difference is there in loading coil current entering the coil and loading coil current exiting the far end? If the antenna beyond the coil has a low self-impedance compared to the impedance of the shunting capacitance from the coil to "ground", the currents at each end of the coil will be essentially equal. It has NOTHING to do with electrical degrees the coil compensates for. In other words if the portion of antenna above or beyond the loading coil is long or has a large area compared to the physical size of the coil, current is essentially equal throughout the coil.

What does significant current taper in the loading coil indicate? It generally indicates a poor antenna design, where the loading coil (or any other application using an inductor) has high stray capacitance to other areas of the antenna system (like the groundplane) compared to the capacitive reactance of the antenna beyond the inductor. Significant current taper indicates a poor loading coil or poor antenna design.

click to view typical installation measurements

The Difference Between a Loading Coil and a Normal Inductor

There really isn't any difference, except the location where the coil is used. Mobile loading coils or loading coils for short antennas often have very high reactance. They have small amounts of capacitance at the end, and so stray capacitances are more of a concern. Stray capacitance from turn-to-

turn increases circulating currents and has the effect of increasing inductance and effective resistance at the expense of reducing bandwidth and Q. Stray capacitance to the outside world causes the coil to behave like an L-network, and transform impedances instead of providing a series reactance. This is why the optimum form factor of a coil becomes longer compared to the diameter with any inductor having very high reactance.

Inductors with low reactance are less critical of stray capacitances. Optimum form-factor in a low reactance inductor leans towards a short coil with the diameter nearly equaling length. In tank circuits or loading coils used with longer antennas or with capacitance hats, an optimum inductor is shorter and larger in diameter.

Most optimized inductors fall between 1:1 and 4:1 length to diameter ratios, the exact value depending on the terminating reactances. A coil is a coil, they behave the same way regardless if used as a loading coil or a tank inductor.

Common myths about inductor behavior:

One common myth is loading coil current is reduced as it passes through the coil. There are two reasons cited for this. One idea is the current is reduced because the loading coil replaces a certain amount of "electrical degrees" of antenna area, like the current taper in an antenna. The other idea is that series loss resistance causes a current reduction.

We often find inexperienced builders of 5/8th wl antennas think the "loading coil" needs to contain 1/8th wavelength of wire in order to make a "3/4wl antenna" and thus cause a low feed impedance. In other cases, some claim a half-wave of wire wound on a form causes a 180-degree delay, and is useful for phasing in a collinear array.

The basic flaw is the above ideas do not account for what happens in a coil with mutual coupling between turns. The flawed viewpoint is that current goes in one end, winds its way around through the physical length of wire in the coil, and after a time delay comes out the other end. There is a physical mechanism that prevents this, as we might intuitively think, from actually happening . The mechanism is the magnetic field in the coil!

What Really Happens

When current flows in the transmitter-end of the coil, a magnetic field is created. This magnetic field causes charges in the other turns to instantly move. This effect ripples through the coil at light-speed, just over 186,000 miles per second. As long as the magnetic flux coupling is high, the delay through the coil is the speed of light over the physical length of the coil. The electrical delay is the physical length of expressed the coil expressed in degrees at the operating frequency.

(Another interesting effect occurs. The increasing magnetic field sets up an "opposing voltage" as it cuts across conductors. This opposing voltage, created as the field expands, is what causes the current to rise slower than the applied voltage. If the exciting voltage is decreased the field collapses, and now the voltage changes polarity and aids current flow! If we don't allow the current to flow, the voltage will rise until it does. This is what causes the kick in a relay coil when we open the relay coil path, or the spark in an ignition when the points abruptly open.)

In an RF system, the physical size of the coil actually does add some "antenna effect". For example, on 160 meters the wavelength is about 550 feet. 1.5 feet is about one electrical degree. A skinny one foot tall coil, with negligible stray capacitance, would have about 0.67 electrical degrees phase delay. This delay occurs because to coil occupies a physical length of .67 degrees. Current at each end would be almost perfectly equal, the taper would be about what we would expect for a fractional-degree-long coil.

(*In the real world, all components have some stray capacitance and flux leakage, so they have a different amount of electrical length and current taper than the "negligible capacitance" case. In good coil designs, the capacitance and leakage is small and can be ignored. I'll show you measurements later to prove this.)*

Now let's look at an extreme case. If the entire antenna is "coil", like a helically wound antenna with no top hat or stinger, current would be reduced to nearly zero at the open end. This is because distributed capacitance over the length of the antenna is fairly high, the shunting capacitance has a low impedance compared to impedance at the end of the antenna, and current is diverted to ground in the form of displacement currents.

Compact loading coils are another matter. In many cases phase delay is negligible or immeasurable by normal methods...flux coupling is nearly perfect. A good example would be a relatively compact toroid or a compact nearly-square L/D ratio loading inductor. I've found it impossible to measure the current taper in a toroid and very difficult to measure in a compact air-core loading coil. (The opposite extreme would be be a perfectly straight wire with no folds or bends or the helical antenna described above.)

In the case of the toroid or compact coil, the behavior would be such that doubling the turns nearly perfectly quadruples inductance. If we doubled turns and inductance simply doubled or increased at a much faster rate, we should know the coil is in a mode other than a pure inductor mode. This is a ***strong*** indicator inductor operating Q is less than optimum, and the inductor might behave less than ideally in critical applications.

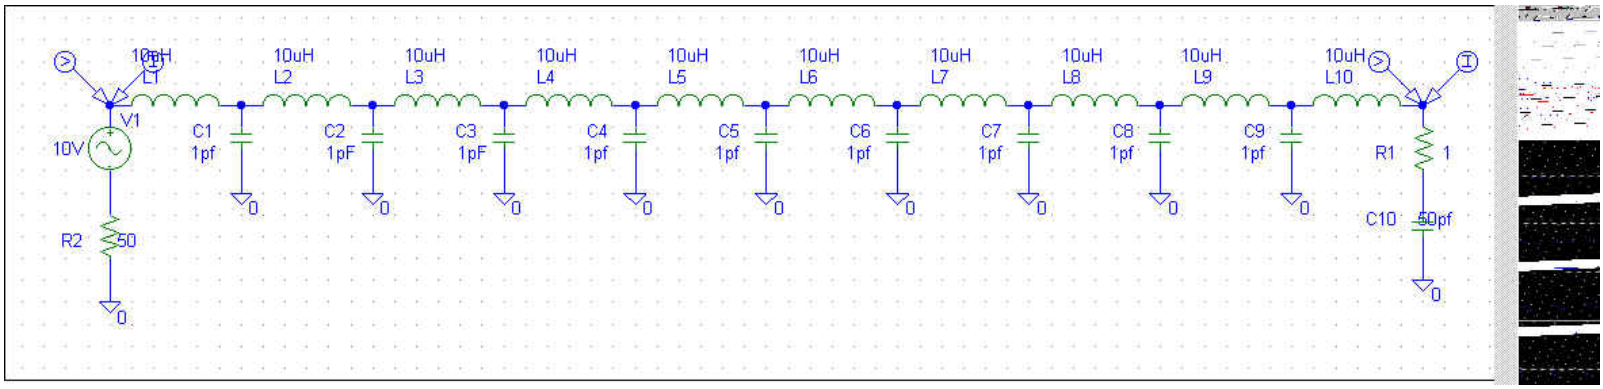
As a matter of fact, observing inductance change while adding turns can be an excellent test for flaws or shortfalls in system design. A linear increase in inductance when adding conductor length indicates design problems.

A perfect impedance squaring effect indicates minimal electrical phase-delay, or "antenna length" of an inductor. Impedance squaring as turns are doubled indicates the undesired inductor stray capacitance has a high reactance compared to the antenna system beyond the loading coil. Of course there can be exceptions, but it is a good general rule that large current taper indicates the loading system is much less efficient than necessary.

Making a Delay Line

It's certainly possible to make a delay line from a coil without opposing flux, but doing so requires stray capacitive reactance to be significant compared to the value of distributed inductance in the coil. This would occur in a very long helice, a very large diameter helice or loop, or an inductor near a large metal counterpoise or ground plane.

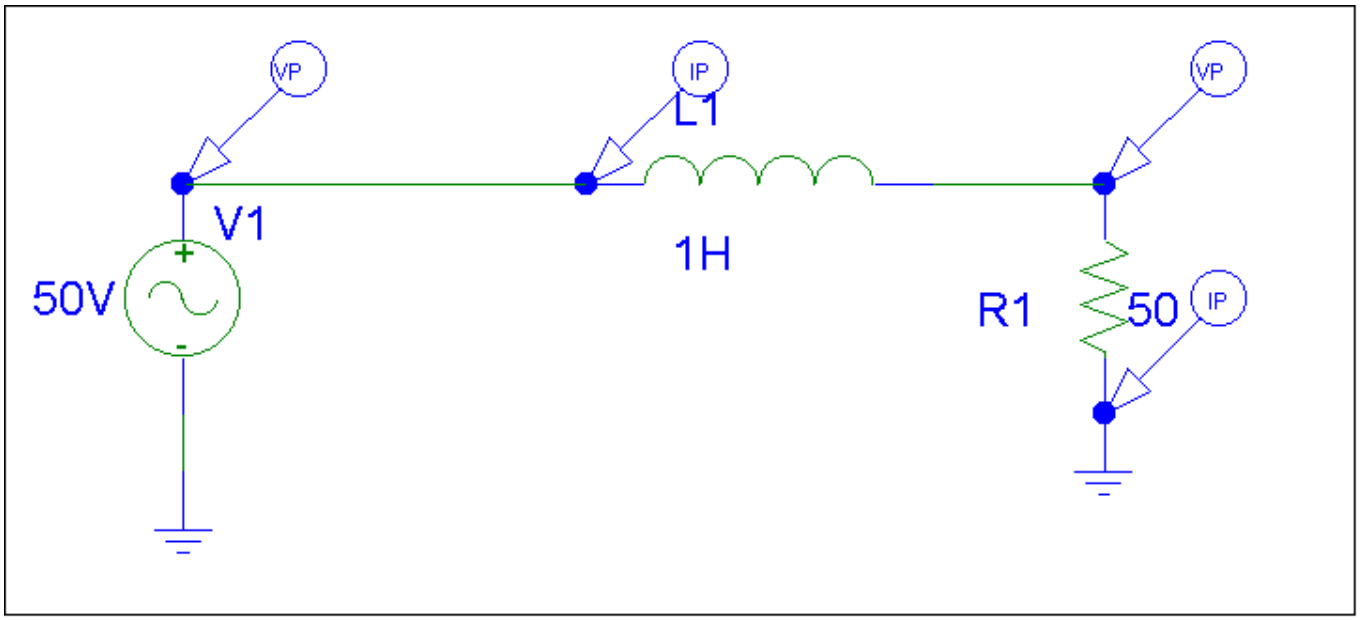
It's important to remember unless a coil is "stretched out" or "expanded" a great deal, the phase delay will not even be close to the physical conductor length. (The exception could be if you had so much capacitance the inductor acted like a series connected string of L/C/L networks as shown below).



In any case while this effect might be good in a collinear antenna or plate choke (assuming you do it right) it is a BAD effect in a short loaded antenna!

Inductor E/I Phase shift

An inductor delays the flow of current in relationship to applied voltages as the magnetic field inside the coil expands. Voltage increases before current starts to flow. This phase relationship between voltage and current is often confused with time-delay phase in the inductor. Say we have this simple circuit:



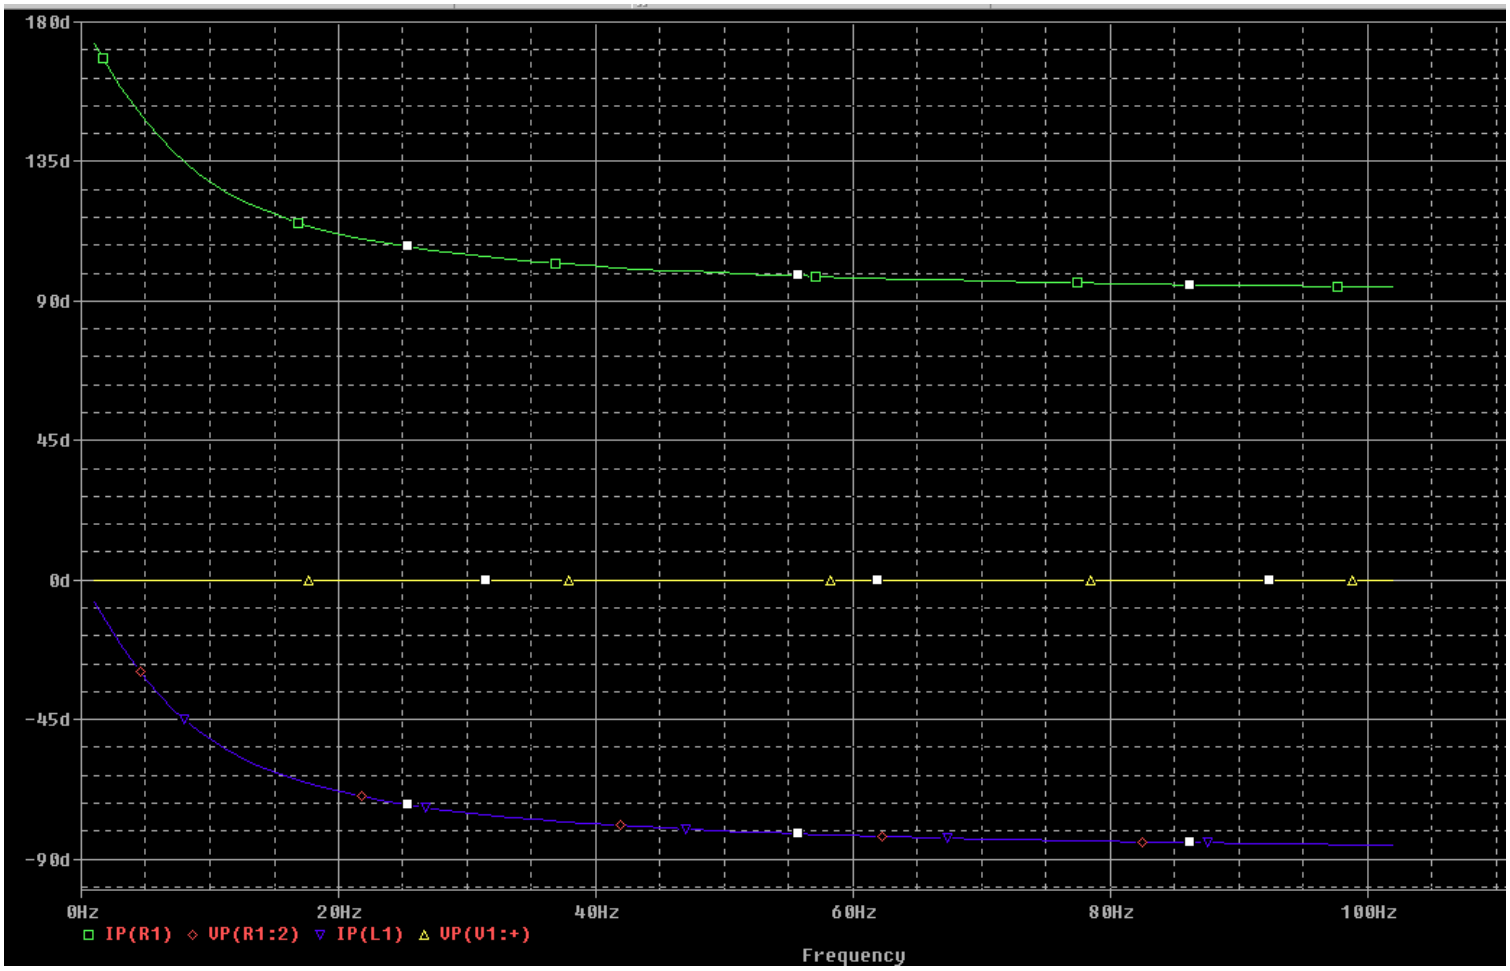
Current and voltage at V1 will be out-of-phase by the effect of L1 "charging" with magnetic flux. Current appears AFTER voltage rises, and falls after voltage falls. Current in R1, however, is exactly in phase with voltage across R1. That's because the voltage across R1 is always E=I*R.

Every component must follow the Laws or electrical rules established for that component.

The current in R1 is delayed from VOLTAGE rise in V1 by the voltage to current phase delay of L1. This does result in a time delay in relationship to voltage rise at V1, but there is NO current time delay through L1! V1, L1, and R1 all have the same peak current at the same time!!!

The notion that antenna loading coil delay current by the same time as they delay response to increased voltage is obviously nonsense.

Here is a graph of phase delays in the above system:



Current in the load, generator, and inductor all exactly track in the same relationship from dc up. There is no "phase delay". The generator voltage is a straight line different than current, and this indicates the generator sees a "reactive load".

The Misplaced Notion

Proponents of the idea that coils replace "antenna length" so far have been unable to define a set of rules or logical reasons why a current reduction and electrical-degree phase delay related to antenna area "replaced" would occur in a two-terminal component. While a long inductor with poor flux linkage from end-to-end or an inductor with low values of stray capacitive reactance to a groundplane compared to series impedance can cause SOME current inequalities or phase delays, the amount is normally immeasurable with normal thermal current meters with a reasonable coil form factor and termination above the coil. The amount of current taper actually rivals the disturbance of the system by adding the measurement device, unless we are very careful in how we construct the measurement device.

Both W7EL and myself made independent measurements that show the fact the coil or inductor is in an antenna has nothing to do with current distribution in the coil. Some people have actually incorrectly reported W7EL's data! Here's what he had to post on rec.radio.amateur.antenna to correct misrepresented claims.

The Need for a Measurement

An article on E-ham claimed measurements proved a new concept about loading coil current. The E-ham article put forth an idea that current disappears as it moves through a loading inductor without a mechanism like displacement currents providing a path. This claim conflicts with established component behavior, so it would indeed be fascinating if it were true! One of the claims supporting the idea that coils in antenna work differently than coils in circuits was that a non-radiating toroid loading inductor showed a current taper when used in an antenna.

I recently constructed a calibrated current meter that slips over whip antennas and masts, and is for all practical purposes totally immune to variations in voltage in the system. It also is mostly plastic, and has minimal effect on stray capacitance of the antenna. The resonant frequency and currents are not significantly perturbed by measurements with this meter. When I added a similar meter used in the other tests, resonant frequency shifted significantly! This is a sure sign the meter's capacitance or inductance is affecting the system.

In late December 2003 and early January 2004, I made additional measurements of loading inductor currents. The results clearly agree with the analysis that had been presented on this page since early 2003. Without displacement currents, currents into and out of a loading inductor *are equal.* That is a hard rule, it agrees with theories defined by people much smarter than me, and I believe it is unbendable unless the works of Faraday, Maxwell, Ohm, and Kirchoff were incorrect.

A sample of measurements above and below the loading coil with various antenna above the coil (current as percent of reference) follow:

	Toroid with hat	Small 2x2" coil with 24" hat up 24"	Long 12x3" coil with 24" hat up 24"	Long 12x3"coil with 6' whip
Current below	100%	100	100	100
Current above	100	94.4	73	76%

	Toroid with whip	long 12x1.5" coil with 6' whip	long 12x1.5" coil with 24" hat	Small 2x2" coil with 6' whip
Current below	100%	100	100	100
Current above coil	100%	79%	75%	96%
Current in whip 1ft above top of coil		73%		

The most revealing thing was how noticeably small changes in stray capacitance near the middle and top of the loading coil affect current distribution. It was quite evident hanging a large meter on each end of the coil would greatly perturb the system.

Clearly we do NOT want:

- **A large hat just above a large coil**
- **A long large coil and a short whip**
- **A coil near large sheetmetal**

More data along with photographs will appear on a new page over the next month or so. Until then, I can assure everyone the conventional theories presented below are accurate, and the theory that "electrical length" the coil "replaces" is incorrect. Loading coils indeed behave like any other inductor in the world.

Independent measurements by a reliable engineer have agreed with my measurements above. Anyone doubting my data need only read the following e-mail from W7EL.

On to the old text in this page:

The Incorrect Assumption

Another commonly misconception is, since voltage increases at the far end of the loading coil, current must logically decrease. After all, we have a fixed amount of power and voltage has increased. The assumption is:

1.) We multiply voltage times current to get power.

2.) If voltage increases current must decrease.

Unfortunately, this is ***not*** correct in reactive systems! Simple P (power) = I (current) times E (voltage) only works when the system is non-reactive. This condition only occurs at resonance, and only ***below*** the loading coil at the antenna feedpoint!

In a reactive system, like in a mobile whip above a loading coil, voltage and current are no longer in phase. As a matter of fact, voltage and current can closely approach being 90 degrees out-of-phase when the whip is electrically very short. Since the antenna area above the loading coil is highly reactive (voltage is not in phase with current), we can not multiply voltage times current without considering phase differences.

You may have heard the term "reactive power" or VAR (volt-amperes-reactive). Reactive power is voltage times current without consideration of phase angle. We can have kilowatts of VAR power with only a low power transmitter, and that is what we actually have in the reactive part of the small antenna.

Coil Q and Changes in Efficiency

Current taper or reduction has been cited as a reason coil "Q" has little effect on signal level in mobile systems. Speculation is only the first few turns of the loading coil carry significant current because the coil "leaks" magnetic fields and radiates, and this is why the coil Q has little effect.

Another idea proposes the loading coil "makes up" a certain missing part of the antenna. It goes on to conclude the loading coil can be accounted for in "electrical degrees", making up the "missing difference" in antenna degrees. This isn't true either. The inductor doesn't know where it is and suddenly change from "x" ohms reactance to electrical degrees! It responds to AC currents and voltages as any inductor in any circuit does. It doesn't suddenly change measurement units.

As an example of this, try to define a 45-degree electrical length inductor at 1.8 MHz. That would mean it is a capacitor at 3.61MHz, where it is over 90-degrees long! How many turns at what length and diameter is a 45-degree inductor?? Where is a formula that allows converting a given size inductor to electrical degrees? This shows how useless and meaningless that definition is!

The inductor adds a certain amount of series reactance, that's all. A 300uH inductor is not 20-degrees long, nor is it 80-degrees long, so far as radiation goes unless it is really that long ***physically***. It is a certain number of ohms reactance at a certain frequency, or a certain number of units called Henries. It is not "electrical degrees" that it adds, it is a non-dissipative reactance (in combination with a loss resistance because of finite quality) at a certain frequency!

A loading inductor can "insert" a large amount of phase shift, but the phase shift is between voltage and current. The only exception to this would be if the inductor had considerable distributed shunt capacitance to the outside world, and acted like a string of series inductors (with the antenna) and shunt capacitors (shunting to the ground system). In that case we could expect coil Q to be extremely low, since it would be the electrical equivalent of a lossy transmission line. That's either an awful loading coil, or it is a less-efficient helical loaded antenna!

The Correct View

Another group of people don't argue against established and proven circuit theory. They understand charges flowing into one end of the loading coil must have someplace to branch off (a virtual third terminal), or they must flow out the other end. Without that additional "virtual" path, charges flowing into the coil would always equal charges flowing out. This is true regardless of radiation, losses, or induction fields.

This makes perfect sense when we think of any dc circuit, antenna, or RF system. Electrical rules are satisfied, the system behaves as it does in the real world.

There is very little change in current, unless the coil is physically very long compared to the rest of the antenna above the coil or unless the coil is laid right against "grounded" conductors and the whip above the coil is very short. This fits perfectly with helical verticals, where the coil is "stretched out" over the length of the antenna.

It also agrees with base loaded antennas, which have nearly as much current into the antenna above the coil as at the feedpoint. It agrees with center loaded antennas, where current below the coil is essentially uniform and the whip above has triangular distribution.

Current ***can*** be different in various areas of an inductor, but ***only*** if shunting capacitances (impedances) to the outside world are significant compared to load capacitance (impedance). Another condition where current can vary substantially is with operation near the condition of self-resonance in what is normally considered or defined as a "series-resonant" mode. This would be a very poor and inefficient loading inductor, such as when a 160-meter antenna is used at a secondary resonant frequency in upper HF.

Circuit Model of a Mobile Antenna

The above model shows what might be a typical mobile antenna installation.

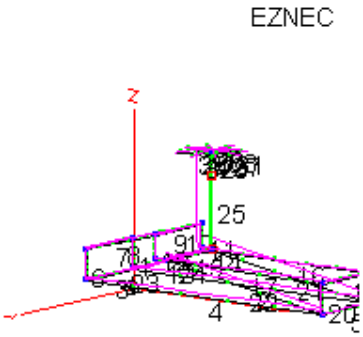
1. Rgnd ground resistance of vehicle normalized to feedpoint
2. V1 coaxial feedline
3. C2 base capacitance
4. Rrbase Radiation resistance of the base area of the antenna
5. L1 loading coil
6. Rcoil coil equivalent series loss resistance
7. C3 coil shunt C to ground
8. Rr top area radiation resistance
9. Cant equivalent antenna capacitance above coil area

My 160 Mobile Antenna

I've worked all continents except Africa while 160-meter mobile. I have CW contacts at over 10,000 miles, and SSB as far as Europe (4000 miles). My mobile antenna consists of an eight- foot antenna with a six-foot hat (made from surplus Ford or Chrysler car antennas) at the top. The loading coil is at 5 feet.

This antenna has been on the truck for thousands of miles, without mechanical failure. It is mounted at the upper left corner of the truck bed, about one foot back from the cab.

The following is a model of the current antenna system on my Ford F-250 HD long bed super cab truck:



The base impedance in the model is:

Frequency = 1.854 MHz.
Source 1 Voltage = 24 V. at 2.35 deg.
Current = 1 A. at 0.0 deg.
Impedance = 23.98 + J 0.9853 ohms
Power = 23.98 watts
SWR (50 ohm system) = 2.087

Actual measurement at my Johnstonville, GA farm in open flat pastures on August 17 at 8AM. Wet soil 25.8 ohms 0j base impedance, pretty close agreement to EZNEC model and earlier data! (I did have to adjust the model for very low ground conductivity, otherwise the resistance was far too low. It's my belief that NEC-2 underestimates ground losses in small radial or counterpoise systems that are close to earth.) Earlier text shows a base resistance of ***28 ohms***, that was dry soil with a slightly different loading coil and antenna.

The modeled current distribution for 1-ampere applied at the base (in 1-foot intervals) is:

1ft= 1.0031

2 ft= 1.0091

3ft= 1.0178

4ft= 1.0318

<Coil>

5ft= 1.0175

6ft= .97512

7ft= .92984

8ft = .89522

Measuring the current into and out of the loading coil with a small thermocouple RF meter, I detect no difference This is in close agreement with the model.

The efficiency of this antenna knowing coil Q, radiation resistance, and base resistance calculates just under 1 percent. The model indicates about 1/3 percent efficiency. This is reasonably close.

Removing the hat (in the model only) shows the following changes:

1ft = 1.0043
2ft = 1.0133
3 ft= 1.0279
4 ft= 1.0566

<coil>

5 ft= .95508
6 ft= .72232
7 ft= .27813
8 ft = open

I haven't tested the above, but with the same loading coil loss resistance the model says efficiency is now around 3dB worse. Removing the hat, with NO change in coil resistance, shows nearly loss nearly doubles. Of course the coil resistance would increase, because the loading coil nearly quadruples in size. Bandwidth is less and efficiency is less, even if I could maintain the same coil resistance.

Examples of Unequal Current

In the above models, we see that current into and out of the one-foot long coil is about the same. There is only about ***2% change in current*** even though the coil occupies 12% of antenna length in the "hat-loaded" antenna, but in fairness I couldn't resolve that change with a reasonably good RF current meter.

The model predicts ***10% change in a non-hat antenna***, but I never measured that antenna to confirm it.

Clearly there is no basis to the claim current is high only in the first few turns of an inductor, or that current tapers in relationship to "electrical degrees". The most accurate way to state the effect would be to say: "When the loading coil is short and the capacitance of the antenna beyond the coil is reasonable (in this case 3000 ohms Xc or less), there is an immeasurable reduction in current in the coil. When the required loading reactance is very high (in this case 8000 ohms), the reduction in current is about what we would expect for an equivalent length of antenna replacing the coil."

Degrees Vs Radiation Resistance

This upper four feet of this antenna resonates near 24 MHz with the hat. We can assume it is 90 degrees long at 24 MHz, which would translate to 6.9 degrees on 1.85 MHz. Following that same logic, this would mean the loading coil would be about 83 degrees long electrically. Using the incorrect logic proposed by others where the loading coil "makes up the difference in electrical degrees", there would be almost no current past the loading coil. Obviously this is not the case, the loading coil has very little "electrical length". As a matter of fact, the electrical length is about equivalent to the physical length!

This goes back to radiation theory, and my favorite saying: "Five hundred feet of wire in a one foot long tube is still one foot of antenna". Some CB manufactures sell antennas to consumers with the claim they use 5/8 or 3/4 wavelength of wire in an eight-foot fiberglass whip, so the antenna has more gain. Obviously this is not true. Let's not let such silly claims spread into amateur radio!

Related topics:

Inductors

The spice inductor model shows one example of how unequal current is created. The model demonstrates a coil having significant distributed capacitance to the point of current return in the system compared to terminating impedance of the coil. In a monopole this return path would be to the groundplane, or anything closer to the potential of the groundplane than the area above the loading coil's position in the antenna system.

Another Practical Antenna Example

Let's assume we have a lossless 15.3 foot long 0.2 inch diameter conductor over a perfect groundplane. Eznec gives the 1.821 MHz base impedance as .3004 -2169j. In other words, the antenna "looks like" .3004 ohms of load resistance in series with 40.32pF on 1821kHz. The return path for current is through the .3004 ohm resistance and 40.32pF capacitance, back to the ground of the antenna (it is a Marconi antenna).

Such a termination (load) would require a series inductance of 2169j (189.57µH) to cancel feedpoint capacitive reactance. A typical 190µH inductor

would be rather large, requiring somewhere around 53 turns when using a 4" by 4" form factor. One would expect a physically large inductor to have noticeable but very small displacement currents to the groundplane, when the small stray coil capacitance is compared to the 40.32pF termination capacitance. This raises two very important design guidelines:

- ***When installing a loading coil of substantial inductance in an electrically short antenna, sheetmetal and dielectrics should be kept away from the coil and areas of antenna above the loading coil. This would include dielectrics on or near the inductor, since the presence of dielectrics would increase undesirable capacitance.***
- ***When inductive reactance requirements are large, as when short thin "stingers" without hats are used above a coil, the coil form factor should lean more towards long and thin. Capacitances near the open end of the coil (high voltage end) should be minimized. This would be true even when the coil length increase results in a small reduction in mutual turns coupling, since the stray capacitance may result in a larger loss penalty than the slight increase in accumulated resistance from additional wire length.***

Efficiency

Efficiency in any antenna near earth is almost always dominated by ground related losses, short-height Marconi antennas are no exception. The overall effect of loading inductor Q and matching system losses are "diluted" or "swamped-out" by ground losses. Ground losses cause most systems to have greatly reduced sensitivity to inductor design.

The only consistently predictable factor in efficiency in fractional wavelength Marconi antennas with limited size ground systems is radiation resistance. Efficiency increases almost directly in proportion to radiation resistance.

Radiation Resistance and Power Radiated

Radiation resistance is probably the most poorly defined term used with antennas. The lack of clear definition creates errors and misjudgments when predicting antenna performance. If you wish more detailed information, this page contains information on radiation resistance. For the purposes of this discussion and to avoid pitfalls associated with using feedpoint impedance as radiation resistance, I'll use the same definitions Jasik, Balmain, and others have used. This definition is based on the IRE definition of radiation resistance being equal to the net or effective current causing radiation squared divided by the power radiated as EM energy, or Rr=Pr/I^2.

Using this definition, a folded dipole has a radiation resistance identical to a conventional dipole of the same physical dimensions (~70 ohms).

Radiation is caused by charge acceleration, there is no magic. The only thing affecting radiation resistance in a short vertical antenna near ground is current distribution over the linear area occupied by the radiation portion of the antenna. The general rules are:

Radiation resistance of a Marconi vertical in the maximum possible radiation resistance case for a given height (this is the case where current is uniform throughout the structure) is equal to 1580*(H/L)^2 where H equals height and L equals wavelength and both are expressed in the same units. Using degrees, we see a 10-degree tall antenna has a maximum possible radiation resistance of 1580*(10/360)^2 or 1580*.000772 = 1.22 ohms. This would apply even if the antenna is a vertical, DDRR, Fractal, or folded unipole with considerable top loading.

If current is triangular, radiation resistance would decrease by a factor of four to 0.305 ohms.

Power radiated is given by I^2*Rr

With 100-watts applied to a 10-degree tall antenna, net current in a lossless antenna with uniform current distribution would be 9.05 amperes. With triangular distribution, such as appears in a small diameter short base loaded whip, current would be approximately 18.1 amperes. We are in serious problems if the inductor reduces current along its length, since the only possible way to radiate 100 watts would be to have somewhere around 9 amperes of effective current integrated over the 10-degree vertical area of space for the radiator!

Ground Losses

All current flowing (or displaced) vertically into the antenna must equal current flowing out of the ground or counterpoise system. Even though ground losses are distributed losses, we must normalize all losses to the feedpoint in order to compare systems. There are cases where this will not always occur, causing us to falsely assume we have lower losses than really exist.

In this tutorial and comparison, I have normalized ground losses to the same point where radiation resistance is considered.

System Losses

(Measured data below of actual antenna given below was from 1995 data taken at a different location near Atlanta with a slightly different loading coil and antenna. There is a slight disagreement with current data. I left this all in so you can see the departure from measurements and models using 8 year old data.)

Base Loaded (Triangular Antenna Current Distribution) with no ground loss

Assuming we have a base-loaded antenna, and the operating frequency has a wavelength of 550 feet (around the 160-meter band), a 15.3 foot vertical would fit the above 10-degree value. Interestingly enough when we compare Eznec to formulas available in older (1950 vintage) engineering textbooks, we find radiation resistance predicted by Eznec is .3003 ohms while the triangular current estimate for the same height radiator is .305 ohms! This is an amazing degree of agreement, illustrating what we could do before modeling programs became available. (With perfect top loading, both Eznec and longhand calculations show approximately 1.2 ohms of radiation resistance.)

Assuming our 15.3 foot tall (10-degree) base-loaded antenna uses a coil Q of 200, the coil has 10.845 ohms of ESR. Total resistance with a perfect ground would be 10.85+.3= 11.15 ohms. Current into this system with 100 watts applied would be around 3 amperes, resulting in ~2.7 watts radiated and ~97.3 watts lost as heat in the inductor.

Doubling coil Q (400) would provide 5.73 ohms of base resistance with 4.18 amperes. Power radiated would be 5.2 watts, power lost as heat would be 94.8 watts. Efficiency does not quite double, changing from 2.7 to 5.2%. This results in a 2.8dB change in signal level.

Top Loaded (with no ground loss)

If we added a four-wire hat with 15-foot wires, current would no longer be triangular. While we wouldn't quite reach the optimum uniform distribution, current at the top would be about 78% of current at the antenna base. Feedpoint impedance would become 0.97 -551j, and the antenna would look like 0.97 ohms in series with 159pF.

Using a coil Q of 200, we would now have 2.76 ohms of inductor loss. Current becomes 5.18 amperes. Radiated power is 26 watts, while power lost as heat becomes 74 watts. Even in the perfect ground case, the change in efficiency caused by top loading is large. Top loading (with only the hat) results in 9.8 dB change in signal level when compared to the base loaded case when coil Q remains 200. Efficiency is 26%. The coil remains at ground level for easy matching and frequency change.

In this case current at each terminal of the loading coil would be essentially the same regardless of poor coil mounting techniques. In order to have significant current taper in the coil or in the bottom of the mast, shunt capacitance would have to be a significant compared to 160pF. The antenna's high input capacitance relaxes inductor and antenna mounting electrical requirements.

Base Loaded (high ground loss)

My F-250HD Super Cab pickup truck, when parked over open medium quality pasture land, has a ground resistance of about 20 ohms (normalized to the feedpoint) on 160 meters. Applying this ground loss to the base loaded antenna, the system has a feedpoint resistance of 20+.3=20.3 ohms. (This is reasonably close to actual feedpoint resistances measured with a similar operating antenna.) Adding coil losses, the system has 20.3+10.85=31.15 ohms. (**NOTE: Current coil is ~8 ohms ESR, 10.85 ohms is from ~8 year old data**) Current is sqrt (100/31.15) or 1.79 amperes.

This results in .96 watts radiated, and 99.04 watts lost as heat. Efficiency is now around .96%.

Substitution of a coil with a Q of 400 results in 25.7 ohms feed resistance, or 1.97 amperes antenna current at 100 watts. In this case efficiency is now 1.16% for 1.16 watts radiated. The change caused by doubling coil Q with high system ground losses is about 0.8dB, compared to almost 3dB in the perfect ground case! With a poor ground (in this case typical of a very large vehicle), a large change in coil Q produces little change in system efficiency.

Another Top Loaded (high ground loss) System Example (made prior to the EZNEC model above)

Using a large hat isn't practical in a moving mobile, although it could apply to fixed stations suffering with poor ground systems. When the hat is smaller, such as a mobile requires, the loading inductor can be moved higher in the system. Such a move would produce uniform current below the loading coil, with a current shape above the coil dictated by the construction of the upper portion of the antenna. My own mobile uses a six-foot diameter hat manufactured from stainless steel automobile antennas arranged in a spoke. I have no problems with wind or occasional obstructions. While unsightly, a modest hat is workable.

In order to keep the systems comparable I'll use the same radiation resistance provided by a large hat, but intentionally add high ground loss as a lumped resistance. This model ignores field losses near the antenna.

In this case we have 0.97 -551j as the inductor termination presented by the antenna. With ground losses normalized at 20 ohms and an inductor Q of

200, we have 20+2.76+.97 = 23.73 ohms of feedpoint resistance. Current is 2.05 amperes, and power radiated is 4.1 watts. Power lost is 95.9 watts.

Efficiency is 4.1%, a 6.3dB increase over a base-loaded triangular current system with the same lossy ground. This system is 8dB down from the same "top-loaded" distribution using a perfect ground.

When the system has significant fixed losses, increasing radiation resistance four times by top loading provides a similar dividend in system efficiency. At the same time a substantial increase in coil Q provides only minimal change in field strength.

Current Through Coil

Inductor spice model

There has been some speculation that current is high only in the first few turns of a loading inductor. Radiation comes solely from charge acceleration or current over spatial (in line) distance.

If any loading inductor shows substantial decrease in current over the length of the inductor, it is an absolute certainty that the inductor is poorly designed and that the system above the loading inductor is not contributing to system efficiency. The reason for this is very simple and straight forward. Any two-terminal component (even considering wire as a "component" applies) MUST have equal charges flowing into and out of each terminal. Voltages to other reference points can be different, but for every charge moving into one terminal a like number of charges MUST move out of the other terminal. Radiation, induction fields, and loss resistances have no influence on this rule.

In order to have any change in current, there must be an additional path or paths for charges. This path can be through leakage resistances, or through fictitious currents called displacement currents. Whatever the path, the total charge movements must be reconcilable. We simply can not have current "disappear".

The normal path upsetting "unbalancing" current into and out of each terminal in an inductor is provided by displacement currents through electric fields. As with any system, the amount of current flow is proportional to potential difference and impedance of the path. In order to shunt a substantial current out of an inductor, the potential difference between the ends of the path has to be high compared to the impedance of the path. The impedance of the stray path must also be reasonably low compared to the normal desired path.

Current diversion is problematic in very large inductors operated at (or very near) internal self resonance, when the self resonance is what we typically refer to as a "series-resonant" condition. This condition is common in plate chokes used in vacuum tube power amplifiers, where the system operates over many octaves of frequency range.

"Series resonances" inside components occur when distributed inductance forms a pair (or multiples of pairs) of "L" networks. The large series inductance from each end of a winding reacts with the small stray capacitance at the center, and forms a very high impedance transformation L network. The electrical potential at the center of the system becomes extremely high, and even the smallest amount of capacitance to surrounding objects will carry a substantial displacement current. The large displacement currents cause the terminal impedances to drop, and allow considerable current to concentrate in small areas of the component. At the same time, considerable voltage can be present. The normal result is arcing or destruction of the component, or failure of the system depending on the choke to operate.

Series resonance always occurs at a frequency higher than the self ***parallel*** resonant frequency of the component. A loading coil operating under such conditions would be required to have serious design errors to fall into this category, since the end termination capacitances should always be substantially higher than stray capacitance throughout the component. Failure to follow this rule would result in needless loss and reduced SWR bandwidth in an antenna.

The speculation or supposition that the first few turns of a loading coil carry most of the current is clearly untrue. In order to shunt current off, high series impedances would have to exist along with high stray shunting capacitance to areas removed from the radiator. Additionally, the remaining coil area connected to the top area of the antenna above the loading coil would have to present a high impedance to the area where current reduction occurs. This would never be the case, unless the top area of the antenna and loading coil are not resonant near the operating frequency.

A reasonable test for proper inductor and system design would be to remove the antenna above the loading coil, measuring system resonance. If resonance does not change substantially, the area above the coil is not correctly terminating the system. First-order self resonance of the inductor (parallel resonance), when removed from the system, should also be far above the operating frequency of the system. If self-resonance comes within three or four times the operating frequency range, the loading coil almost certainly will have needless performance shortfalls.

Conclusion

A normally functioning inductor has essentially equal currents throughout the inductor, loading coils are no exception. Any current difference requires a substantial current flow through undesired stray capacitances or leakage currents. Neither radiation or induction could change this, it is a basic rule of circuitry.

In a reasonably well-designed system, current into and out of the loading inductor should be substantially equal. Differences in current would indicate excessive and problematic undesired stray capacitance in the loading system design, or measurement errors.

Reduced sensitivity to coil Q is primarily a function of additional losses in the system, not reduction of current through the coil.

NVIS - What It Is and How To Use It

By Patricia Gibbons - WA6UBE

NVIS , short for Near Vertical Incident Skywave, utilizes high-angle skywave paths between stations instead of ground-wave or surface-wave in order to communicate via HF radio. NVIS was originally evaluated by U.S. Army Forces in Thailand during the Vietnam conflict in the mid-1960's It was found that Mobile stations, using whip antennas bent parallel to the ground, could communicate more reliably with their base-stations. Signal strengths would be weaker using high-angle skywave but communications would be more reliable, less subject to fading, and consistent between stations. This was because the intervening terrain was less of an absorber of signals. Terrain obstructions between stations, such as hills, mountainous areas, jungle growth, built-up areas with tall buildings, no longer become path obstructions with stations when NVIS techniques are employed. For distances out to 400 miles between stations, one F-layer hop, at vertical angles of 45 degrees or higher are used. It is not necessary to have high power transmitters. Typical 100 watt power levels are fine. It is necessary that all stations on an NVIS radio network use antennas that are parallel to the ground and the frequencies used are chosen via a radio propagation prediction program in order to have best results.

Frequently asked questions about NVIS:

1: Isn't NVIS, when using a horizontal Dipole antennas, what amateur radio operators always have used? What is so different about it?

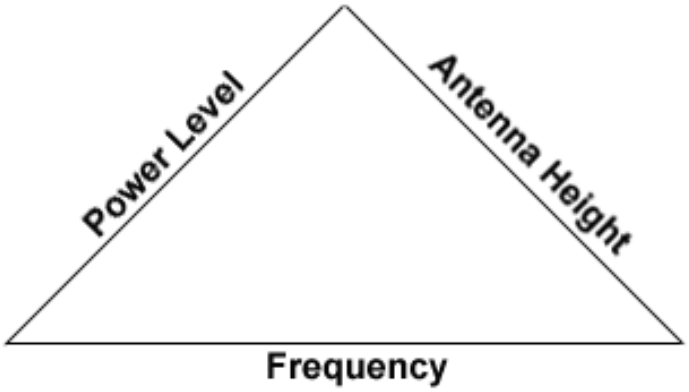
ANSWER: NVIS can be viewed more as a "Systems Concept" and not just what antenna to use. The concept of NVIS is to have reliable communications anywhere within an 800 mile diameter circle, in which your station would be located at the center of this circle.

2: What is the advantage of having the antennas close to the ground? I always thought that a radio antenna had to be as high in the air as possible.

ANSWER: Stations communicating via high-angle sky-wave may also be close enough to each other to receive a ground-wave or surface-wave signal. Stations receiving both a sky-wave and ground-wave will have heavily distorted received signals. This will include multi-path distortion because of the extreme difference in the lengths of the twp paths. Keeping antennas close to the ground will reduce the generation of a ground-wave signal.

3: Does NVIS work with low-power transmitters??

ANSWER: Yes. In fact, reliable communications between stations are based on three major factors. These can be viewed in triangle form as follows:



After much research and testing of antennas over the past 5 years, I have determined that the most important leg of the triangle is choice of correct frequency. Specific results will be discussed later on this page.

4: What are the typical frequency ranges used for NVIS?
ANSWER: Usually between 2.0 and 10 Mhz. Exact frequency is dependant on the degree of solar sunspot activity. The best choice of frequency is through the use of a propagation prediction program.

ACTUAL TEST RESULTS
Summer of 1990:

A field test of NVIS was planned between myself and Carl Sato, AA6CF. Carl was located in San Francisco, California. The plan was for my station to run RTTY on the amateur 40 meter band and for Carl to log the field strength of my transmitter at Carl's location. I would try different types of antenna arrangements. The plan was to have a "blind test" in that AA6CF would not know which antenna I would be on at any particular time. My station was parked in a local park in Morgan Hill, California, which is approximately 70 miles from Carl's station in San Francisco. My station was a mobile arrangement consisting of a restored military communications truck and used one of the following three antenna arrangements for the test:

1. 100 Ft horizontal long-wire at six feet above the ground and end-fed with an antenna tuner.
2. 15 foot military whip antenna tuned with an SGC model SG230 "smart-tuner" with the antenna in a vertical position. The base of the vertical antenna was 7 feet off the ground.
3. The same 15 ft military whip antenna but placed in a horizontal position behind the vehicle which allowed the horizontal whip antenna to be 7 feet above, and parallel to the ground.

The amateur 40 meter band was used. The mobile station was set up to transmit 50 watts of "mark-idle" signal. AA6CF would then tell me the signal strength of the signal received as I rapidly changed between one of the three antenna configurations as listed above.

TEST RESULTS:
The received signal strength from AA6CF on each of the three antennas were:

1. Horizontal wire antenna = S9
2. Horizontal Whip antenna = S9
3. Vertical Whip antenna = S8

Fall of 1990:

During the Boy Scout "Jamboree on the Air" (JOTA) event. My communications truck was set up at the San Jose Red Cross facility in their large parking lot.

Antenna Used: 1/2 Wavelength Dipole antenna, center-fed via 6 feet of ladder line and an MFJ-989C antenna tuner. Antenna was spaced 24 inches off the ground on orange traffic cones that were spaced six feet apart. The antenna was free from nearby obstructions as it was located in the center of a large empty parking lot.

Transmitter used: Yaesu FT70/G Paramilitary "Manpack" transceiver

Power used: 10 watts on CW

Frequency used: CW portion of 40 meter amateur band. 7025 - 7150 Khz.

Location of stations worked: All within a radius of 200 miles in the area of San Francisco, Emeryville, Sebastopol, Oroville, Woodland, Sacramento, and Dublin, California.

TEST RESULTS:
All stations reported my signal to be from "S8" to " 10 over S9" with exception of one station located in Plesanton California. The station in Pleasanton was using a Trap Vertical antenna. All other stations reported using horizontal or "Inverted Vee" Dipole antennas.

Spring of 1993:

Purpose of test: To compare two dipole antennas. One at 10-1/2 inches off the ground, and the other at 6 feet off the ground. Ground conditions were chosen to provide a "worst-case" as far as attenuation of the signal due to soil proximity. Soil conditions were extremely wet due to recent rainfall at a local park.

Antenna Used: Two types of antennas:

1. Dipole antenna at 10-1/2 inches off the ground supported by plastic tent stakes.
2. Dipole antenna at 6 feet off the ground and supported by short military telescoping masts.

Both antennas were balanced systems using ladder line from an MFJ989C antenna tuner.

Transmitter used: Yaesu FT70/G paramilitary "Manpack" transceiver

Power used: 10 watts on Single Sideband

Frequency used: Voice portion of 40 meter amateur band. 7225 - 7300 KHz

Location of stations worked: Wanted to find one station within NVIS range but far enough distance not to copy any ground-wave. Station worked was located in Menlo Park, California. This was a distance of 20 miles.

TEST RESULTS:
The station in Menlo Park, California reported my 10Watt PEP signal as:

1. "10 dB over S9" using the dipole antenna that was 6 feet off the ground.
2. "S8" using the dipole antenna that was 10-1/2 inches off the ground.

Post-Test equipment check: The Yaesu FT70/G was checked with a Motorola Model 2410 Communications Service monitor to verify the actual difference in meter indications for an "S" meter reading of "S8" and "10 dB over S9" The actual difference in level was shown to be "15 dB".

"Rules of Thumb" based on the above operations on the 40 meter band:

A. Assume a half-wave dipole at 1/4 wavelength above ground as a reference for comparison
B. A half-wave dipole at 6 to 7 feet off the ground will have an attenuation of approximately -4 dB
C. A half-wave dipole 10-1/2 inches off lossy ground will have a worst-case attenuation of approximately -20 dB
D. Assuming correct choice of frequency and a 10.7 cm solar flux value in the 200 range, a half-wave dipole at 1/4 wavelength above the ground would provide a 20 dB over S9 signal reading at the

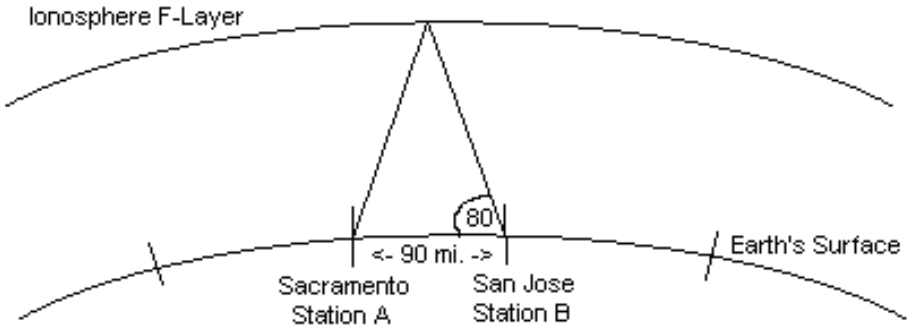
distant station when the transmitter has a power output of 100 Watts.

E. If the transmitting station uses antenna "B" above, the resultant signal strength would be: 16 dB over S9
F. If the transmitting station uses antenna "C" above, the resultant signal strength would be: S9

Based on actual documented tests between the station in Menlo Park and my station at the "San Jose Rose Garden" Municipal Park, This data tends to show that the antenna height above ground would not be the prevalent factor in establishing communications. For a 10 Watt radio to receive an "S8" signal report with a half-wave dipole at 10-1/2 inches off the ground on plastic tent stakes, it is apparent that the most important factor is proper choice of operating frequency. The Rose Garden tests were able to be done during a time when our Solar Sunspot activity produced a 10.7 cm solar flux value appropriate for the operating frequency used for this test. As of today's writing of this article (June 29th, 1995) report solar flux indexes are in the low to mid "70's".

Assume the crude drawing as follows:

Ionosphere "F-layer"



\ distance = 90 miles / Vertical radiation angle to reach from station "A" to "B" = 80 Degrees

FURTHER COMMENTS ON NVIS:

The U.S. Army did quite a bit of study toward the end of the Vietnam conflict on how to use HF radio more effectively and reliably. This effort was published in issues of "Army Communicator" magazine by Lt. Colonel David Fiedler starting in the early 1980's. Lt. Col Fiedler found that other countries, including German Ground Mechanized units of WWII, and the Soviet Union of today had implemented NVIS Since the summer of 1990, I have presented the NVIS concept at two west coast ARRL conventions and many local radio club meetings, as a way of publicizing this concept within the amateur radio community. Also, Ed Farmer, AA6ZM wrote a very extensive and well researched article on NVIS in the January 1995 issue of QST Magazine.

As a result of this work, Stanly Harter of the State of California Office of Emergency Services has taken a serious look at the value of HF communications for disaster communications. This is especially valuable for units like our California State Division of Forestry where operations in remote areas not served by the usual VHF and UHF mountain-top repeater sites could impact their ability to communicate effectively. Stanly Harter has also made recommendations for changes in HF antenna designs on their facilities used by State OES in order to effectively utilize the NVIS Concept.

In 1989, Just prior to the Loma Prietta earthquake here in the bay area, I had finished an equipment recommendation for the Director of our GSA-Communications Division with the City of San Jose. Included in the design of the radio equipment to by used by our San Jose Office of Emergency Services was an HF station which emphasized the use of NVIS high-angle skywave so that our center would have both County-wide and also solid, Northern and Central California coverage via HF communications. The Antenna consists of a 55 foot end-fed wire antenna mounted between two radio towers on the roof of our dispatch facility. At the top of one of these towers is an SGC "Smart-Tuner" which can then tune this horizontal wire on any frequency from 1.6 to 30 Mhz. The HF Radio used is a model RF3200 made by Harris/RF Communications Group. This HF station meets Part 90 rules for commercial type acceptance, and also covers any frequency from 1.6 to 30 Mhz. In an emergency, this station is capable of communications with State of California's Office of Emergency Services over their "Operation Secure" HF radio system.

Dr.Earl Stevens, Our Chief Radio Officer has his hand pointed to the ground to show relative scale.

Completed dipole antenna feed with ladder line installed 10 inches off the ground on plastic tent stakes.

10infeed shows the manner of connecting the antenna system to 3/4 inch ladder-line by the use of dual-banana plugs.

NVIS: Near Vertical Incidence Skywave

[What is NVIS?](#)
[What are the advantages and disadvantages of NVIS?](#)
[What kind of antenna works well for NVIS?](#)
[How do I select a frequency for NVIS operation?](#)
[NVIS related links](#)

What is NVIS?

NVIS, or Near Vertical Incidence Skywave, refers to a radio propagation mode which involves the use of antennas with a very high radiation angle, approaching or reaching 90 degrees (straight up), along with selection of an appropriate frequency below the critical frequency, to establish reliable communications over a radius of 0-200 miles or so, give or take 100 miles. Although not all radio amateurs have heard the term NVIS, many have used that mode when making nearby contacts on 160 meters or 80 meters at night, or 80 meters or 40 meters during the day. They may have thought of these nearby contacts as necessarily involving the use of groundwave propagation, but many such contacts involve no groundwave signal at all, or, if the groundwave signal is involved, it may hinder, instead of help. Deliberate exploitation of NVIS is best achieved using antenna installations which achieve some balance between minimizing groundwave (low takeoff angle) radiation, and maximizing near vertical incidence skywave (very high takeoff angle) radiation.

As hams, we often faithfully follow the advice: get your antenna up as high as you can get it! We do this, and other things (like choosing antennas that have a low angle of radiation) in order to maximize the distance over which we can communicate. An antenna with a particularly high angle of radiation is often somewhat disparagingly referred to as a "cloudwarmer", the implication being that if the signal isn't radiated at a low enough angle, it's being wasted. For NVIS, we ignore all this traditional advice, and select instead techniques which will maximize not our DX, but our ability to reliably communicate with other stations within a radius of 0-300 miles.

Not just any old frequency will work for NVIS. Successful NVIS work depends on being able to select, or find (through trial and error), a frequency which will be reflected from the ionosphere even when the angle of radiation is nearly vertical. These frequencies usually are in the range of 2-10 MHz, though sometimes the limit is higher. The trick is to select a frequency which is below the current critical frequency (the highest frequency which the F layer will reflect at a maximum--90 degree--angle of incidence) but not so far below the critical frequency that the D and/or E layers mess things up too much.

Note: If you're already familiar with the ionosphere's role in HF radio communications, you may want to skip to the explanation of what's special about NVIS.

There are two main types of propagation at HF, known as "groundwave" and "skywave". Groundwave

propagation occurs when the receiving station is sufficiently close to the transmitting station, and is able to receive the portion of the transmitting station's signal which clings to the ground. The range of groundwave propagation varies with the type of antenna at the transmitting station, the characteristics of the ground between the transmitting station and the receiving station, and other factors. It can be anywhere from a few miles, to a few dozen miles. Distances beyond the range of the groundwave signal are covered by skywaves. Skywaves are the waves which radiate upward at some angle from the antenna, and (we hope) are reflected from the ionosphere, to return to earth further away.

The ionosphere is a high altitude region of the Earth's atmosphere which is composed of gaseous atoms which have broken into ions. The sun is the source of the ionizing energy, so the condition of the ionosphere varies with time of day, season of the year, the 11-year sunspot cycle, and the 27-day rotation of the sun. The layers of the atmosphere that effect radio propagation are the D, E, and F layers. I won't go into much detail in outlining their roles. If you're interested in this topic, entire books have been devoted to it. In a nutshell, it's the F layer which is usually involved in reflecting our signals back to earth, while the D layer absorbs our signals. The E-layer can either help, or hinder.

Long distance propagation of radio waves is usually achieved by their being reflected from the ionosphere, and returning to earth some distance away from their point or origin. (Follow along with the diagram if you wish.) Radio waves which have been radiated at a very low angle of radiation travel a long way before finally making it up to the ionosphere, strike the ionosphere at a very shallow angle (A) and return to earth far away from their point of origin (A'). As the angle of radiation goes up, the radio waves strike the atmosphere at a more moderate angle (B), and return to earth closer to their point of origin (B'). For any given frequency and current state of the ionosphere, there may be some maximum angle of incidence at which the ionosphere will reflect signals back to earth. Signals which strike the ionosphere at a higher angle of incidence than the current maximum will not be reflected at all, but will continue on out into space, instead (C). The area of the earth to which the reflection would have occurred will be in what we call the "skip zone" (unless it's close enough to the signal source to receive the groundwave signal). The skip zone is the region consisting of areas of the earth's surface which are outside the radius the transmitting station's groundwave will reach, and yet not far enough away to receive reflections of skywaves.

NVIS techniques concentrate on the areas which are often in the skip zone. The idea is to radiate a signal at a frequency which is below the critical frequency, at a nearly vertical angle, and have that signal reflected from the ionosphere at a very high angle of incidence, returning to the earth at a relatively nearby location. (See illustration.) Of course, no antenna radiates all its signal at exactly one angle, so the best we can get is a range of angles, ranging from perfectly vertical, to nearly vertical. The portion of the signal which is radiated at a vertical, or nearly vertical, angle reflects back to earth over some radius, which is determined by the lowest angle at which the antenna radiates much signal. Absorption by the D layer, and other factors, determine some minimum frequency below which the signal will no longer be usable, and usually some distance beyond which signals will no longer be usable.

For areas which are within the groundwave range of the transmitting station, the groundwave's presence

may interfere with the reflecting skywave. It may very well help, too. It all depends on whether the groundwave and the skywave arrive in phase, out of phase, or somewhere in between, and their relative strengths. If the groundwave arrives at about the same strength as the skywave, and the two are out of phase, the signal will disappear. Since the height of the ionosphere varies with time, phase alignment may drift from in phase, to out of phase, resulting in signal fading. For this reason, it's best to minimize groundwave radiation when using NVIS techniques, so that it will be less likely to interfere with the skywave.

Although this discussion has focussed mainly on the transmission of signals, there is a corresponding advantage of using NVIS techniques in reception, and a trick or two that are useful mainly for reception. The corresponding advantage is that if your antenna favors high angles for transmission, it will also favor high angles for reception. An antenna optimized for radiating at the high angles used for NVIS will also be optimized for receiving the skywaves which will be arriving at a high angle from the ionosphere. An antenna which does not radiate much groundwave signal will also probably not receive groundwave signals as strongly. When both stations are using antennas which are optimized for NVIS, the mode is favored both in transmission and reception, and those advantages add together, increasing the chances of reliable communication.

There is also an advantage inherent in the use of NVIS style antennas which applies only to receiving. The frequencies which are useful for NVIS (usually 2-10 MHz) are the same frequencies which are most susceptible to atmospheric noise. A major source of atmospheric noise is distant thunderstorms. Nearby thunderstorms are the worst, of course, but the noise from all possible sources adds together. Unless there is a nearby thunderstorm, most noise will be the sum of the noise from distant sources which are all propagated to the receiving antenna. Since an antenna optimized for NVIS is listening mostly to signals propagated from relatively nearby areas, and does not favor the reception of signals, static crashes, and other sources of noise and interference from more distant sources, it will not hear as much noise or interference as an antenna optimized for DX operation. The result is a better signal/noise ratio.

Often, taking measures which optimize a station's NVIS capabilities will drop the noise level substantially. Sometimes, the drop in noise can be maximized at the expense of some signal strength, and result in a communication circuit which has lower signal levels, but even more dramatically lower noise levels, for an even better signal/noise ratio than could be achieved by focusing only on maximizing signal levels.

So, selecting a frequency below the critical frequency, but not too far below it, and selecting an antenna which will radiate skywaves at a high angle, and minimize groundwaves and the reception of noise, are the essential tricks of establishing reliable communication in the 0-200 mile radius which is so often a challenge for HF operation.

What are the advantages and disadvantages of NVIS?

Among the many advantages of NVIS are:

- NVIS covers the area which is normally in the skip zone, that is, which is normally too far away to receive groundwave signals, but not yet far enough away to receive skywaves reflected from the ionosphere.
- NVIS requires no infrastructure such as repeaters or satellites. Two stations employing NVIS techniques can establish reliable communications without the support of any third party.
- Pure NVIS propagation is relatively free from fading.
- Antennas optimized for NVIS are usually low. Simple dipoles work very well. A good NVIS antenna can be erected easily, in a short amount of time, by a small team (or just one person).
- Low areas and valleys are no problem for NVIS propagation.
- The path to and from the ionosphere is short and direct, resulting in lower path losses due to factors such as absorption by the D layer.
- NVIS techniques can dramatically reduce noise and interference, resulting in an improved signal/noise ratio.
- With its improved signal/noise ratio and low path loss, NVIS works well with low power.

Disadvantages of NVIS operation include:

- For best results, both stations should be optimized for NVIS operation. If one station's antenna emphasizes groundwave propagation, while another's emphasizes NVIS propagation, the results may be poor. Some stations do have antennas which are good for NVIS (such as relatively low dipoles) but many do not.
- NVIS doesn't work on all HF frequencies. Care must be exercised to pick an appropriate frequency, and the frequencies which are best for NVIS are the frequencies where atmospheric noise is a problem, antenna lengths are long, and bandwidths are relatively small for digital transmissions.
- Due to differences between daytime and nighttime propagation, a minimum of two different frequencies must be used to ensure reliable around-the-clock communications.

What kind of antenna works well for NVIS?

Dipole

Once again, the dependable dipole antenna proves itself useful. One of the most effective antennas for NVIS is a dipole positioned from .1 to .25 wavelengths (or lower) above ground. When a dipole is brought very close two ground, some interesting things happen. The most interesting thing, from an NVIS perspective, is that the angle of radiation goes up. In the range of .1 to .25 wavelengths above ground, vertical and nearly vertical radiation reaches a maximum, at the expense of lower angle radiation (which we'd like to minimize, anyway, for NVIS). A dipole can be used at even lower heights, resulting in some loss of vertical gain, but often, a more substantial reduction in noise and interference from distant regions. Heights of 5 to 10 feet above ground are not unusual for NVIS setups, and some people use dipoles as low as two feet high with good results (relatively weak signals, but a very low noise floor).

Another interesting thing that happens with very low dipoles is that their feedpoint impedance goes

down. An acceptable SWR with 50 ohm coax is likely. Plan to bring your tuner along just in case, but you may get by just fine without it.

Yet another fortunate thing about low dipoles is that they are easily erected. Finding a tree which will serve as a support is often easy, and it's not hard to get a line in a branch which will suffice. Masts made of PVC tubing are practical at these heights. Very low dipoles can be supported by traffic cones with a notch cut in the top, or a simple tripod made from short sections of PVC pipe or wooden dowels, and bungee cords.

With the exception of the very lowest dipoles, most dipoles will gain an extra 2 db or so of vertical gain if you allow the center to droop a few feet. Allowing the center to droop means that the end supports don't have to be as sturdy, which makes installing a good NVIS dipole that much easier.

Inverted Vee

The dipole's close cousin, the inverted vee, is another good NVIS antenna, which can be even simpler to support. An inverted vee will work almost as well as a dipole suspended from a slightly lower height than the apex of the inverted vee, so long as the apex angle is kept gentle--about 120 degrees or greater. An inverted vee is often easier to erect than a dipole, since it requires only one support above ground level, in the center.

Counterpoises

The high angle radiation of a dipole (or inverted vee) can be enhanced by adding a counterpoise wire below it, about 5% longer than the main radiating element, to act as a reflector. The optimum height for such a counterpoise is about .15 wavelengths below the main radiating element, but when the antenna is too low to allow for that, a counterpoise laid on the ground below the antenna is still effective.

A knife switch at the center point of the counterpoise can be used to effectively eliminate the counterpoise from the antenna system. This technique is useful for using a dipole for NVIS and longer distances, too. A counterpoise is installed at ground level, or as high as the switch can easily be reached, and a dipole is mounted .15 wavelengths above the counterpoise. When the switch is closed, the vertical gain will increase, and the noise levels will drop. When the switch is open, lower angle gain will increase, improving the antenna's performance for non-NVIS use.

How do I select a frequency for NVIS operation?

The selection of a optimum frequency for NVIS operation depends upon many variables. Among the many variables are time of day, time of year, sunspot activity, type of antenna used, atmospheric noise, and atmospheric absorption. To select a frequency to try, one may use recent experience on the air, trial and error (with some sort of coordination scheme agreed upon in advance), propagation prediction software, near real-time propagation charts (available on the Internet) showing current critical frequency,

or even just a good educated guess. Whatever the strategy used for frequency selection, it would probably be best to be prepared with some sort of "Plan B" involving communicating through alternate channels, or following some pre-arranged scheme for trying all available frequency choices in a scheduled pattern of some sort.

In this discussion, some of my comments will assume that the reader's choice of frequencies is restricted to the amateur bands, but much of the discussion will be more general.

Instructions

Model HF6V

WARNING: DO NOT INSTALL THE ANTENNA WHERE ANY PART OF IT CAN COME INTO CONTACT WITH POWER LINES IN THE EVENT OF STRUCTURAL FAILURE, DURING INSTALLATION OR IN THE COURSE OF NORMAL FLEXING AFTER INSTALLATION FOR SUCH CONTACT CAN RESULT IN DAMAGE TO PROPERTY, BODILY INJURY OR EVEN DEATH!

WARNING: IN NO CASE SHOULD THE ANTENNA BE INSTALLED WHERE STRUCTURAL FAILURE OF ANY PART OF THE ANTENNA OR ITS SUPPORTING SYSTEM CAN ENDANGER PERSONS OR PROPERTY.

CAUTION! A GROUNDED ANTENNA WILL BE AT D.C. GROUND POTENTIAL! TO AVOID THE DANGER OF SHOCK CONNECT ALL STATION EQUIPMENT TO A GOOD EARTH GROUND. IT IS ALSO RECOMMENDED THAT ALL STATION EQUIPMENT BE DISCONNECTED FROM THE POWER MAINS BEFORE CONNECTING THE FEEDLINE TO THE ANTENNA. PLEASE CONSULT THE A.R.R.L HANDBOOK OR OTHER REFERENCE MANUALS FOR ADDITIONAL SAFETY PROCEDURES WHEN WORKING WITH ELECTRICAL EQUIPMENT.

NOTE: PLEASE READ ALL INSTRUCTIONS THOROUGHLY BEFORE PROCEEDING TO ASSEMBLY.

NOTE: HIGH PERFORMANCE BUTTERNUT VERTICAL ANTENNAS REQUIRE A RADIAL SYSTEM FOR ALL INSTALLATIONS.

Butternut offers three systems for installing vertical antennas:

- Model GRK Ground Radial Kit for ground mounting—160 thru 6 meter operation
- Model RMK-II Roof Mounting Kit for roof mounting—80 thru 6 meter operation
- Model CPK Capacitive Counterpoise Kit for compact installations below 25 ft (7.6 m) above the earth—80 thru 6 meter operation

Please refer to TECH NOTES—GROUND/RADIAL SYSTEMS, at the end of this instruction, for other mounting schemes and assistance in designing your own radial system.

REQUIRED TOOLS

Flat blade screwdriver and pliers. A 1/4", 11/32" and 3/8" nut driver will be helpful.

ASSEMBLY

Refer to the appropriate diagrams and proceed as follows:

1. Check to be sure that all parts are present.

2. Install tube w/insulator (A) per instructions packaged with mounting system or Tech Notes Ground/Radial Systems.

NOTE: A small packet of anti-seize/anti-oxide compound (Butter-It's-Not™) will be found inside tube w/insulator (A). This compound should be applied lightly to each tubing joint and to the inside of all clamps that must make good electrical contact with the tubing sections.

3. Locate tube (B) and tube (B1). Slide the insulator end of tube (B1) into the end of tube (B) with hole located 1/4 in (6.4 mm) from the end of the tube. Pass a # 8 x 1 1/2" screw through both parts and secure with a lock washer and hex nut.

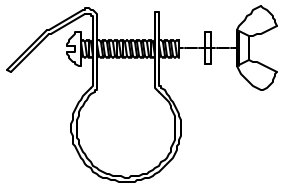
4. From the center of the insulator, measure downward to a point that is 13 in (33 cm) along tube (B) and make a pencil mark.

5. From the center of the insulator, measure upward to a point that is 9 3/8" (23.8 cm) along tube (B1) and make a pencil mark.

6. Locate coil assembly 80/40 meter (C) and slide the clamp at the outer end of the larger 80 meter coil over tube (B1), lowering the entire assembly until the middle clamp can be positioned around the insulator between tube (B) and tube (B1).

NOTE: The middle clamp may have to be pulled open slightly to pass the bolt that goes through tube (B1) and the insulator.

7. Position the center coil clamp of coil assembly 80/40 meter (C) in the center of the insulator between tube (B) and tube (B1). Pass a #10 x 1" screw through the clamp as shown. Secure with a flat washer, lock washer and wing nut.



NOTE: The outer tab of this clamp may be bent back slightly to provide clearance for the bolt, bending it back into place after assembly.

8. Stretch the 40 meter (smaller) coil on the coil assembly 80/40 meter (C) until the top of the upper clamp is even with the upper mark. Secure with a #10 flat washer, lock washer and wing nut.

9. Stretch the 80 meter (larger) coil on the coil assembly 80/40 meter (C) until the bottom of the lower clamp is even with the lower mark. Secure with a #10 flat washer, lock washer and wing nut.

10. Locate the capacitor assembly 80/40 meter (D) and install capacitor bracket 80 meter (D1) on the larger 200 pF capacitor using the installed screw.

NOTE: DO NOT USE EXCESSIVE FORCE OR OVER TIGHTEN THE SCREWS ON EITHER CAPACITOR AS YOU WILL DAMAGE THEM. DO NOT DROP THIS ASSEMBLY AS YOU MAY FRACTURE THE CAPACITOR'S CERAMIC SHELL.

11. Locate capacitor bracket 40 meter (D2) and install on the smaller 67 pF capacitor as above.

12. Install the above assembly onto the #10 screw protruding from the tab of the center clamp on the coil assembly 80/40 meter (C). Align capacitor bracket 80 meter (D1) alongside the larger 80 meter coil of coil assembly 80/40 meter (C). Secure with a #10 flat washer, lock washer and hex nut.

13. Attach the tab end of capacitor bracket 80 meter (D1) to tube (B) with capacitor bracket clamp and secure with # 8 x 1" screw, lock washer and a hex nut.

14. Attach the tab end of capacitor bracket 40 meter (D2) to tube (B1) as above.

15. Insert the un-slotted end of tube (E) into tube (B1) and secure with a # 8 x 1 1/2" screw, lock washer and hex nut.

16. Locate coil support tube 30 meter (O) and measure to a point 9 7/8 in (25.1 cm) down from the plastic insulator. Mark this point with a pencil.

17. Locate coil support tube 30 meter L bracket (O1) and place the tabbed end inside of the coil support tube 30 meter (O) securing it with a # 8 x 3/4" screw, lock washer and hex nut.

18. Place a #10 washer, lock washer and wing nut on the lower single clamp of coil/capacitor assembly 30 meter (P).

19. Place a #10 washer, lock washer and hex nut on both upper clamps of coil/capacitor assembly 30 meter (P).

20. Pass the lower single clamp of coil/capacitor assembly 30 meter (P) over the insulator end of coil support tube 30 meter (O) and slide the coil downward along the tube until the upper edge of the upper clamp is flush with the end of the insulator. Align the upper clamp with the coil support tube 30 meter L bracket (O1) and tighten the hex nut.

21. Stretch the coil until the bottom of the bottom clamp on the coil/capacitor assembly 30 meter (P) is even with the mark on coil support tube 30 meter (O) and tighten the wing nut.

22. Slide the remaining clamp from the above assembly over tube (E) and position it so the coil support tube L bracket (O1) is even with fourth turn, counting from the top of the 40 meter coil on the coil assembly 80/40 meter (C) and tighten the hex nut.

23. Hook the coil support tube 30 meter L bracket (O1) around the fourth turn of the 40 meter coil on coil assembly 80/40 meter (C). Secure with a # 8 x 3/4" screw, lock washer and hex nut.

24. Position wire clamp 0.875" 15 M w/insulator (K) around tube (F) and use a # 8 x 1" screw, lock washer and hex nut finger tight.

25. Insert the un-slotted end of tube (G) into the slotted end of tube (F) and secure with a # 8 x 1 1/4" screw, lock washer and hex nut.

26. Locate wire clamp 0.750" 15 M w/insulator (N) and position it around tube (G).

27. Insert the un-slotted end of tube (H) into the slotted end of tube (G) and secure with a # 8 x 1" screw, lock washer and hex nut.

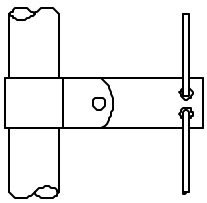
28. Locate wire clamp 0.625" 15 M w/insulator (M) and position it around tube (H).

29. Insert the un-slotted end of tube (I) into the slotted end of tube (H) and secure with a # 8 x 1" screw, lock washer and hex nut.

30. Position wire clamp 0.500" 15 M w/wire around tube (I) so the top edge is 13.5 in (34.3 cm) from the upper end of the tube.

31. Measure from the rivet of wire clamp 0.500" 15 M w/wire (L) to a point 11 ft 3 in (3.4 m) along the stranded wire and mark this point.

32. Pass the free end of the stranded wire from wire clamp 0.500" 15 M w/wire (L) through the small holes in wire clamp 0.625" 15 M w/insulator (M) and wire clamp 0.750" 15 M w/insulator (N) as shown.



33. Loop the end of the wire through the hole in wire clamp 0.875" 15 M w/insulator (K) sliding it on tube (F) until the mark on the wire appears. Wind the wire back on itself. Do not cut off the excess wire.

34. Line up wire clamp 0.875" 15 M w/insulator (K), wire clamp 0.750" 15 M w/insulator (N) and wire clamp 0.625" 15 M w/insulator (M) with wire clamp 0.500" 15 M w/wire (L) and tighten all clamps making sure the wire is moderately taut but not enough to cause the upper tubing section to bow.

ASSEMBLY

35. Place the protective cap on one end of tube (J).

36. Slide the uncapped end of tube (J) into the slotted end of tube (I) until only 25 in (63.5 cm) extends and secure with compression clamp small adjustable.

NOTE: In the following steps the antenna will be assembled and raised to its full vertical height. If the antenna is to be installed in an elevated position where it is unsafe or inconvenient to make in-place adjustments, the antenna may have to be installed in one piece. It will probably be necessary to raise and lower it and its supporting structure a number of times to arrive at the *ideal* adjustment on all bands. If so, every precaution should be observed in order to avoid possible contact with power lines and to prevent structural failure that can cause injury to persons or property.

37. Place the lower end of tube (B) through tube (E) over the insulator on tube (A) w/insulator. Line up the holes and secure it with a # 8 x 2" screw, lock washer and hex nut.

WARNING: AVOID POWER LINES!

38. Raise the assemble of tube (F) through tube (J) and slide the lower end into tube (E) fastening it securely with a # 8 x 1 1/4" screw, lock washer and hex nut.

39. Install coax 75 ohm matching (R) as shown placing the lug from the center conductor over the screw on tube (B) and the braid over the screw on tube w/insulator (A).

40. Place # 8 washers over each screw and install coil (Q) base matching. Secure with washers, lock washers and hex nuts.

NOTE: Attach radials and ground to tube w/insulator (A) using the remaining # 8 hardware.

WARNING: MAKE SURE THAT THE STATION EQUIPMENT IS CONNECTED TO A GOOD EARTH GROUND! DO NOT HANDLE CABLE CONNECTED TO STATION EQUIPMENT WITHOUT FIRST DISCONNECTING THE EQUIPMENT FROM THE POWER MAINS. YOU COULD BE ELECTROCUTED!

41. Connect coax 75 ohm matching (R) to any length of 50-53 ohm coaxial cable. Connector PL258 (S) is provided. Seal the connection with the small roll of Konnector-Kote.

CHECKOUT AND ADJUSTMENT

The dimensions and coil settings given above should produce reasonably low VSWR readings over the entire 10, 15, 20 and 30 meter bands and over at least 250 kHz of the 40 Meter band. Bandwidth on 80/75 meters should be at least 30 kHz for VSWR of 2:1

or less at the low end of the band and may be as much as 100 kHz at the high end of the band, depending on the efficiency of the ground system used, greater bandwidth being associated with lossy ground systems. It should be remembered that on those bands where the physical height of a vertical antenna is less than a quarter wavelength, the earth (or the resonant radial system in above-ground installations) will have a good deal to do with VSWR and antenna tuning, bandwidth and overall performance.

Low VSWR by itself does not mean that a vertical antenna is operating efficiently, and if low VSWR is obtained with no more than the usual *quick and dirty* ground connection, it most likely means the opposite. In general, poor operation or improper tuning of vertical antennas can usually be attributed to inadequate (or even reactive) ground systems or to other vertical conductors in the vicinity of the antenna. For these reasons it is suggested that the antenna be placed as much in the clear as possible and used with the best ground system that conditions permit. For a more complete discussion of the interrelationships between vertical antenna efficiency, bandwidth, VSWR, etc., a standard text such as the A.R.R.L. Antenna Book is recommended. See also the material included at the end of these instructions.

For adjustment purposes a simple VSWR indicator may be used. More accurate measurements may be made at the antenna (i.e., at the junction of the coax 75 ohm matching (R) and the main transmission line) than at the input end of the line, but the tuning conditions that exist at the transmitter will usually be of greater interest in that one's principal concern will be to couple power from the transmitter into the transmission line.

1. Determine the frequency at which VSWR is lowest on 80/75 meters. The coil setting given earlier should produce resonance and lowest VSWR at approximately 3700 kHz. To raise the frequency of resonance of the lowest VSWR, simply loosen the wing nut on the lower coil clamp of the coil assembly 80/40 meter (C) coil on tube (B) and stretch the coil a bit more. To lower the frequency, compress the coil. A 1 in (2.5 cm) change in the setting of this coil will produce a frequency shift of approximately 125 kHz.

NOTE: Remember that the antenna tunes very sharply in this range and that high values of VSWR may be encountered only a few kHz either side of the lowest VSWR readings, so it would be well to take VSWR readings every 25 kHz or so to avoid *running past* the frequency of resonance and lowest VSWR.

NOTE: To minimize interference to other stations and to avoid erroneous reading use only enough power to produce full-scale deflection of the meter in the *forward* or *r.f. out* position.

2. Once the proper coil setting has been found for the desired band segment, coil (Q) base matching at the base of the antenna may be adjusted for even lower VSWR. If earth losses are moderate to high a good match may be possible if coil (Q) base matching is left fully compressed; if earth losses are low (as with an extensive radial system) coil (Q) base matching may have to be stretched to twice its compressed length or more for a good match. In any case, a single setting for coil (Q) base

matching should suffice for operation over most of 80/75 meters provided the 80 meter coil is readjusted for each different band segment.

3. Determine the frequency of minimum VSWR on 40 meters. The coil setting given earlier should produce resonance and lowest VSWR at approximately 7150 kHz. The 40 meter VSWR and resonance curve may be shifted in the same manner as on 80/75 meters by changing the setting of the upper coil clamp of coil assembly 80/40 meter. On this band the setting is much less critical, and a 1 in (2.5 cm) change in the clamp setting will shift the VSWR curve approximately 80 kHz. Be sure to loosen the clamp around tube (E) that supports the 30 meter assembly and to reposition it as needed to avoid distorting the 40 meter coil.

4. Check VSWR on 20 meters. Tuning is quite broad on this band because the antenna is physically much taller than a quarter wavelength. To raise the frequency of the lowest VSWR, reposition the 30 meter assembly so that the coil support tube 30 meter L bracket (O1) can be replaced on the next lower turn of the 40 meter coil. Alternatively, to lower the frequency of lowest SWR, reconnect the coil support tube 30 meter L bracket (O1) to the next higher turn of the 40 meter coil. In some cases moving the tap point a full turn up or down may cause more of a frequency shift than is desired, in which case the entire 30 meter assembly may be rotated around tube (E) to permit adjustments of less than one full turn.

5. Check VSWR on 15 meters. The VSWR curve may be shifted upward or downward by changing the length of the stranded wire between wire clamp 0.500" 15 M w/wire (L) and wire clamp 0.875" 15 M w/insulator (K). To raise the frequency, simply shorten the wire by wrapping a longer *tail* back on itself and sliding the lower clamp upward to maintain tension. To lower frequency, feed more of the *tail* back through the hole in the insulator to increase the length of the wire between wire clamp 0.500" 15 M w/wire (L) and wire clamp 0.875" 15 M w/insulator (K). A change of 2 in (5.1 cm.) will shift the VSWR curve approximately 300 kHz.

6. Check VSWR on 10 meters. To raise the resonant frequency loosen the small hose clamp over the slotted end of tube (I) and slide tube (J) farther into tube (I); to lower the frequency, slide tube (J) farther out of tube (I) and retighten the hose clamp. A length change of 3 in (7.6 cm) should move the VSWR curve approximately 200 kHz.

7. Check VSWR on 30 meters. To raise frequency, loosen the wing nut on the bottom coil clamp of coil/capacitor assembly 30 meter (P), stretch the coil and retighten the wing nut. To lower frequency, compress the coil. A change of only 1/4 in (6.4 mm) will shift the VSWR curve approximately 100 kHz. Large changes in the setting of coil/capacitor assembly 30 meter (P) may affect 20 and 40 meter tuning, in which case it may be necessary to repeat steps 3 and 4. In general, the point at which the 30 meter coil taps on to the 40 meter coil will be the major factor in 20 meter tuning.

8. Adjustments for 40, 30, 20, 15 and 10 meters should have little or no effect on the previous adjustments for 80/75 meters, but a final VSWR check for this band should be made as in step 1 above.

NOTE: In above-ground installations it will usually be found that

resonance and lowest VSWR occur at slightly higher frequencies on all bands compared to ground-level installations. Therefore on 15 and 10 meters, where length adjustment is the means of getting antenna resonance, it is recommended that the length of the stranded-wire between wire clamp 0.500" 15 M w/wire (L) and wire clamp 0.875" 15 M w/insulator (K) be increased approximately 3 in (7.6 cm.) and that tube (J) be extended approximately 6 in (15.2 cm.) beyond the original dimensions given if any above-ground installation is contemplated. These are merely recommended preliminary settings, for it is impossible to indicate precise settings that will produce resonance or lowest VSWR at a given frequency in all installations.

In the preceding steps it has been assumed that the antenna has been installed in a more or less clear spot away from other vertical conductors such as TV antenna feedlines, towers and masts, and that a minimal ground system (or a system of resonant radials in the case of above-ground installations) has been installed.

If those fairly basic conditions have not been met it is likely that resonance and low VSWR will be impossible on some or even all bands. One should bear in mind that VSWR, even with a resonant antenna, will depend in large measure on local ground conductivity, height above ground in the case of an elevated antenna, the extent of the radial, counterpoise or other ground system used, and on other factors over which the operator may have little or no control. Fortunately, the evils of VSWR greater than unity have been grossly exaggerated in recent decades, and the only practical difference between a VSWR of unity and one of, say, 3:1 in the average case lies in the reluctance of modern equipment to deliver full power into lines operating at the higher VSWR without the help of a transmatch or other outboard matching device. Transmitters having so-called broadband solid-state output circuits (no tuning or loading controls) may be especially troublesome in this regard, whereas the older vacuum tube pi-network transmitters can usually be adjusted for maximum output over a tuning range where the VSWR does not exceed 2:l.

THEORY OF OPERATION

The first L/C circuit generates enough reactance to bring the whole HF6V to resonance on 80 meters allowing it to act as a 1/4 8 radiator. It also generates enough *capacitive* reactance to produce another discrete resonance at about 11 MHz. The second, 40 meter L/C circuit generates enough reactance to resonate the whole HF6V allowing it to act as a 1/4 8 radiator. In order to minimize conductor and I^2R losses an 80 and 40 meters where the antenna is physically shorter than a 1/4 8 and thus operates with lower values of radiation resistance, large-diameter self-supporting inductors and low-loss ceramic capacitors are employed. Where the height of the HF6V is slightly greater than a 1/4 8 on 30 meters, an L/C series tuned circuit taps onto the 40 meter coil for the extra inductance to pull the earlier 11 MHz secondary resonance down to 10 MHz. At the same time, a portion of the 40 meter coil is shorted out which allows the circuit to resonate on 30 meters The addition of this circuit also produces additional resonances at 14 MHz and 28 MHz. On 20 meters the entire radiator operates as a 3/8 8 vertical with much higher radiation resistance and VSWR bandwidth than conventional or *trapped* antennas having a physical height of 1/4 8 or less. Because the 20 meter radiation resistance will be several

THEORY OF OPERATION

times as greater as that of conventional vertical antennas, an electrical 1/4 8 section of 75-ohm coax is used as a *geometric mean* transformer to match the 100-odd S of feedpoint impedance on that band to a 50 S main transmission line of any convenient length. The HF6V operates as a slightly extended 1/4 8 radiator on 15 meters, a 1/4 8 stub decoupler providing practically lossless isolation of the upper half of the antenna on that band. On 10 meters the HF6V becomes a 3/4 8 radiator with considerably greater radiation resistance and efficiency than 1/4 8 trapped types.

ELECTRICAL AND MECHANICAL SPECIFICATIONS

Height (adjustable): 26 ft (7.9 m)
Shipping Weight: 14 lbs (6.3 kg)
Feedpoint Impedance: Nominal 50 ohms through included matching line.
VSWR at resonance: 1.5:1 or less all bands
Power rating: 2 kW PEP 75/80, 40, 20, 15, l0 meters; 500 W PEP 30 meters
Wind loading area: 2 ft^2 (.19 m^2)
Bandwidth for VSWR of 2:1 or less: entire band 10, 15, 20, 30 meters, 250-300 kHz
40 meters, 40-100 kHz 75/80 meters

GUYING

The HF6V is designed to survive winds of up to 80 mph (129 kph) without guying in the absence of ice loading or heavy precipitation, but over a period of time it is to be expected that frequent or even constant flexing or vibration will reduce the chances for survival in winds that would not damage a newly installed antenna. Therefore in areas of frequent or heavy winds a set of short non-conductive guys should be used to reduce the stresses that wind loading will impart to the lower sections of the antenna. In this connection, it should be noted that light nylon twine is totally unsuitable as guying material because it has too much stretch per unit length, although the heavier sizes of nylon rope (or even sash cord) may be suitable if used in short runs. Polyethylene rope may be used, but because some grades tend to deteriorate fairly rapidly, periodic inspection should be made. A single set of guys placed just above the 30 meter circuit will contribute greatly to the stability and the longevity of the antenna, provided that the guys retain a slight amount of slack and do not come off at too steep an angle. At Angles of less than 45/ the guys begin to exert a downward compressive force on the structure that can be more of a threat to survival than lateral wind loading on an unguyed structure. Under no circumstances should guys be placed higher than one-third of the way up the antenna. The upper two-thirds of the HF6V has little more than its own weight to support, so these sections may be allowed to bend with the wind with no serious risk of damage. It is the lower third of the antenna that must support both the weight of the upper sections and the wind loading on them and are thus more likely to receive damage in severe winds.

TECH NOTES—GROUND RADIAL SYSTEMS

MOUNTING TUBE INSTALLATION

When tube w/insulator (A) is ground mounted, it should be protected against corrosion if placed in concrete, damp acidic or alkaline soil. Asphalt roofing compound, polyurethane varnish or other sealant that protects against moisture may be used.

Concrete may be used in areas of high winds for greater strength, in which case the post may be twisted slightly during setting for easy removal later.

Tube w/insulator (A) must be installed in a hole approximately 21 in (53.3 cm) deep so that the upper end of the fiberglass insulator is approximately 7 in (17.8 cm) above ground level. Pack earth tightly around tube w/insulator (A) so that it remains vertical.

NOTE: HAMMERING TUBE W/INSULATOR (A) INTO THE EARTH MAY CAUSE THE INSULATOR TO SPLINTER. If the post must be hammered into the earth, protect the end of the insulator with a block of wood

NOTE: DO NOT USE U-BOLTS TO ATTACH TUBE W/INSULATOR (A) TO A MAST, TOWER ETC. U-BOLTS WILL EVENTUALLY CUT INTO THE TUBING AND WEAKEN THE INSTALLATION. If U-bolts must be used, place a larger diameter metal, such as the MPS Mounting Post Sleeve over tube w/insulator (A). Similar precautions should be observed when using TV style towers with locking bolts.

The RMK-II Roof Mounting Kit includes the MPS as well as the STR-II Stub Tuned Radial Kit.

GROUND MOUNTING

A vertical antenna in its simplest form, is electrically equivalent to one-half of a dipole antenna stood on end. When the antenna is mounted close to the ground, the earth below takes the place of the "missing" half of the dipole. If ground conductivity is fair to good, a short metal stake or rod may provide a sufficiently good ground connection for resonant and low SWR operation on the bands for which the antenna is designed. This basic arrangement is shown in figure 1.

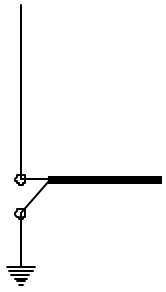

Figure 1

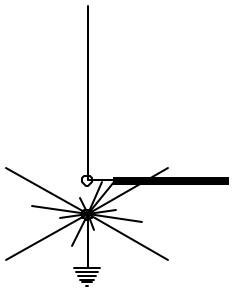

Figure 2

The way it works is that the capacitance between the vertical radiator and the ground causes *return* currents to flow along the earths surface back to the transmitter. If they have to come back along untreated lossy earth thy get back to the source greatly attenuated. This *return* loss is like a resistor in series with the antenna radiation resistance and will therefore affect the feed point impedance. In almost every case the efficiency of a vertical antenna will be greater if radial wires are used to improve ground conductivity as in figure 2. It's important to note that there's no point in cutting radials to any particular length when ground mounting because the earth will detune them anyway. All you want to do is make the surface of the earth around the antenna more conductive than it is ordinarily.

TECH NOTES—GROUND RADIAL SYSTEMS

If you can't copper-plate the backyard, the best approach is to run out as many radials as possible, each as long as possible around the antenna in all directions. Radials may be left on top of the ground however they should be buried for the sake of pedestrians and lawnmowers.

How long should radials be? A good rule is no shorter than the antenna is tall because 50% of your losses will occur in the first 1/4 8 out from the antenna. If you have more than a dozen radials, they must be longer to get the most out of them which is why the FCC specifies 113 wires each .4 8 for AM broadcast stations—the equivalent of a zero-loss ground plane. Obviously, for most ham work this would be overkill.

In some cases wire mesh (i.e. chicken wire) may be used as a substitute for radial wires and/or a ground connection, the mesh or screen acting as one plate of a capacitor to provide coupling to the earth beneath the antenna.

It should be noted that a ground rod is useful only as a d.c. ground or as a tie point for radials. It does little or nothing to reduce ground losses at r.f. regardless of how far it goes into the ground.

Bare wire, insulated, any gauge, it doesn't matter. The current coming back along any one wire won't amount to that much.

EFFICIENCY

The importance of reducing losses in the ground system can be seen from an examination of a vertical antenna's feedpoint impedance which at resonance consists of three components: antenna radiation resistance; conductor loss resistance; and earth loss resistance. An unloaded quarter-wave vertical antenna has a radiation resistance of about 35 ohms with negligible ohmic or conductor loss, but ground loss resistance may be very great if no measures are taken to reduce it, and in some cases ground loss R may even exceed the antenna radiation resistance. These three components may be added together to arrive at the feedpoint **impedance** of a **resonant** (no reactance) antenna. For the sake of illustration, assume that the ground loss beneath a quarter wavelength vertical antenna is 15 ohms, that conductor loss resistance is zero, and that the radiation resistance is the textbook figure of 35 ohms. The feedpoint impedance would then be 15 + 0 + 35 = 50 ohms, and the antenna would be perfectly matched to a 50 ohm coaxial line. Since the radiation resistance is an index of the amount of applied power that is consumed as useful radiation rather than simply lost as heat in the earth or in the conductor, the radiation resistance must be kept as high as possible in relation to the total feedpoint impedance for maximum efficiency. Efficiency, expressed as a percentage, may be found by dividing the radiation resistance by the total feedpoint impedance of a resonant antenna, so under the conditions assumed above our vertical antenna would show an efficiency of 35/50 = 70%. As a vertical antenna is made progressively shorter than one-quarter wavelength the radiation resistance drops rapidly and conductor losses from the required loading inductors increase. A one-eighth wave inductively loaded vertical would have a radiation resistance of something like 15 ohms and coil losses (or trap losses for multiband antennas) would be in the range of 5 ohms. Assuming the same value of ground loss resistance (15 ohms), the feedpoint impedance would become 15 + 5 + 15 = 35 ohms and

the efficiency would be 15/35 = 43%. From the above calculations it is clear that the shorter a vertical antenna must be the less efficient it also must be for a given ground loss resistance. Or to state the matter another way, more elaborate ground or radial systems must be used with shorter verticals for reasonable efficiency. If the ground loss of resistance of 15 ohms from the preceding example could be reduced to zero ohms, it is easy to show that the efficiency of our one-eighth wavelength loaded vertical would increase to 75%. Unfortunately, more than 100 radials each one-half wavelength long would be required for zero ground loss, so lower efficiencies with shorter radials must usually be accepted for the sake of convenience. In spite of their limitations, short vertical antennas over less than ideal ground systems are often more effective DX performers than horizontal dipoles which must be placed well above the earth (especially on the lower bands) to produce any significant radiation at the lower elevation angles. Verticals, on the other hand, are primarily low-angle radiators on all bands.

ABOVE GROUND (ELEVATED) INSTALLATIONS (rooftop, tower, mast. etc.)

The problem of ground loss resistance may be avoided to some extent by mounting a vertical antenna some distance above the earth over an artificial ground plane consisting of resonant (usually 1/4 8) radial wires. Four resonant radials are considered to provide a very low-loss ground plane system for vertical antennas at base heights of 1/2 8 or more. This arrangement contrasts favorably with the more than 100 radials for zero ohms loss resistance at ground level, and since 1/2 8 is only about thirty-five feet at 20 meters, very worthwhile improvement in vertical antenna performance can be realized, at least on the higher bands, with moderate pole or tower heights. At base heights below 1/2 8 more than four radials will be required to provide a ground plane of significantly greater conductivity than the lossy earth immediately below the antenna: even so, a slightly elevated vertical with relatively few radials may be more effective than a ground-level vertical operating over a larger number of radials if only because the former is apt to be more in the clear. Resonant radial lengths for any band may be calculated from the formula:

$$Length\ (ft) = \frac{240}{Frequency\ (MHz)}$$

Figure 3 shows the basic ground plane system for elevated verticals. Radials may slope downward as much as 45 degrees without any significant effect on operation or performance. Radials for different bands should be separated as much as possible and the far end of each radial insulated from supporting wires. Figure 4 shows a ground plane system that uses four resonant radials for 40 meters, another set of four for 20 meters, and a third set for 10 meters. A separate set for 15 meters is not ordinarily required because the 40 meter radials operate as resonant 3/4 8 radials on that band. At the lower heights the separate wires of this system may provide enough capacitance to ground to permit low SWR operation on 80/75 meters as well, but it is probable that at least one resonant radial will be required for low SWR on that band. It's important to note that cutting each conductor of rotator cable to a specific frequency will not work unless you separate it, angling each conductor away for most of its length because the longer ones will detune the shorter ones.

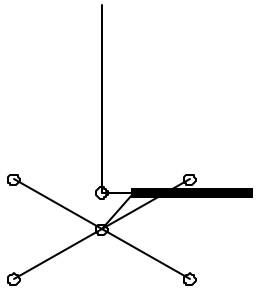

Figure 3

TECH NOTES—GROUND RADIAL SYSTEMS

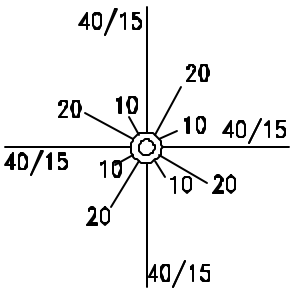

Figure 4

The 12-radial system of Figure 4 is a very good one, but it requires at least 12 tie-off points. Butternut has developed a multiband radial made of 300-ohm ribbon that resonates simultaneously on 40, 20, 15 and 10 meters. Four such radials offer essentially the same ground plane performance as the system of Figure 4 but require only 4 supports. These multiband radials plus additional wire for an 80 meter radial are available separately (our STR-II kit) or as part of the Butternut roof mounting kit (RMK-II).

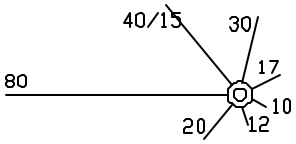

Figure 5

There are times when physical restrictions will dictate the use of fewer than four radials, and at least one manufacturer recommends 2 radials per band, the radials for each band running 180 degrees away from each other. A simpler (and no doubt less effective) system is shown in Figure 5. Since only one resonant radial is used per band the antenna will radiate both vertically and horizontally polarized energy, and the pattern will not be completely omnidirectional. For true ground plane action and predominantly vertical polarization no fewer than three equally-spaced radials should be used.

Figure 6 illustrates the construction of a multi-band radial which is resonant on 40, 20, 15 and 10 meters. Good quality 300 ohm TV ribbon lead should be used (velocity factor is critical), and the conductors should employ at least one strand of steel wire to support the weight of the radial. Four such radials will be the practical equivalent of the system shown in figure four for operation on 40 through 10 meters.

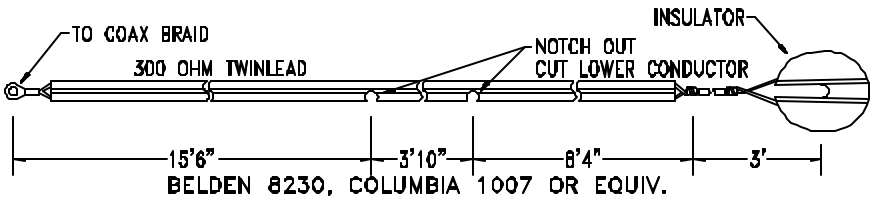

Figure 6

Regardless of the number of radials used in either elevated or ground level systems, all radials should be attached to the ground connection at the antenna feedpoint by the shortest possible leads. An elaborate radial system at ground level, for example, cannot be used with a vertical antenna on a rooftop or on a tall tower, for the length of the ground lead would effectively become part of the antenna, thus detuning the system on most or all bands.

METAL TOWERS AND MASTS

If a metal mast or tower is used to support a vertical antenna all radials should be connected to the mast or tower at the ground connection of the antenna feedline. This is because one of the functions of a resonant radial is to detune a supporting metal structure for antenna currents that might otherwise flow on the structure and thus turn the vertical antenna system into a vertical long wire with unwanted high-angle radiation.

OTHER MOUNTING SCHEMES

In cases where a resonant vertical antenna may neither be ground mounted nor used with an elevated ground plane, operation may still be possible if connection can be made to a large mass of metal that is directly connected or capacitively coupled to the ground, e.g., central air

conditioning systems or structural steel frames of apartment buildings. Some amateurs have reported good results with vertical antennas extended horizontally or semi-vertically from metal terraces which serve as the ground connection. Alternatively, a quarterwave vertical may be window mounted if a short ground lead to a cold water pipe or radiator can be used. If a long lead must be used, tuned radials may be required for resonance on one or more bands. Great care should be exercised in such installations to avoid power lines and to keep the antenna from falling onto persons or property.

MOBILE HOME AND RV INSTALLATION

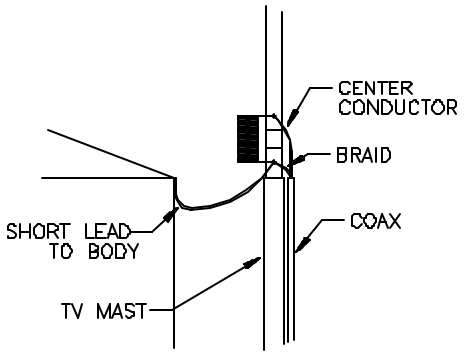
The principles of vertical antenna installations for use on mobile homes or RV's are the same as for other installations, and they all boil down to two main considerations. The first is that of erecting the vertical in the clearest possible spot, away from obstacles (including the MH or RV) that can interfere with radiation from the antenna. The second is that of installing the beat possible ground system beneath the antenna in order to minimize losses from r.f. currents flowing in the earth below the antenna. Fortunately, the metal bodies of both MHz and RVs can be used as highly conducting ground planes for vertical antennas in exactly the same way that automobile bodies, etc., provide the ground system for shorter vertical antennas for mobile operation. The metal body of an automobile, MH or RV may be viewed as one plate of a capacitor. Since the surface area of even a small automobile is quite large and in close proximity to the earth, its body is tightly coupled to the earth below and may be considered simply as an extension of the earth itself—a kind of hill as far as radio frequencies are concerned, but one having higher conductivity than the earth itself. RVs and especially MH having much greater surface area, will therefore provide a more extensive and effective ground system than a large number of radial wires occupying the same space as the MH or RV.

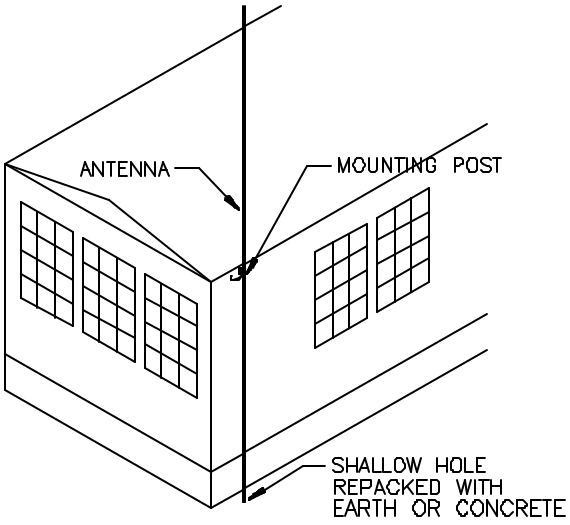
As in mobile installations, a vertical antenna may be mounted almost anywhere on the body of the vehicle or MH and made to operate with reasonably low VSWR, but it is generally considered that the best possible location for a mobile antenna is in the middle of the roof of the vehicle, i.e., at the center of the vehicle's ground plane and at a point where the antenna will not be in the "shadow" of any part of the vehicle. It is not usually convenient, or even practical to install a relatively tall vertical on the roof of an RV or MH for any number of reasons, so the next best procedure would be to install a vertical antenna with its base at the same level as the roof, preferably near the middle of one of the longer sides. The exact way in which this may be done is a matter of convenience, but a short mast extending from ground level to the roof of the MH and RV and placed alongside the building or RV would provide a stable and sturdy support with a minimum of mounting brackets and other modifications to the RV or MH. For portable operation such a mast could simply be lashed alongside the RV with the base in a shallow hole in the ground for additional support, and there would be no harm in extending the mast a few inches above the roof level to permit attachment of ropes which could be used to hold the mast firmly against the side of the vehicle and to prevent side sway.

This system has been used successfully with various types of RVs, travel trailers and even passenger automobiles during portable operation. For "L" shaped mobile homes a vertical antenna should be placed in the corner of the "L" so that the metal roof will provide groundplane coverage over 270 degrees.

TECH NOTES—GROUND RADIAL SYSTEMS

In all cases the base of the vertical antenna should not be more than a few inches away from the MH or RV so that the shortest possible lead may be run from the ground connection of the antenna to the metal body, as the length of this ground lead will effectively lengthen the antenna itself on all bands, and detuning can occur in some cases. A good electrical connection between the body of the RV or MH and the antenna is important, and in the case of mobile homes it would be a good idea to make sure that good electrical contact exists between the different parts of the metal body. Discontinuities can often lead to the production of harmonic radiation and TVI. The essential circuit connections are shown in the diagram above.





For permanent installations the bottom of the mast may be set deeper in the ground, and concrete may be used for greater strength and stability. The upper portion of the mast should be securely attached to the side of the building. Steel TV mast sections are readily available in lengths of ten feet and the mounting posts of Butternut HF verticals will slide into those which have an outside diameter of 1 1/4 inches and a wall thickness of .058 inches. Other vertical antennas may use different mounting techniques and requirements, so be sure to select a mast that will be suited to the particular situation. The main point to keep in mind is that the mast should not extend more than a few inches above the level of the roof so that the ground lead may be kept short.

LIGHTNING PROTECTION

Modern solid state amateur equipment is particularly vulnerable to damage from lightning or static induced transients that may appear on transmission lines, and conventional air-gap lightning protectors may provide no real protection at all for solid state gear. A line of very effective lightning and static protectors has been developed by ALPHA DELTA COMMUNICATIONS, P.O. Box 571, Centerville, Ohio 45459, for use with solid state equipment, and since these devices feature much faster transient discharge times than earlier designs, they should be investigated for possible use with all vertical and other antenna systems.

TROUBLESHOOTING

Check out your installation again, looking for loose connections and checking all dimensions. Then refer to the list of possible symptoms below:

Symptom: Few or no signals heard: bands seem *dead*, SWR is very high.
Look for: Open or shorted feedline, open or shorted matching line, broken connection at base of antenna (feedpoint).

Symptom: High SWR on 20 meter; other bands OK.
Look for: Missing matching line. Antenna not properly tuned. 20 meter radials not present or wrong length. Consult instructions for tuning and radial information; install matching line *RG-11 75 ohm coax, 11 ft 4 in (345.4 cm) if solid dielectric, 13 ft 6 in (411.5 cm) if foam type*.

Symptom: High SWR on some bands, but signals heard on all bands (conditions permitting).
Look for: Missing or defective radial system. Install as per instructions and check connections to radials and ground system. Keep this connection 6 in or less.

Symptom: High SWR on one band when antenna is roof-mounted. Radials are in place, but antenna will just not tune.
Look for: Radials of wrong length or running close to metal rain gutters or roof flashing. Tune radials and/or reroute them away from metal.

Symptom: Tuning is *sharp* with narrow bandwidth on 80 meter (and 160 meter if TBR-160-S is in place).
Look for: Normal condition. The total length of the antenna represents such a small percent of a wavelength on these bands that sharp tuning is a normal condition.

Symptom: Antenna was installed on the ground and tuned OK, but tuning changed over a period of weeks or months.
Look for: Antenna installed over poor ground system. Ground conditions have changed, causing shift in resonance. Install radial system as per instructions. Check connection to radial system. When you see this problem, you may assume that a ground rod without a radial system is not enough.

Symptom: Resonant point changes during wet weather.
Look for: Normal condition.

Symptom: Insulation arcs over between 80 meter and 40 meter coils damaging fiberglass.

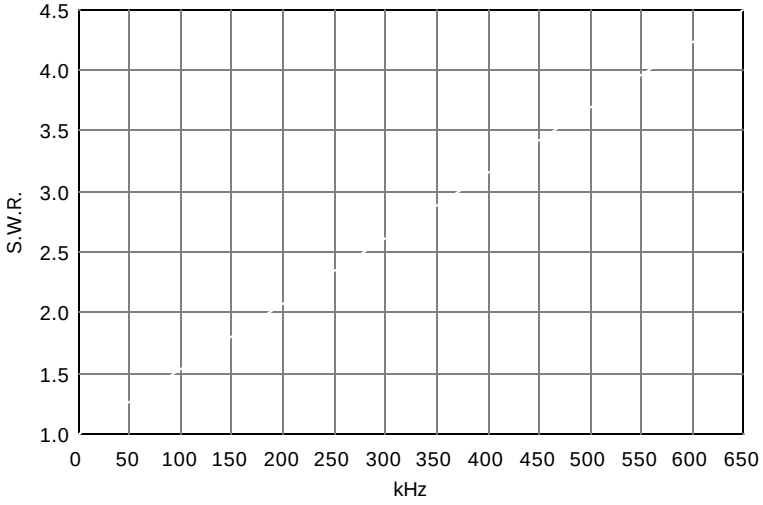
TROUBLESHOOTING

Look for: Operation at high power levels in areas where salt or pollution deposits have built up on the insulators. The cure is to keep insulators clean through routine maintenance.

Symptom: Intermittent operation. SWR jumps up and down suddenly, and reception is also intermittent.
Look for: Loose connections in the feedline or matching line (if used). Bad relay in rig. Bad antenna switch or connecting cable. Broken or corroded connections at the feedpoint. Bad radial/ground connection. Radial or antenna contacting metal when wind blows. Loose hardware on the antenna. Check and secure all connections.

Symptom: Antenna displays generally degraded performance after long period of time.
Look for: Lack of routine maintenance. Coax may be waterlogged or damaged. Build up of salt or pollution deposits on insulators and capacitors. Radial system corroded or rotted away. Owner must do routine maintenance at intervals, according to local conditions.

Symptom: SWR is OK on 75 meter, but goes up gradually when high power is applied. This is accompanied by heating of 200pF capacitor.
Look for: Bad ceramic capacitor. Replace.



Symptom: Antenna doesn't tune 80 meter or 160 meter, even though radials are in place and of proper length.
Look for: Antenna far out of tune; operator has not followed systematic tuning procedure. Start with suggested settings in instructions. Make an SWR chart to determine point of resonance. Adjust coils *carefully!* Remember, tuning, is *sharp* on these bands, so it is easy to pass the resonant point, then assume erroneously that the antenna isn't tuning.

BEFORE you call the manufacturer for help, please double check your installation, including all connections and dimensions. Tune carefully and systematically. Have SWR curves available. Be prepared to describe your installation in detail.

LIMITED WARRANTY

Butternut Manufacturing Co. warrants on the terms hereof, to a Customer who has purchased a Product from a Seller, for a period of one year from the date of the purchase, that the Product was not Defective, but this warranty is void if the Product has been subjected to improper or abnormal installation or usage, or a serial number on the Product has been defaced or removed.

If a Customer believes that a Product is Defective, the customer may, within such one-year period, return the entire product to Butternut at Butternut's factory, all shipping charges pre-paid by the Customer. If the Product was Defective, Butternut will at its option and expense repair or replace the Product and will at its expense return the repaired or replaced Product to the customer, in a manner selected by Butternut, at the address from which the Customer sent the Product to Butternut.

THE ABOVE WARRANTY AND REMEDY ARE EXCLUSIVE AND ARE IN LIEU OF ALL OTHER WARRANTIES, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE.

NO SELLER WILL BE LIABLE FOR ANY LOSS, INCONVENIENCE OR DAMAGE, INCLUDING DIRECT, SPECIAL, INCIDENTAL OR CONSEQUENTIAL DAMAGES RESULTING FROM THE USE OF OR INABILITY TO USE A PRODUCT, WHETHER THE LIABILITY WOULD RESULT FROM BREACH OF WARRANTY OR UNDER ANY OTHER LEGAL THEORY.

For instance, this warranty does not cover damage to or caused by an antenna (a) by reason of the antenna acting as a lighting rod, (b) by reason of corrosion or strain from exposure of an antenna to wind or weather, (c) from improper assembly, installation or use of an antenna, or (d) from failure periodically to inspect and maintain an antenna and its installation. The Customer is responsible to insure that installation and use of an antenna complies with applicable laws (such as zoning laws) and regulations (such as condominium regulations).

SOME LAWS DO NOT ALLOW THE EXCLUSION OF IMPLIED WARRANTIES, AND IF THESE LAWS APPLY, THEN ALL EXPRESS AND IMPLIED WARRANTIES ARE LIMITED IN DURATION TO SUCH ONE-YEAR PERIOD. NO WARRANTIES OF ANY KIND APPLY AFTER THAT PERIOD.

Such repair or replacement is the Customer's sole and exclusive remedy for a Defective Product. Specifically, Butternut is not liable (to the Customer or otherwise) for (a) any loss or damage arising in any way from a Product or from actual or anticipated sale, lease, license or use of a Product, or involving any matter such as interruption of service, loss of business or anticipated profits, or delay in receiving, repairing, replacing or returning a Product, or (b) any incidental, indirect, special or consequential damages.

No other person (such as an employee, agent or dealer) is authorized to change this warranty in any way, or to give any other warranties of any kind on behalf of Butternut. This warranty gives a Customer specific legal rights, and a Customer may also have other rights, which vary from state to state.

As used herein the *Customer* is the initial end-use purchaser of a Product from a Seller, a *Product* is an antenna or accessory therefor manufactured by Butternut, a Product is *Defective* if and only if the Product was not free of defects of material and workmanship when manufactured, and a *Seller* is Butternut and any authorized Butternut dealer.

My 2004 Dayton Hamvention Power Point presentation on Small Verticals can be downloaded here... DAYTON 2004.

The main points when dealing with small antennas are:

There is no magic bullet or magic cure to make a small antenna act like a large one. It all comes down to current distribution over linear distance.

Small antennas require extraordinary care to obtain high efficiency.

How do we make a *small* antenna as efficient as possible?

- First, we make current as uniform as possible over the length of the antenna.
- Second, we use low loss loading such as optimum form (size, length, and diameter) loading coils.
- Third, we make the antenna as large and straight as possible in a line. We don't fold, bend, zigzag, or curve the antenna especially in the high current areas.
- We keep the high voltage points (the open ends) away form other things (like lossy earth), and the high current areas away from other large lossy conductors.
- Most important, we keep current as high as possible throughout the length of the antenna by using as much capacitance as possible at the antenna ends.

What this does is maximize radiation resistance (while at the same time minimizing loss). The text below explains how radiation resistance and loss interact.

Radiation Resistance

Radiation resistance is probably the most abused and misused term in antennas. The reason it is so often misused is the lack of clear definition. When a term has several nebulous meanings and uses, it is only natural that misuses will appear. The lack of a firm well-accepted definition allows meanings to slip from one application into another, where a totally erroneous conclusion can be drawn from what otherwise would be a good formula!

Common Uses

There are two commonly used "correct" meanings of radiation resistance and one totally incorrect use. The "correct" uses are:

- The resistive part of an antenna's feedpoint impedance that is caused by radiation from the antenna
- The total EM power radiated in all directions divided by the square of net current causing the radiation

Neither of the above definitions include loss resistances of any type! The moment loss resistance is included, we have the third commonly used (but totally useless) definition. This definition, which includes losses, must be considered incorrect because it is comprised of resistances that have nothing to do with radiation. The misused definition is:

- The real (or resistive) part of an antenna's feedpoint impedance including loss related resistances.

The correct name for the third "radiation resistance is actually the antenna ***feedpoint resistance***, not radiation resistance!

Of the above ***good*** definitions, the first definition is the most commonly abused through mistake. The second definition is an IRE definition (albeit a good one that never caught on). In every case I've seen, it is the second good definition that always provides the most direct and useful answer.

Examples of Misuse

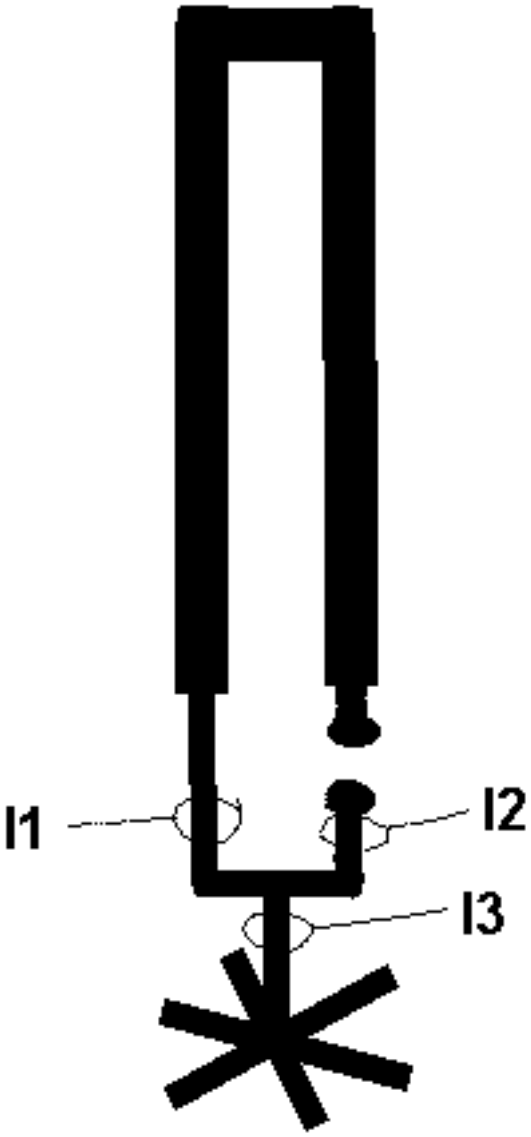
Folded Monopoles

Folded monopoles probably provide the best examples of misuse of the term radiation resistance. Quite often, in discussions of folded monopoles, claims are made that multiple drops increase the radiation resistance and lower losses. The justification for this incorrect claim is the folding raises

radiation resistance, and % eff = 100 * Rrad/(Rrad + Rloss) .

What folded monopole fanatics forget is that all losses must be normalized to the point where radiation resistance is taken, otherwise the efficiency formula won't mean a thing!

Let's look at what actually happens in a folded element, and use it to understand how the poor definition of radiation resistance causes the misunderstanding.



Consider the unipole above. Lets assume we short the open terminals, and feed it as a normal Marconi vertical with a feedpoint at the point where we measure I3. I3 is ALWAYS the vector sum or in-phase combination of currents I1 and I2. With continuity through each leg, I1 and I2 share all of the ground current. This happens regardless of where the feedpoint is located in the lower portions of the antenna.

With 1/4wl height and a reasonable element diameter, the radiation resistance (fed as a traditional monopole) would be about 36-ohms.

Assume ground loss, normalized to the point where we measure I3, could be represented by 14 ohms. Applying 500 watts would make current I3 equal 3.16 amperes. **Power loss in ground resistance would be I^2R, or 3.16^2 times 14, about 140 watts.** Feedpoint resistance would be 50 ohms. Feedpoint power, as a check, would be 3.16^2 times 50 ohms or 500 watts. With equal diameter legs, that current would divide and 1.58 amperes would flow in each upper leg.

Let's use the formula %eff = 100*Rrad/(Rrad+Rloss). We have 36/36+14 = .72 so the result is 72% efficiency, 28% loss. **28% loss times 500 watts is 140 watts in ground losses.** This matches the other method just above.

Opening the terminals and feeding as a folded unipole, half of the radiator current is in I1 while the other half is in I2. Current is halved to 1.58 amperes at the feedpoint and power remains the same. The feedpoint resistance now becomes 200 ohms. We can confirm this with I squared R, or 1.58^2 *200=500 watts. It all works out great so far!

Now let's MIS-use the same efficiency formula, like Orr does in his Handbook and others do in various places. We would have 200/200+14 = .9346 or 93.46 % efficiency.

We know we still have 3.16 amperes flowing as I3, and we know ground resistance is still 14 ohms (normalized to the point where I3 is measured). I-squared-R losses are 3.16^2 * 14 = 140 watts! We have exactly the same power loss.

Let's transform the ground loss value that was normalized at 14-ohms where I3 is measured to the feedpoint by the same impedance multiplication as the feed resistance, or 1:4. We'd now think ground resistance would be 4*14 = 56 ohms. 56 ohms of the feedpoint resistance is loss. Trying that same efficiency formula, we get:

144/144+56 = .72, or 72% efficiency!!! Now everything checks out fine.

The Common Mistake

Orr and others have used the first definition of radiation resistance, the portion of the terminal

resistance of the feedpoint responsible for radiation. Unfortunately ***they failed to normalize ground losses to the same point where the radiation resistance was taken!***

We can not use a formula that is based on everything being normalized to one point, unless we actually do that for every term in the formula!

There is no change in efficiency when the NET radiator current remains the same, and when ground current remains the same. It is pathological engineering to think otherwise.

Using The Second Definition

If we use the second IRE definition of radiation resistance, where the effective current causing radiation is compared to power radiated, we find nothing changes. A folded dipole or monopole has the same radiation resistance as a regular dipole or monopole the same size, and a small loop has the same radiation resistance regardless of turns.

The magic vanishes along with the incorrect definitions and perceptions.

You can read about this in textbooks. The "Antenna Engineering Handbook" by Jasik in 3-13, 19-3, and in other sections uses correct definitions and descriptions.

Quad's and other Loops

We find the same efficiency misconceptions in articles about small loops and large quads. Authors sometimes assume, incorrectly, radiation resistance changes in a favorable proportion to loss resistance as we make the feed impedance increase. What we really are doing is placing the feedpoint in series with a smaller portion of NET current causing radiation.

With a large full-size quad element the pattern under some conditions will slightly change, but efficiency remains basically the same. With a small loop antenna, losses can actually increase with more turns!

Terminated Folded Elements

Another abuse of radiation resistance is found in terminated antennas. Some manufacturers and authors claim a resistance can be inserted in series with one leg of a folded monopole or folded dipole, and the other leg fed. The usual arm-waving claim is the antenna isn't really resistor loaded, and that efficiency is very good because radiation resistance is high.

That claim is absolute nonsense!

A large terminated Rhombic is well-known to have poor efficiency. Rhombic gain is actually low compared to other antennas having the same sin/sin x antenna pattern, because Rhombic efficiency is generally less than 50%. At least half of the power is consumed in termination and ground losses below the antenna. The actual gain may be reasonably high compared to a dipole, but not to other efficient antennas with the same half-power beam width.

The typical manufacturing buzz-word is that terminated monopole and dipole antennas are "traveling wave antennas" and by some magic (that even large terminated Rhombic antennas can't achieve) have broad bandwidth and high efficiency.

A Rhombic focuses energy (that is not transformed into heat) into a narrow beam that has considerable gain, but if it sprayed the radiation around in a non-focused pattern, a regular dipole would win hands down. Throw a resistor on that dipole to smooth SWR variations, or on a vertical, and efficiency suffers.

I listened to a station on 75 meters 600 miles away testing a Sommer T-25 vertical. He was 30 over nine using a dipole, and dropped to S6 with the vertical. The European he was working reported a similar change. By removing the termination resistor and base-loading the same vertical, a local Ham gained almost 25dB on 80 meters!

When we abuse or misuse radiation resistance, we can invent all kinds of magical antennas. We can have CFA's, E-H antennas, terminated dipoles, small magnetic loops, and verticals with all sorts of magical claims. Few, if any, of the claims are ever correct. Any time we see a claim that efficiency changes a ***large amount*** because of feed method change, it should be a red flag.

Increasing Radiation Resistance

Radiation resistance, at least under the useful IRE definition, can be defined by the following formula:

$$Rrad := 160 \cdot \pi^2 \cdot \left(\frac{He}{\lambda}\right)^2$$

which would translate to:

$$Rrad := 1580 \cdot \left(\frac{He}{\lambda}\right)^2$$

Where *He* is the effective height center of accelerating charges that cause radiation. In other words,

He is the effective height, expressed in fractions of a wavelength, of the distributed common-mode current in the structure.

(Common-mode current is the vector sum of all currents, or the effective in-phase current at any point, or the current we would measure if we placed a giant clamp-on current probe around ALL of the conductors at that any given height.)

He and λ must both be in the same units, either given as degrees or decimal fractions of a wavelength.

As an example, a uniform current single conductor antenna has an actual physical height of 15.19 feet on 1.8 MHz, where one wavelength is 546.67 feet, the effective height is:

15.19/546.67= 0.0278 wl

Since charges are distributed evenly throughout the structure the full height is used. The effective height is .027 wl, the same as the physical height. The height in electrical degrees is .0278 * 360 = 10 degrees

We have a radiation resistance of:

$He := .0278 \qquad \lambda := 1$

$$Rrad := 160 \cdot \pi^2 \cdot \left(\frac{He}{\lambda}\right)^2$$

$$Rrad = 1.22$$

We can express this graphically in a chart, such as one found in the Antenna Engineering Handbook by Jasik:

Finding 10-degree height on the graph above, and following that line until we reach the crossing for

unity current ratio, we see the ~1.27 ohm radiation resistance is in agreement.

Notice that the number of vertical conductors does NOT enter into the equation! This is the absolute maximum possible radiation resistance we can obtain for a given radiator height.

Non-uniform Current

Radiation resistance is purely a function of the effective current distribution and height of the radiator, and is limited by height (spatial length)! Current throughout the antenna will not remain uniform if we reduce the size of the flat-top or hat.

Current will become zero at the very top with no hat, and 100% base loading. In this case, with no change in height, radiation resistance will be approximately 1/4th the value of the uniform current example. The result is exactly like a 50% reduction in effective element height.

If we follow the 10-degree line to the intersection point with 0 top current, we find radiation resistance to be around .32 ohms. 1.27 ohms, the radiation resistance for uniform current, becomes 1.27/4 or .3175 ohms.

If we stay on the uniform current line, we find that .3175 ohms would be the radiation resistance of a 5-degree monopole with uniform current.

Efficiency

It often helps to look at the extremes, so we can get a feel for the effect of changes.

Let's look at the poor ground extreme and assume we have system losses, normalized to the current maximum, that are many times the radiation resistance. This would be the case for a short 160 or 80 meter mobile antenna.

In such a system radiation resistance would dominate any change that would affect efficiency. Current distribution would mean everything to efficiency.

Assume we have a base loading coil, either good or poor, and a thin mobile whip above the coil. Efficiency would increase by a factor of approximately four times by installing a capacitance hat with several times the distributed capacitance of antenna conductors below the hat.

Moving the coil would have little or no effect on efficiency.

A six-foot antenna with a large hat would be electrically equal to a 12-foot antenna without a hat.

This is why very poor inductors used on antennas in mobile shootouts, with large hats, equal or beat very large high-Q coils in similar height antennas that do not have large hats. One case in mind was a Hamstick lash-up in a mobile. The Hamstick, a notoriously poor efficiency antenna for 75-meters, soundly trounced Bugcatcher antennas when a large hat was added to the Hamstick.

Moving the coil up on the antenna has the effect of making current below the coil uniform, but without a hat current above the coil is a triangular taper that reaches zero at the element tip. The effective height of the area above the coil is 50% of actual height.

If we add a large hat at the bottom of the whip, current in the whip is actually reduced! At the same time, we change nothing below the coil. The effect of adding a large hat below the whip is to reduce the effective height of the antenna, when considered as a percentage of physical height. Radiation resistance and efficiency is generally reduced by adding a hat just above a coil, even if the hat allows us to use a smaller coil!

Adding a large hat at either end of a coil also reduces coil Q, since a large portion of the hat capacitance directly shunts the inductor.

Conclusion

We can reach the following conclusions:

- Radiation resistance, or at least the useful definition of radiation resistance, is limited by spatial area (or height in the case of a vertical) any antenna occupies.
- Radiation resistance is maximized by making current as large as possible over the entire spatial area of the antenna.
- Surrounding objects generally reduce radiation resistance and efficiency, even when they are NOT resonant, because they reduce effective height! This includes dielectrics that increase capacitance of the antenna to ground, since any increase in capacitance appearing well below the top of an antenna reduces effective height.
- Radiation comes from charge acceleration, nothing else. The longer the linear spatial distance we move charges in, the fewer charges we need to move at any point for the same amount of EM radiation. This is just another way of saying radiation resistance is higher in physically longer structures, especially when they carry uniform current.
- Any antenna (including Linear Loading, Helical Loading, Folded Monopoles, Fractal shapes, CFA, E-H, and so on) claiming to increase radiation resistance beyond the limits outline above is based on misunderstandings or untrue distortions of basic antenna principles.

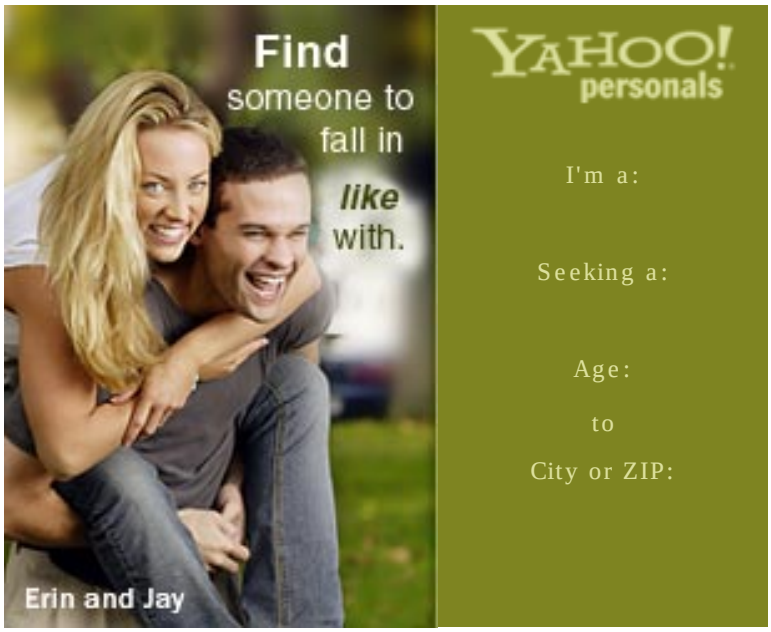
Subject: Slingshot method for hanging SkyWires.



Slingshot method for hanging SkyWires.

Guys,

In my youth (19 years old), fresh out of Marine Corps Boot Camp, I would climb to the tops of trees like a monkey, while friends on the ground would yell "that's high enough!!" to put up Owl Nesting boxes, etc.. What they didn't know was it was much easier that most of the stuff the Corps had me doing.

That was then and this is now. Now Walter no longer leaves the ground unless I have a boarding pass, and a coach ticket.

After reading a few articles I decided to try the slingshot

method of
hanging a wire antenna.

Its Pretty easy.

You need the following items.

A fishing pole, a dozen 1 oz. Lead egg sinkers, a good Crossman or
Wrist-Rocket slingshot, a large spool of Trout Line, Large Nails,
a hammer, and a Fishing pole holder, if you can't find someone
to
help.

I've seen ads in radio magazines for a slingshot-fishing reel combo,
for $100. If you have $100 to blow, take you wife out to a fancy
restaurant. I believe it's a much better investment that this.
The
slingshot, and a fishing rod and reel will set you back about $30..

I use trout line because it is very strong, and given its to be used
in water, its waterproof, and seems to hold up very well, and is
cheap. But if someone knows of another rope that works better, please
let me know.

You can find all of this at your local bait and tackle store. I pay
about 20 cents for each egg sinker, I use egg sinkers because they
are about as aerodynamic as fishing weights get, and because the
shape doesn't allow them to get hung up in the tree branches as
much
as others do, but it still happens.

I have heard of people using a Bow and Arrow. I can see some
advantage to this, but I think the risks outweigh the benefits. With

a 1 oz. Egg sinker, you have to be careful it doesn't come down on a parked car's windshield, or dent the hood. With an Arrow, it could put a hole in someone's roof, or worse, if you neighbor or his kids are outside, they could end up impaled and looking like Gregory Peck in the last scene of the movie "The Omen". We don't want that…

When shooting the egg sinker, you want to be on the "Antenna side" of the tree.

Take the pole holder, and place it in the ground at an angle, facing the target tree. Put the fishing pole in the holder.

I have read that if you paint the egg sinkers blaze orange, you can see them better when they come down. I haven't tried this, but it makes sense. Having a florescent fishing line in your fishing reel helps in locating the downed egg sinker, but is not necessary.

If you are right handed, taking the slingshot in the left hand, and stand with the fishing pole to the right of you. If left handed, do the opposite. Place the egg sinker in the sling with the fishing line coming out of the top, and clear from the rubber bands.

Make sure not to stand too close to the tree, you want the egg sinker to clear the tree, and fall on the far side, if you are too close, you will be shooting at too high an angle and the egg sinker won't fall on the far side, but on the shooting side.

Shoot the egg sinker and pay attention to the direction of

where you
shoot, and see if you can judge where it should have landed before
you walk over to the far side of the tree.

Then go find it. You may find that you need to take the fishing pole
and "play" with the line a bit to get the egg sinker to fall down to
ground level from the higher branches.

If it gets hung up, you will just have to reel it back and start
over. I have about a 50/50 success rate.

Once I find the egg sinker, I cut it off, then tie the trout line to
it and go back to the fishing pole and reel the trout line back over
the top of the tree.

When the trout line reaches the pole, cut the line, and tie your dog
bone insulator on to it.

Go back and cut the trout line from the trout line spool, and take
two large nails and hammer each of them about half way into the trunk
of the tree. The nails should be about a foot or so apart and angled
away from each other forming a cleat.

I like to hammer the nails high enough that some kids don't come
along and decide to undo my work. If this is a real concern, you may
consider using a ladder and nail them higher up on the trunk of the
tree. Plus, the higher up, generally the less visible it is too.

Tie the trout line around one nail.

Repeat these steps on all the trees in your SkyWire system.

Once you run your antenna wire through the dog bone insulator

you can
then begin to raise the antenna by taking the slack out of the trout
line. Just begin wrapping the trout line around the both nails in a
loop until the antenna reaches the desired height.

That's about it.

I am currently working on a fuse system that uses a bungee cord, and
counter-weight, so that when bad weather hits, and high winds put too
much pressure on the SkyWire, that the "fuse" will break causing
about 20 feet of extra trout line to be unleashed, and letting the
SkyWire fall limp, but not letting it break. This would allow you to
easily recover the extra trout line, and put a new "fuse" back into
the system after the storm passes.

Once I have the dynamics of this worked out, I will post it.
(sometime this fall, I hope)..

Thanks,

Walter

Traps

[Home] [Up]

This article is from a talk I gave about antenna traps. It contains measurements of traps, performance of trap antennas using models of traps, and ideas on how to make trap antennas more efficient.

Try taking this Trap-Q test! Be honest.

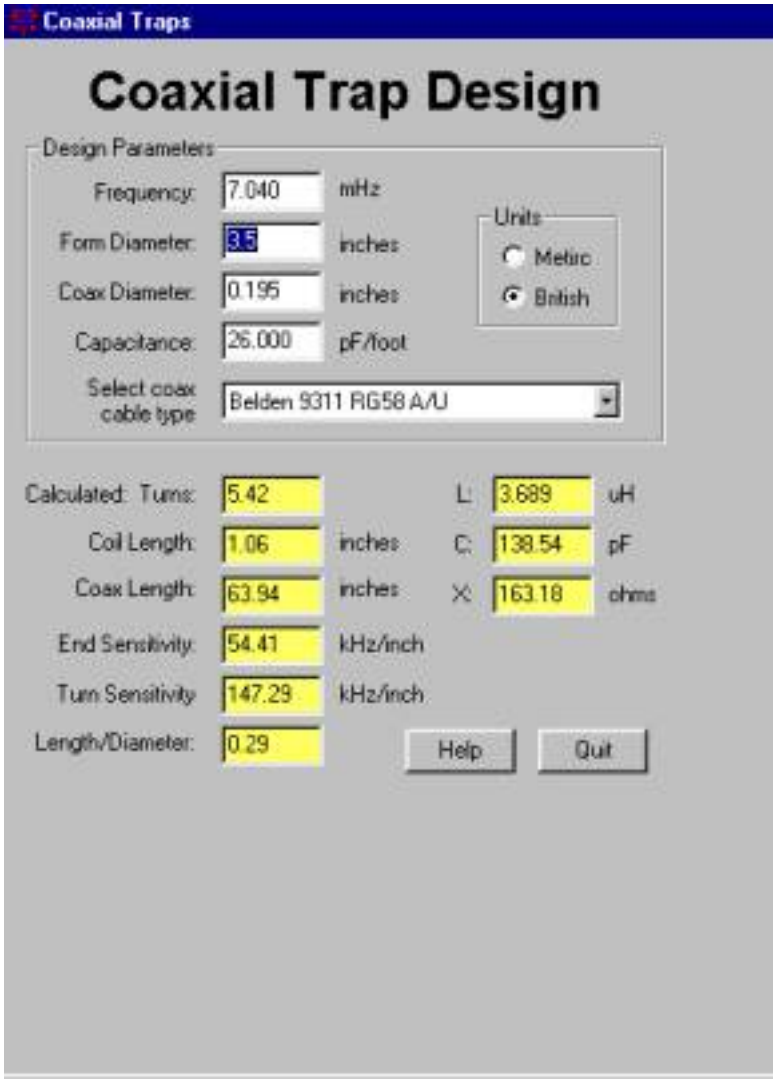
1.) Is it best to make the trap resonant close to the desired operating frequency?

2.) Does bandwidth decrease with increasing trap Q?

3.) Do traps create noticeable loss, perhaps one dB per trap typically?

4.) Does higher trap operating Q always mean lower loss?

Coaxial Trap Designer by VE6YP (Tony Fields)



This is a good program to get you in the ballpark with a trap design. It was available as freeware. (Unfortunately coaxial traps are relatively lossy on the trapped frequency compared to other types.)

The software is available at **http://members.shaw.ca./ve6yp/index.html**

7.04 MHz 3.5 inch diameter form RG58/U into the VE6YP program yields calculated values of:

Calculated	Actual Measurement
L= 3.689µH	3.116µH
C= 138.5 pF	164 pF
64 inches	59 inches

Using the program TLA by N6BV (from ARRL), we would estimate capacitance of a 59" RG-58/U cable as:

R .22 –j143.61 or about 157 pF (Q=650)

Measuring a real-world stub, capacitance was 164pF (Q=590).

While that Q seems high, remember a typical transmitting-type air-variable capacitor has a Q of several thousand!

Coaxial Trap Articles and Programs use capacitance/ft multiplied times length….

26 pF * 4.917 feet = 127.84 pF in trap program

C164 pF measured. This error, 36pF low from 164pF, occurs because the transmission line making up the "coaxial capacitor" is not actually treated as a transmission line in the modeling program.

Fortunately the error is in a useful direction, because we can shorten the cable! Coaxial capacitors are really open stubs, and should be treated that way once they are more than a few degrees long.

CONCLUSION: The difference between TLA and an actual measurement was around 4%. This is very close, but the result has significant difference from the coaxial trap program since it only considers pF per foot as the capacitance. A longer cable (in fraction of a wavelength) results in greater error by using pF per foot. The error comes because a coaxial cable capacitor is really a stub, NOT a pure capacitor!!

Trap Measurements (at resonance)

Type	F MHz	R parallel	X
Coax RG-58	7.034	17,800	0
UT-141-75 semi-rigid	7.045	45,330	0
100pF 7.5kV & #12 wire	7.040	99,850	0
60pF 15 kV & #10 wire	7.040	250,000	0
60 pF vac & Copper tubing	7.040	300,000	0
Coax RG-58	3.700	23,200	0
Coaxial with fixed mica capacitor	7.040	21,660	0

Highest R parallel equivalent is best!! Lower Rp means more loss.

Trap Measurement summary:

- **Coaxial trap poorest**
- **Once #10AWG wire is used, not much improvement**
- **Space-wound bare wire makes best inductor**
- **Transmitting-type capacitors noticeably better than capacitors made from coax**

10 Meter (Tribander) Traps

Type	Freq	R parallel	X
Coax RG-58	29.00	13,800	0
Mosley TA-33	30.64	43,100	0
Mosley Pro-57	27.46	66,080	0

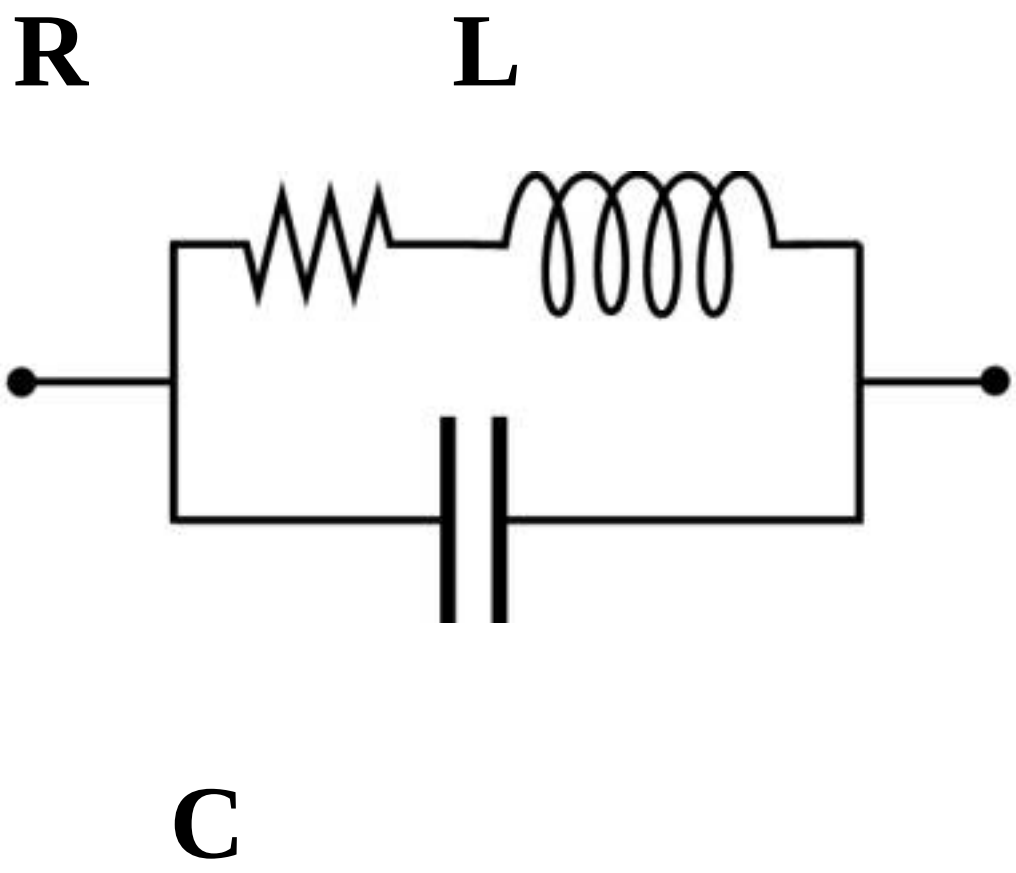
Cushcraft A3	**28.78**	**110,000**	**0**
HyGain TH-3	**29.67**	**140,200**	**0**

Traps are not all that bad when you plug them into models.

15 Meter (Tribander) Traps

Type	Freq	R parallel	X
Coax RG-58	**21.00**	**13,980**	**0**
Cushcraft A3	**21.43**	**76,270**	**0**
Mosley TA-33	**21.68**	**79,000**	**0**
HyGain TH-6	**22.23**	**142,000**	**0**

Trap Model



Measured Values Coax 7 MHz Trap

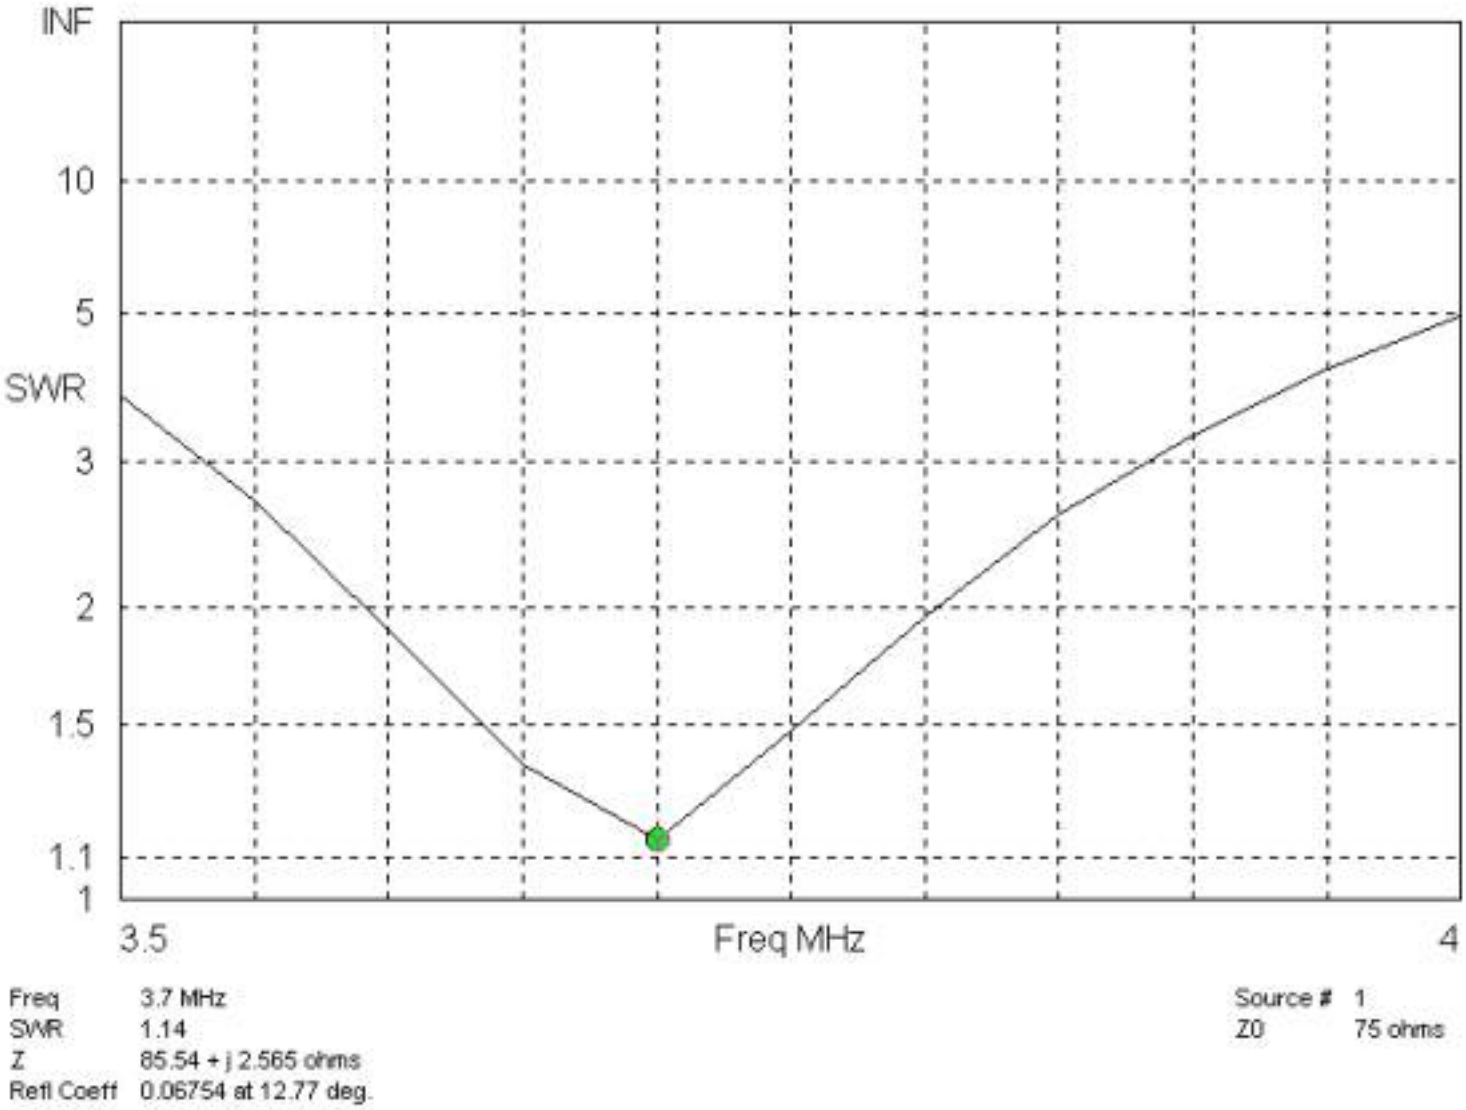
Freq	Imp	R	Xc	Q	L uH	C pF
7.04	17,800 j0	1.03	138	134	3.114	164

3.7	1.1 j 97	.6	283	88	3.114	152

Measured Values L/C 7 MHz Trap

Freq	Imp	R	Xc	Q	L uH	C pF
7.04	99,850 j0	.36	215	465	4.92	105
3.7	0.53 j 156	.25	409	294	4.92	105

SWR Bandwidth



7 MHz RG-58 TRAP

80 m 75 ohm VSWR

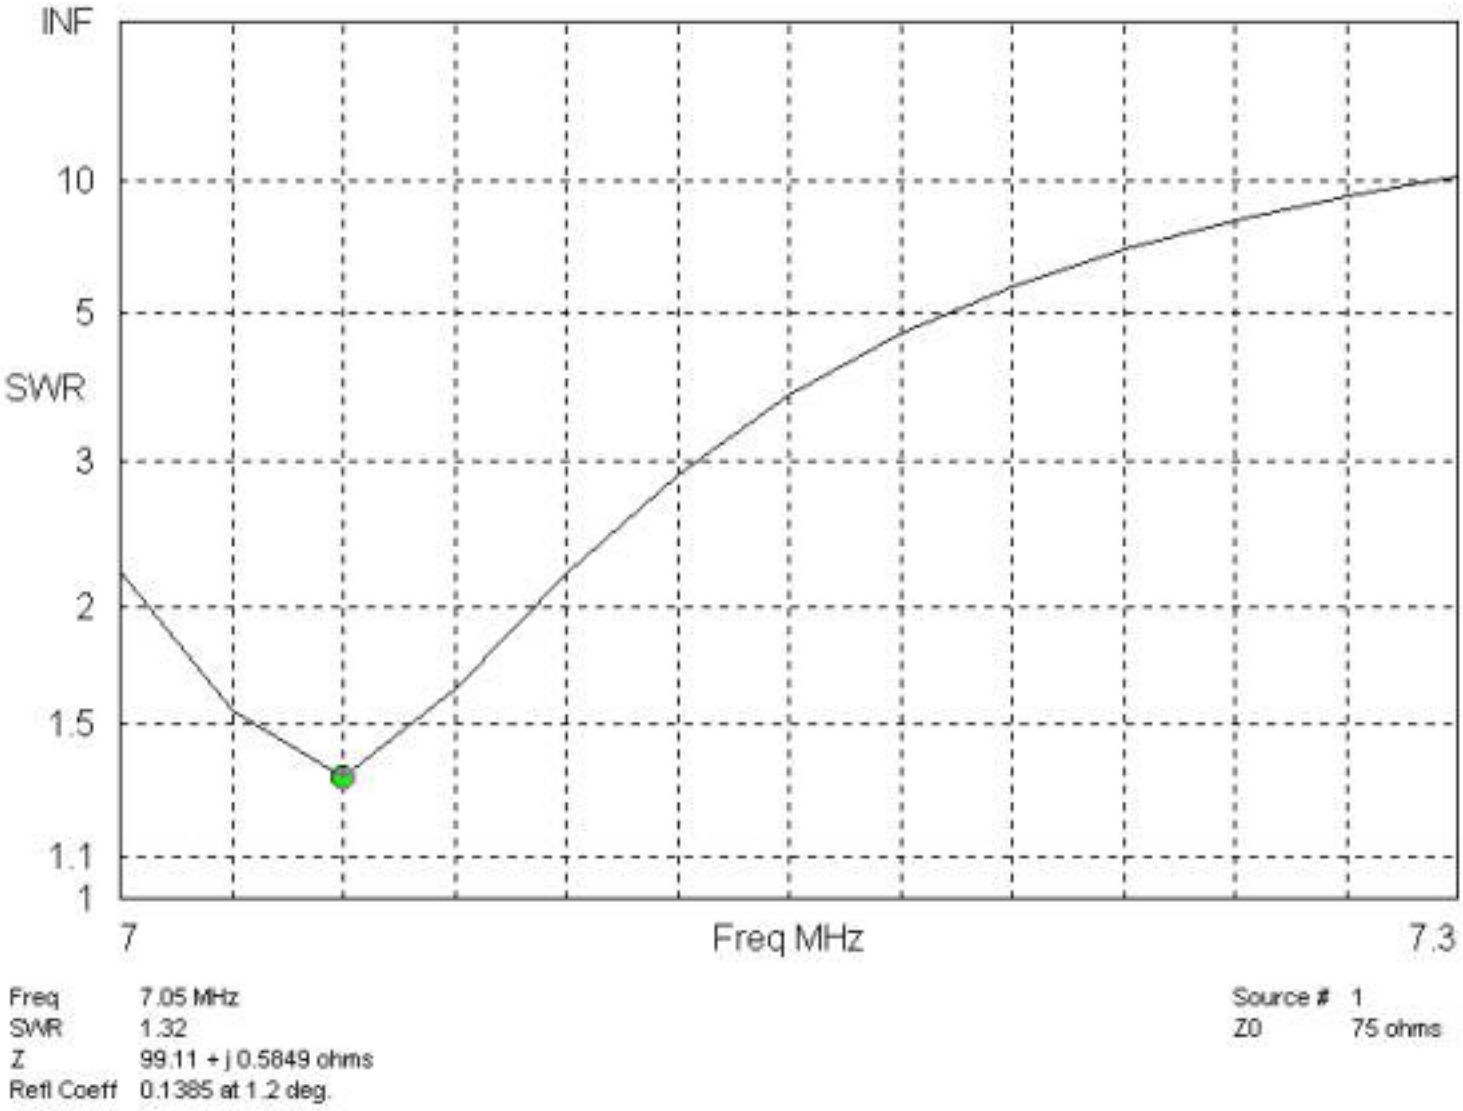
EZNEC #12AWG dipole

Coax trap 80m 2:1 VSWR ~210 kHz

Total trap loss = 0.05 dB

RG-58 TRAP, 75 ohm VSWR, 40 METERS

VSWR BW



Coax trap 40 meter 2:1 VSWR ~ 80 kHz

Total coaxial trap loss at resonance on 40m= 1.6 dB

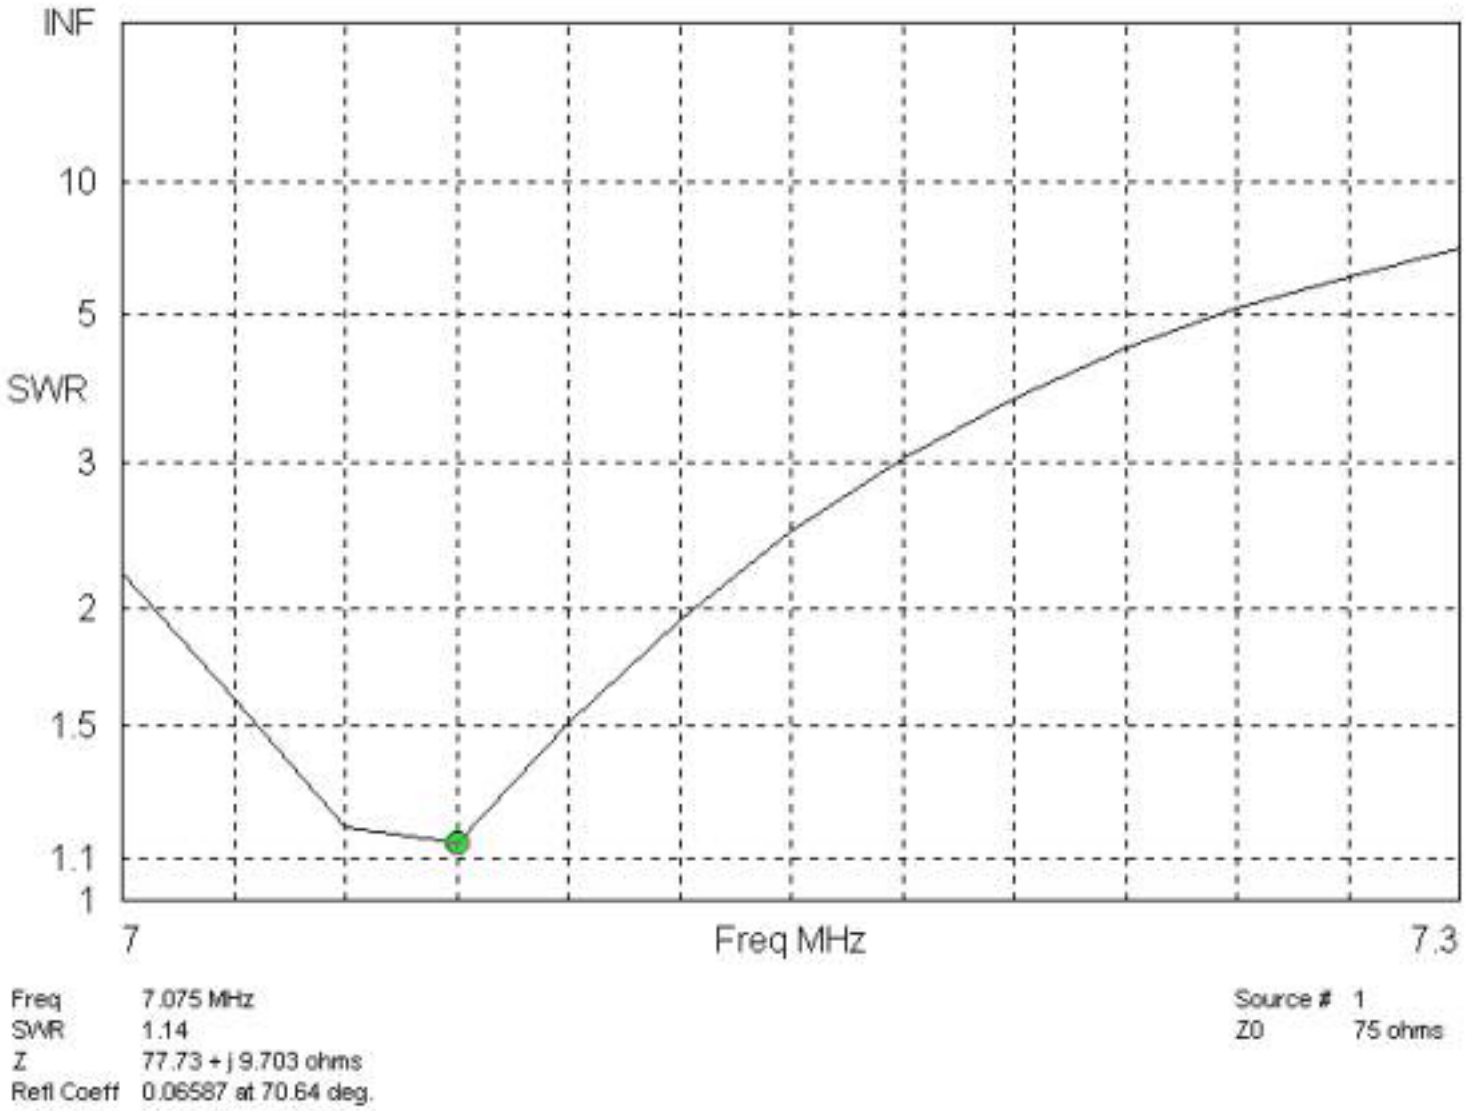
Total coaxial trap loss 100kHz off-resonance (at 7.15 MHz)= 1.06 dB

Note that loss is maximum at trap resonance!!!

Never make a trap resonant on the desired operating frequency!!

W2LH ARRL Handbook Trap Design

100pF #12awg Miniductor trap

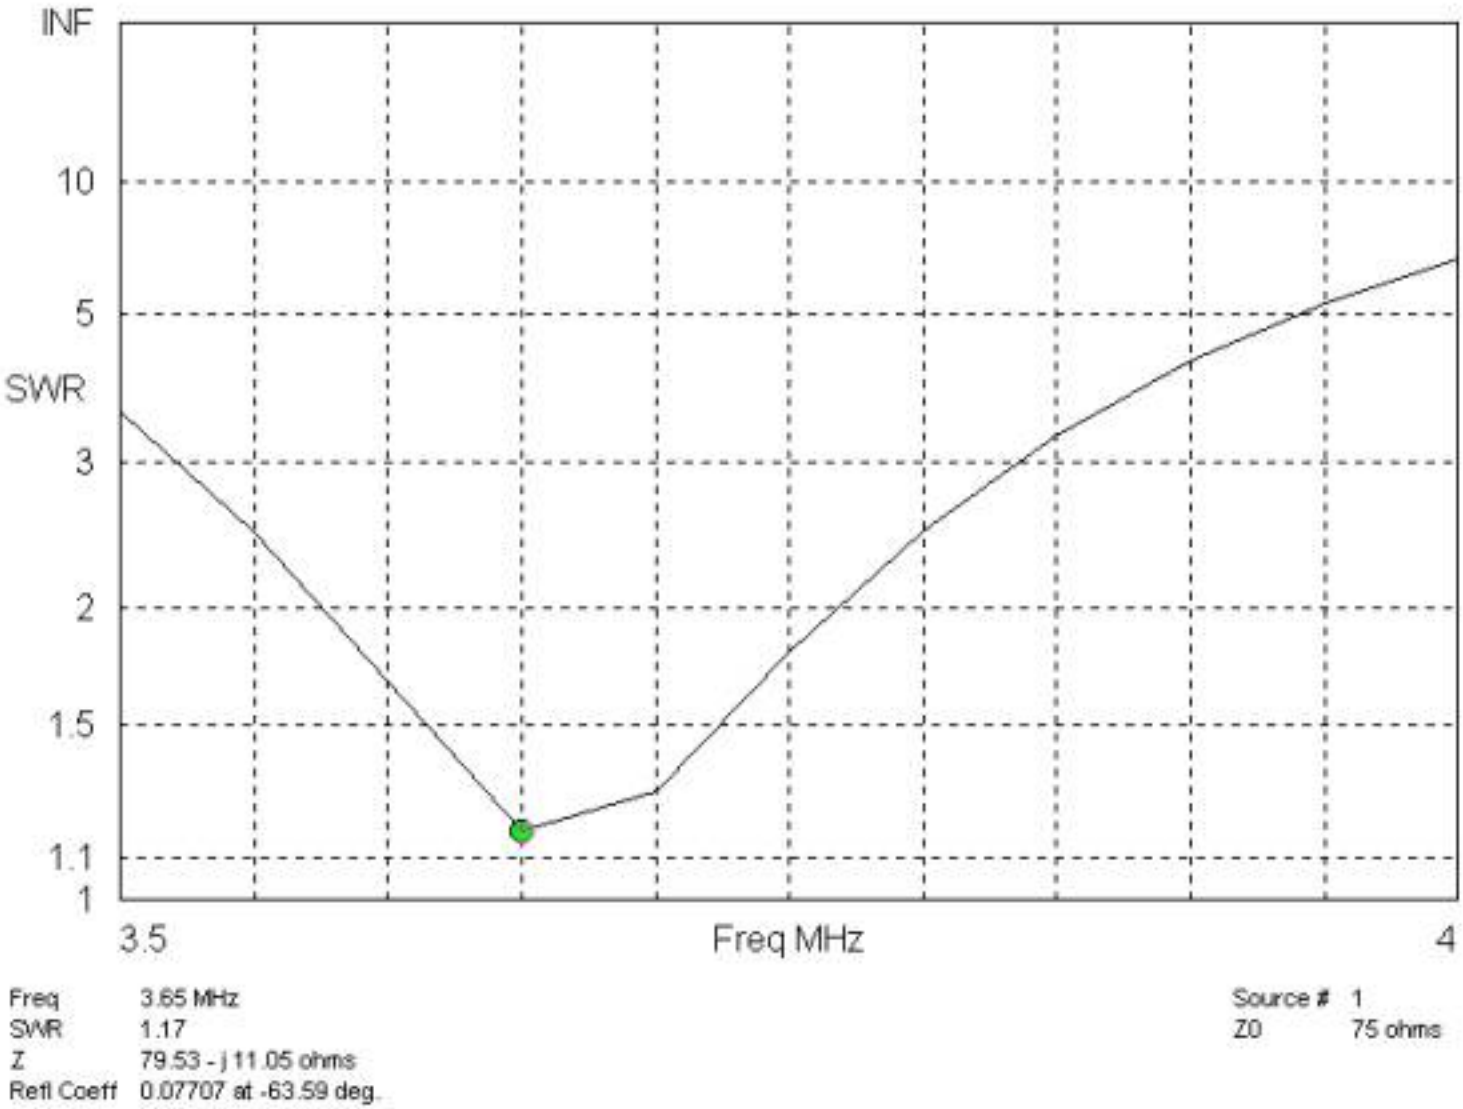


40m 2:1 VSWR ~120 kHz

Total loss = 0.24 dB

W2LH ARRL HANDBOOK TRAP 80m

VSWR

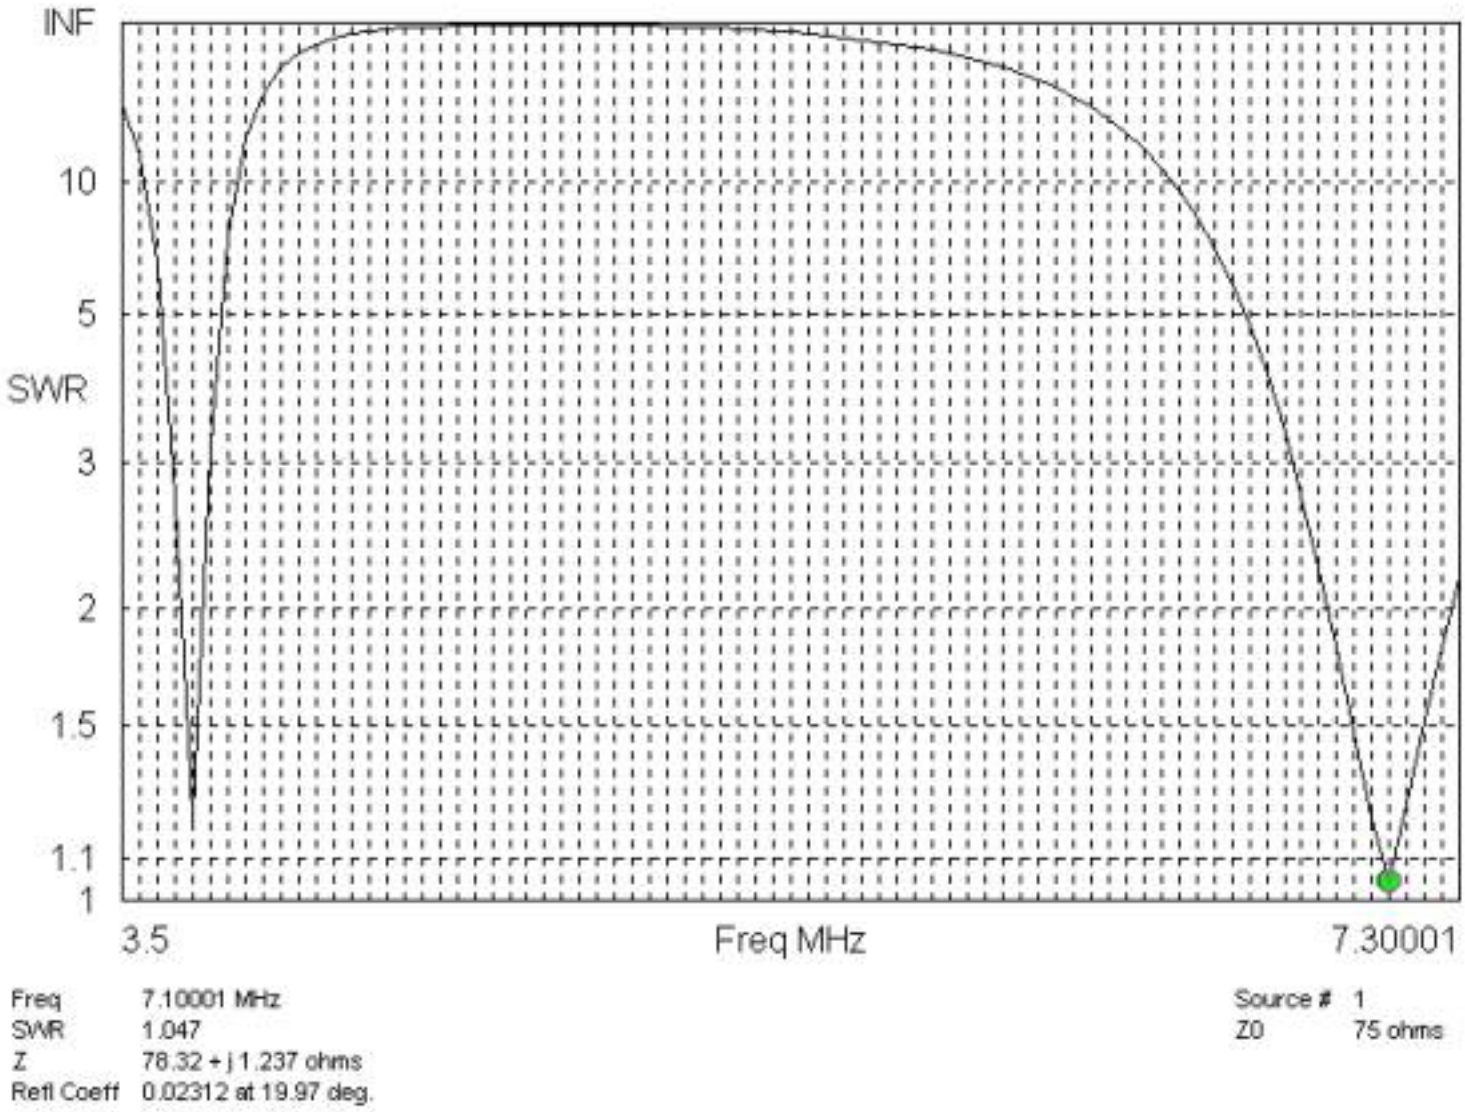


80m 2:1 VSWR BW ~ 200 kHz

Total trap loss = 0.026 dB

What happens if trap is not in band?

VSWR Bandwidth of 6.51MHz trap in 80/40 dipole



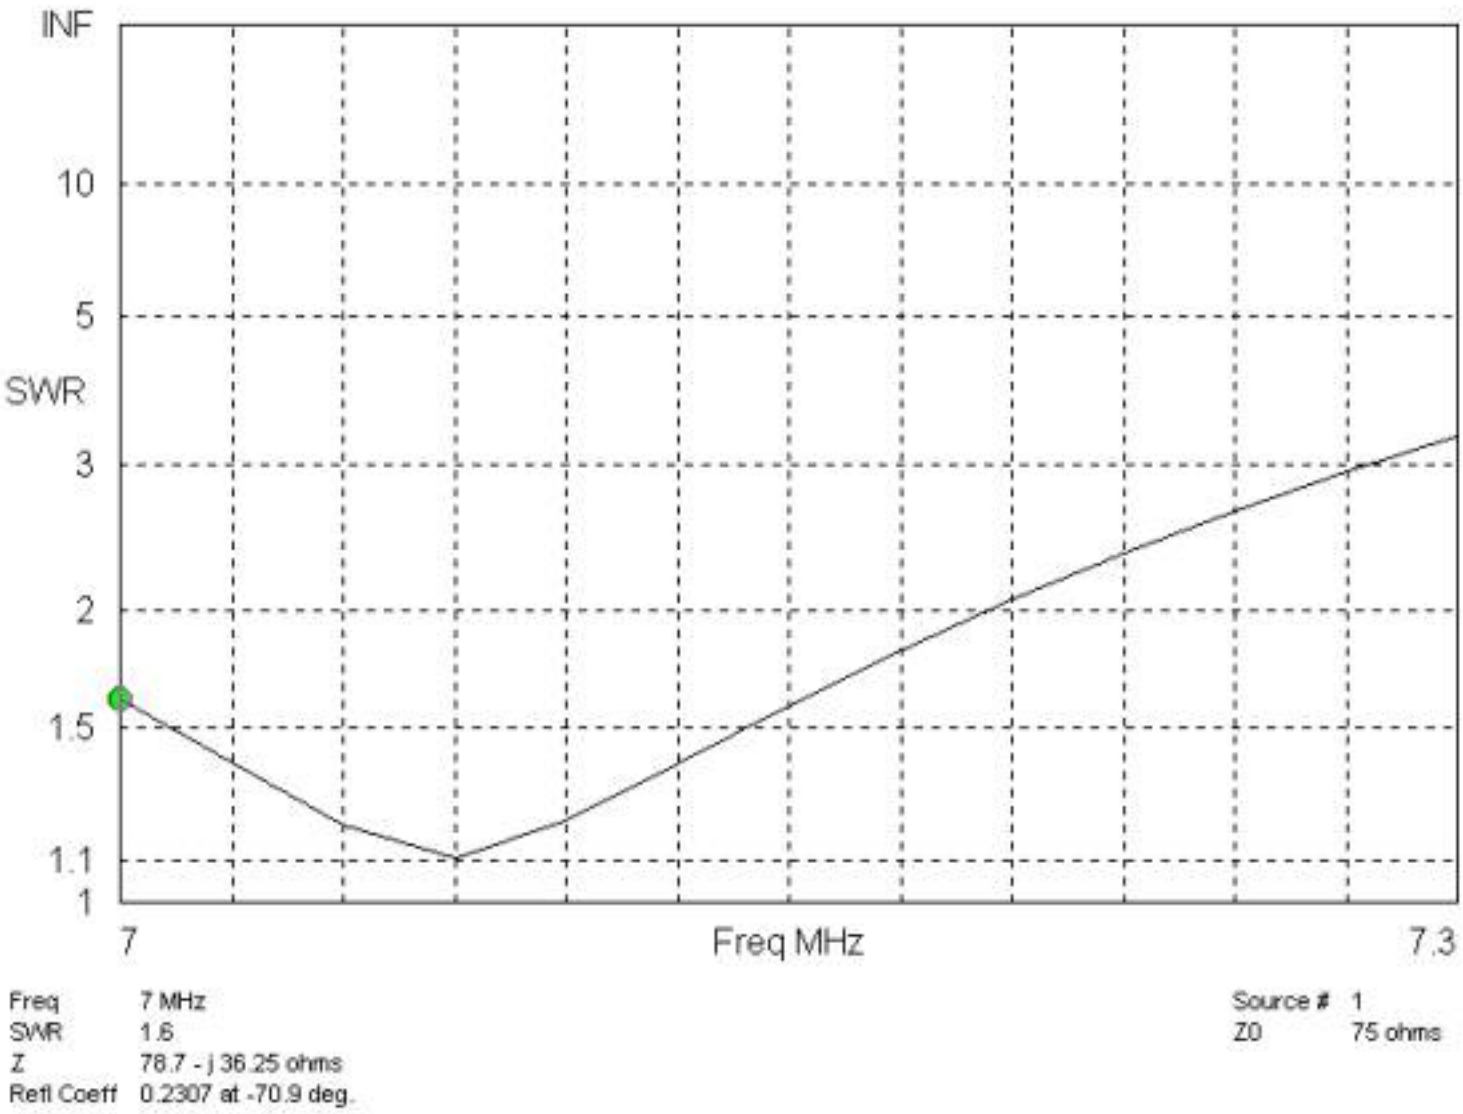
Trap at 6.51 MHz Q=130

Loss at 7.15 MHz = 0.314 dB

Loss at 3.7 MHz = 0.324 dB

This is a 104-foot long antenna, with very poor Q traps, and loss is less than .4dB! The reason loss is low is we have moved the trap slightly out-of-band.

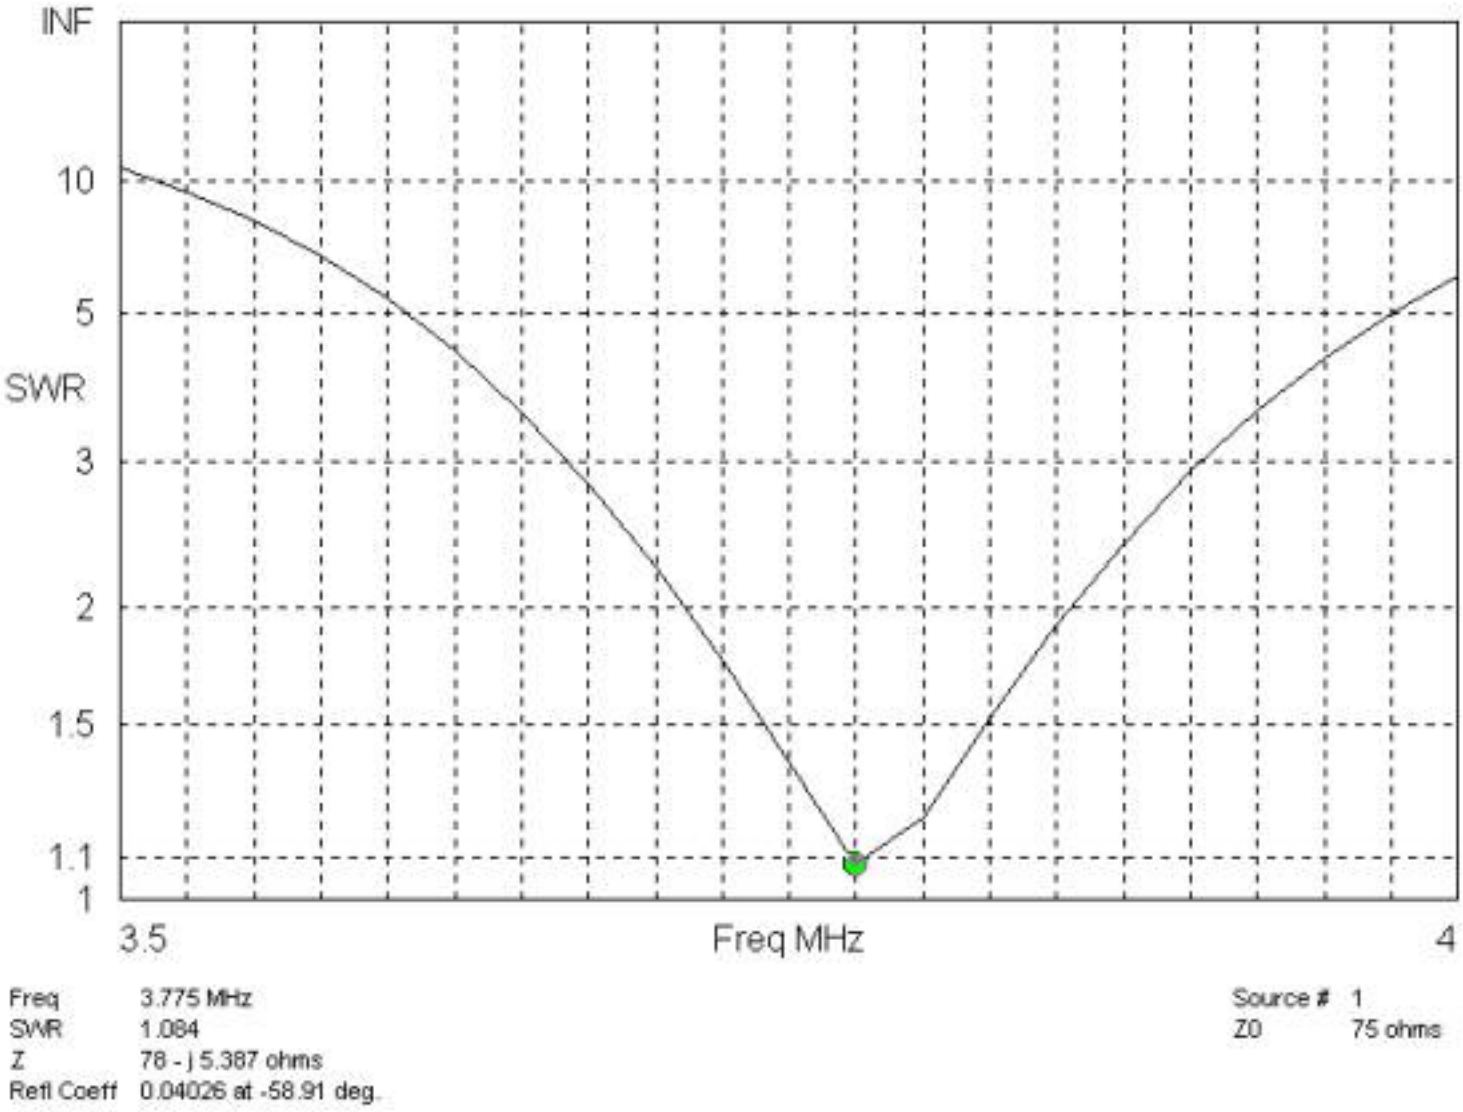
6.15 MHz Q=130 TRAP 40m VSWR



7 MHz 2:1 VSWR BANDWIDTH ~200kHz

Trap Q at resonance = 130 7 MHz loss ~ .3 dB

6.15 MHz Q=130 TRAP 80m VSWR



80M 2:1 VSWR BW ~130 kHz

Loss at 3.7 MHz = 0.324 dB

1.) Is it best to make the trap resonant close to the desired operating frequency?

NO! Loss is highest when the trap is resonant at the operating frequency!

2.) Does bandwidth decrease with increasing trap Q?

NO! Bandwidth is a function of many variables, trap Q actually has one of the smallest influences on BW.

3.) Do traps create noticeable loss, perhaps one dB per trap typically?

NO! Even the worse traps (coaxial traps) in the worse possible condition of operation are only 1.6dB loss for BOTH traps!

4.) Does higher trap operating Q always mean lower loss?

NO! Loss depends on many factors, including trap resonant frequency.

Conclusions:

- Trap loss has been greatly exaggerated by advertising hype
- Traps should not be resonant at the actual planned operating frequency
- Coaxial traps are more lossy than articles conclude
- Coaxial stubs used as capacitors can not be calculated using pF/ft unless the stub is a very small fraction of a wavelength long (less than a few electrical degrees)
- Coaxial stubs have low Q (are relatively lossy) compared to normal lumped components.

Aerials and Trees

[Home] [Up]

Click ***HERE*** for the Amazing **Online Ham Radio Flea Market**

6.7m fibreglass poles for sale click ***HERE***

From time to time we all need to get wires or lines over trees to support aerials. With a small tree of say 5-7 metres high it is quite easy just to throw a weighted line over the top. But what if the tree is larger?

Over the years I have tried quite a few ways but the best by far has been the use of a catapult - suggested to me by Dave G3YXM who also uses a bow and arrow! Catapults can be bought from fishing shops and are used to throw ground bait. Look for a high power model and for maximum accuracy and power, choose one with an arm brace (see picture below). But don't leave the fishing shop just yet as you will need some more things. First get a cheap casting reel. They are often available for about £5. This needs to be fastened on to the catapult. I used some cable ties. The casting reel ensures that the line flows freely. Laying the line on the ground generally fails as it gets caught or tangled. For line, you need to choose something thin and light - this line will not be used to support the aerial, it is just to get it over the tree. Use 12-15 pound breaking-strain monofilament. You will also need a weight to fire. I use a 2 oz sinker. I paint them orange to make them easier to see in trees! Tie the weight on to the line using the special knot that works with monofilament (called a blood knot I think). This knot is described in fishing books. I have also had success with a figure-of-eight knot.

Search G3CWI's site

Now you are all set. Safety must be your first consideration. Make sure that the area around the tree is clear of any people, animals, overhead electricity cables and anything else that could either endanger you or could be in danger from your efforts. Fire the weight aiming well clear of the top of the tree, an angle of between 45 degrees and 60 degrees to the horizontal seems best. If all is well the line should pay out cleanly but generally the weight will not reach the ground. Gently pull on the line several times, letting the weight drop further each time. Then go and see if you can find it. The paint helps here! If you fail to get it in the right place, you have two choices, either cut the line and let the weight drop or try to pull it back. If you do try to pull it back be very careful as the weight can easily fly out of the tree in your direction as you pull on the stretchy monofilament.

If all is well and the weight has reached the ground in the right spot, then cut the weight off the line and tie on a thicker line that will be used to support the aerial. I use 40 pound or 100 pound monofilament. Pull this line back through the tree, tie on the aerial, pull it up and you're on the air. I have used this method successfully with trees up to 90 feet tall (27 metres).

EMERGENCY OPERATIONS & YOUR HT

Before I begin, I would like to give credit to C. Edward Harris, KE4SKY, AEC for Fairfax County ARES in Virginia for his article on "Getting the most from your Hand Held Transceiver." Much of this script has been taken from that article. Some minor editorial changes have been made to make it more readable over the air.

<PAUSE for the Repeater to reset >

HT Antennas

It shouldn't come as a surprise to anyone that when limited to "barefoot" operation with a "rubber duck" on simplex, HTs are not adequate as a primary rig for emergency communications. The National Institute of Standards and Technology (NIST) ran some tests (back when they were still the NBS) on Public Safety high band and amateur 2-meter antennas. They found that a "rubber duck" has -5db gain compared to a quarter wave antenna held at shoulder height. In terms of effective radiated power (ERP), a 5w HT with rubber duck antenna, held at shoulder height would actually radiate 1.5 watts. Placing the HT on your belt attenuates the signal another 20db, reducing ERP to only 15 milliwatts! UHF results weren't found to be much better.

<PAUSE for the Repeater to reset >

A simple and inexpensive improvement that can be made to the "rubber duck" is the addition of what is called a "tiger tail". You can make one of these using a quarter-wavelength (19-1/4" for 2 meters) piece of #14 through #20 stranded wire, crimped and soldered to a battery clip. Reinforce the soldered connection with heat shrink tubing or tape to resist flex. Clamped to the outer collar of the BNC connector on your HT antenna, it acts as a counterpoise so that RF from the HT doesn't couple with your body. A "tiger tail" is directional and can be used to change both radiation angle and direction. It gives best simplex performance when pointed in the general direction of the station you are trying to "hit".

<PAUSE for the Repeater to reset >

Almost any antenna works better than the "rubber duck" that comes with an HT. A

flexible ¼ wave or telescoping half-wave antenna are both improvements. A ¼-wave used at shoulder height with a counterpoise has "unity" gain, which is a 5 db improvement over a rubber duck, because most of the signal is radiated. Using an HT at 5 watts with a ¼ wave mag mount on an improvised ground plane, or telescoping half wave with a "tiger tail" improves simplex readability even further.

<PAUSE for the Repeater to reset >

In marginal locations, a telescoping half-wave is a good performer. A half wave used without a ground plane has the same unity gain as a ¼ wave when used with a ground plane. Adding an effective ground plane or counterpoise to a half- wave produces roughly 2 db of gain. A telescoping half wave can also be attached to a coax jumper and pulled into a tree, dangled out a window, attached to a window pane with suction cups or used with a window clip door mount.

<PAUSE for the Repeater to reset >

Telescoping antennas work best when operating stationary or in the open, avoiding side impacts or rough handling. Extend and retract the radiating elements very carefully. If you note any wobbling or looseness, replace the telescoping radiator, if possible, or replace the entire antenna. Keep a close watch on your HT's connector also. It can become loose after extended use of a telescoping antenna.

<PAUSE for the Repeater to reset >

Flexible antennas are safer when working in close quarters around people and are more durable when walking through dense vegetation during search and rescue operations. They are a good choice for dual-band transceivers, but are usually optimized for one band and merely "acceptable" on the other. Most approximate a ¼ wave on 2 meters and a 5/8 wave on 70 cm. How efficient a particular antenna is can be determined only by controlled testing.

<PAUSE for the Repeater to reset >

If you want to buy one emergency HT antenna, without risk or experimentation, the telescoping half-wave, flexible 5/8 wave or quarter wave mag mount all offer the best "bang for the buck" in my opinion. A telescoping half-wave boosts practical simplex range of a 5 watt, 2-meter HT from several miles with a rubber duck to many miles over suburban terrain. Adding a tiger tail further extends readable simplex range under the same conditions.

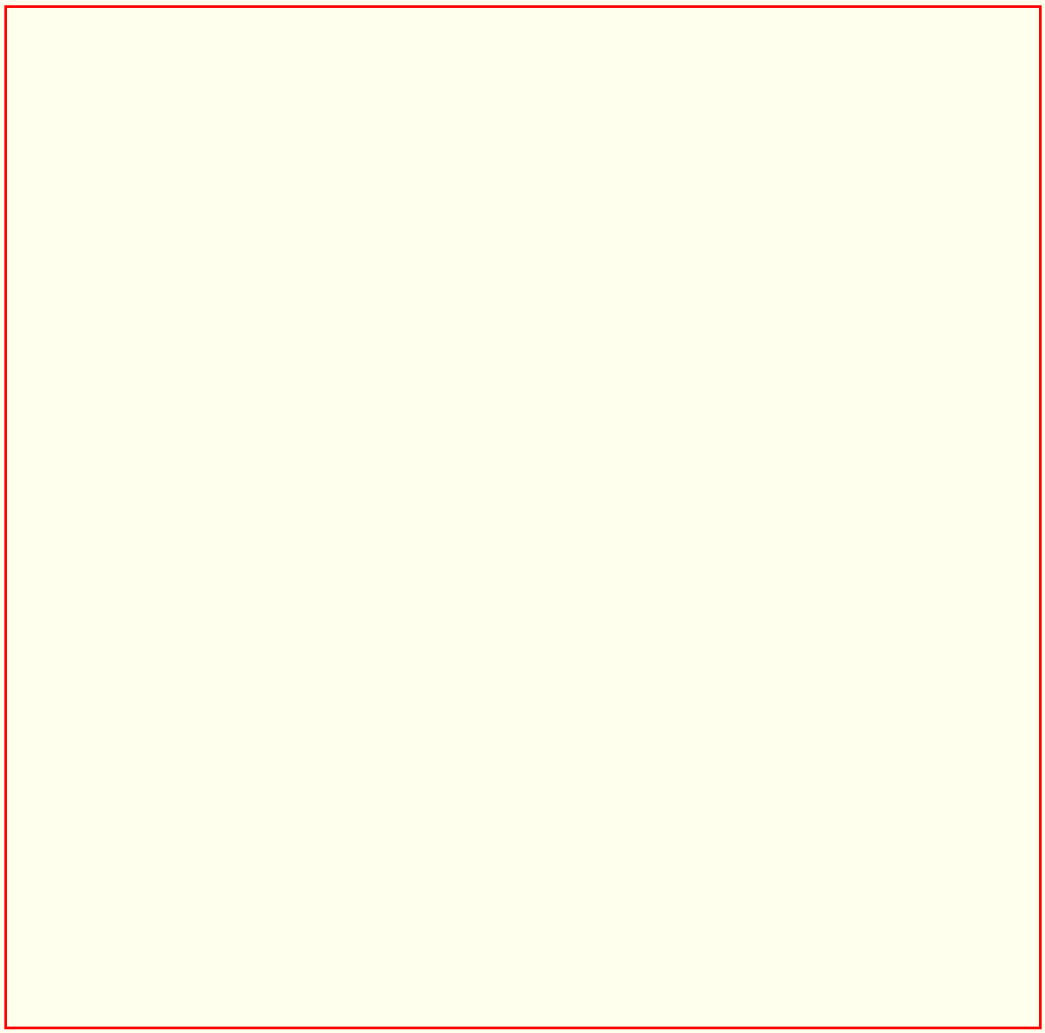
<PAUSE for the Repeater to reset >

Whatever antenna you choose, try to find one that is rated for at least 25W so that it can also serve as an emergency antenna for the HT with a power amplifier at medium power. A ¼ wave mag mount connected to a power amplifier works best on a car, but a suitable improvised ground plane can usually be found around the home or office. A metal filing cabinet, rain gutter, refrigerator, balcony railing or other large metal object may work just as well. If all else fails, place aluminum foil over a large piece of cardboard .

<PAUSE for the Repeater to reset >

A good possibility for Fixed position Emergency Operations is the so-called Roll Up J-pole . It's made from 300 Ohm TV Twin-lead and should give you several dB of gain over a rubber duck. I've used mine for the past year and one-half as a base antenna and have been quite happy with it. It is well worth the money spent (~ $20). Let me reset and I'll give the dimensions.

<PAUSE for the Repeater to reset >



<PAUSE for the Repeater to reset >

Would anyone like any of the dimensions repeated?

<PAUSE for the Repeater to reset >

Another antenna that is a good performer for fixed operations is the " American Legion J-Pole ". They are generally available at both the Foothill and Livermore Flea Markets for a reasonable price. Attach it to the top of a 10 foot section of PVC pipe and mount this to a camera tripod. Attach weights to the legs for stability. This makes a very nice fixed station antenna with good gain.

<PAUSE for the Repeater to reset >

BATTERY BASICS

For Emergency Operations, it is highly recommended that you carry two fully charged nicad packs and an extra AA battery case and batteries. The nicads will power your HT for at least the first full day of operations and the AA's will allow you to continue to operate if you can't recharge your nicads. It's also important in cold weather to keep nicads warm, and not exposed on your belt.

<PAUSE for the Repeater to reset >

As an alternate or primary power source, use 12-volt, 2 Ahr or higher Sealed Lead-Acid or Gel Cell batteries. They fit in a coat pocket, run an HT all day or power a 2 meter mini-amp for 3 hours at a typical duty cycle. Sealed Lead-Acid or Gel Cell batteries have many advantages. They will allow you to:

- **Operate when other forms of power are not available**

- **Operate longer than with NiCad or Alkaline batteries; 1–3 Ahr batteries are still small enough to be hand carried.**

- **Operate mobile, portable or fixed at a higher output power**

- **Operate at a lower cost; Gel Cells and SLA's are less expensive than NiCads or alkalines.**

- **Operate with fully charged batteries at all times; It's possible to keep these batteries on a "smart" charger continuously.**

<PAUSE for the Repeater to reset >

Sealed Lead-Acid batteries are used to power medical diagnostic instruments, alarm systems and Un-interruptible Power Supplies (UPA) just to name a few. Depending on the criticality of the application, some organizations replace their batteries on a regularly scheduled basis well before they are worn out and require disposal as hazardous waste. EC's should write or call local hospitals, explaining how batteries they discard are useful for emergency communications activity. It may be possible to obtain a quantity free for the asking, with no more trouble than signing a hand receipt to satisfy the environmental officer and writing a thank you letter to the hospital administrator. Remember, a hospital's "donation" to your ARES group eliminates their disposal cost.

<PAUSE for the Repeater to reset >

Besides hospitals, and alarm companies, batteries are also available locally at reasonable prices. For example, Halted Specialties usually carries new 12V, 7Ahr batteries for around $20. For those wanting to buy a complete commercial package, HRO sells the "Hot Pocket" which is a 12V, 2Ahr SLA for $78. It comes with its own pouch for attaching to your belt and a wall charger.

<PAUSE for the Repeater to reset >

If you decide to use Sealed Lead-Acid or Gel Cell batteries, you'll need a battery charger. 12 V Battery Chargers are available from various sources:

- **Jade Products offers a "Smart Charger" for charging Gel Cells and SLA's. It's $126.95 in kit form.**

- **A & A Engineering also offers a "Smart Charger" for Gel Cells and Lead-Acid batteries. Their charger is $59.95 in kit form or $79.95 finished .**

You can also use so-called "Wall Warts", but the general consensus is that your batteries won't last as long on these inexpensive chargers.

<PAUSE for the Repeater to reset >

Of course, you can always build you own. Two very good articles are the:

June '87 issue of QST entitled "A New Chip for Charging Gelled-Electrolyte Batteries"

This article uses the Unitrode UC3906 "Smart Chip".

March ‘94 issue of QST entitled "A Lead-Acid Battery Charger"

There is also some very good information available on the internet. I have several good URL's that I can pass along if anyone is interested.

<PAUSE for the Repeater to reset >

AUXILIARY CONNECTIONS

Power cords for connecting to automobile cigarette lighter plugs or gel cell batteries will be needed for extended operation. Be aware that cigarette lighter plug power may be unreliable due to contaminated cigarette lighter sockets. Also, the sockets themselves vary in size, allowing the plug to vibrate loose. As an alternate source of power, however, everyone should still have the capability since they are readily available.

<PAUSE for the Repeater to reset >

Be sure to assemble any auxiliary power cords for your HT or small power amps following the standard wiring configuration shown in your respective SPECS or SVECS manual. The configuration that follows is taken from the ARRL ARES Resource Manual. The SVECS manual agrees with this configuration; I’m not certain of the SPECS manual. This configuration uses twin lead 12 to 16 gauge "zipline" with Molex Series 1545, 2-pin polarized connectors and .093 diameter pins. In ARES practice, the

female pins are assembled into the male plug which is attached to the power source, and the male pins into the female receptacle which is attached to the rig. This description will make more sense to you when you have the parts in front of you and are assembling the connector.

<PAUSE for the Repeater to reset >

The plug, receptacle and pin sets are available from Radio Shack, Part No. 274-222 and are rated at 12 amps, which is adequate to power small amplifiers up to 50w output. Wiring is simple. The end of the two-pin Molex plug in cross section resembles a little 2-story house with peaked roof. Remember proper polarity by using the word associations "red roof" and "black basement" for the positive and negative terminals respectively. Crimp the wires in place before soldering to ensure a strong connection. After inserting the pins into the plug and receptacle, check the fit of the assembled fitting and reinforce the wires behind the plug and receptacle with heat shrink tubing or tape.

<PAUSE for the Repeater to reset >

For re-charging the battery, attach crimp type .187" female tab terminals to fit the male tabs on the battery. The other end of the battery connection will go to a standard cigarette lighter socket. Next, wire a plug onto the leads of a 12-15v, 500 to 900mah charger. A depleted battery can be restored in 4 to 6 hours by plugging it into your car's battery. Gel cells and SLA's larger than 5 Ahr may be left on a 12-14V DC "smart" charger of 1 amp without harm. A word of caution here . . . . . become very familiar with your particular charger and the types of batteries that you intend to charge before leaving a charging battery unattended. A malfunctioning charger can create a very BIG mess very quickly.

<PAUSE for the Repeater to reset >

HAND HELD DUTY CYCLE LIMITS

If you subject compact HTs to frequent full power 5w transmissions of several minutes duration they will overheat and the final power transistors may fail prematurely. Kenwood and Yaesu state in their service manuals that their HTs are rated for 20% duty cycle at maximum RF output, or 30 seconds of transmit to 2 minutes of standby.

<PAUSE for the Repeater to reset >

Of the popular 2-meter HT's, Standard does not restrict duty cycle on theirs, rating their amateur hand helds equal in that respect to their aviation, marine, commercial and public safety portables. Unless your HT is a Standard, older Icom or converted

commercial gear, it is best to use your HT mostly on medium or low power for long winded rag chews and restrict full power 5w use to short transmissions to save the finals. If you have a need for high power transmissions of several minutes duration and can't replace or supplement your hand held with a mobile rig, I would advise getting a power amplifier to do the heavy work. Just remember to reduce your HT's output power going into the amplifier, otherwise, you will still burn up your finals.

<PAUSE for the Repeater to reset >

ADVICE ON POWER AMPLIFIERS

An excellent way for HT owners to upgrade their portable ARES/RACES equipment is to purchase a power amp. An ideal amp should weigh less than 1 pound, be capable of 10 to 15w output when driven by an HT at 1w, or 20 to 40w output when driven by the same HT at 2 to 3w output. It should draw no more than 8 amps of current at its maximum rated output, enabling it to operate safely from the .093 diameter pin Molex Series 1545 connector or fused cigarette lighter plug.

<PAUSE for the Repeater to reset >

An FM-only amplifier without a preamp will be adequate in most cases. A preamp tends to accentuate intermod due to paging transmitters. Unless you equip your portable station with a notch filter and/or cavity bandpass to suppress this intermod, the preamp will serve no useful purpose. Be wary of bargain "no-name" amps you see at hamfests or in discount catalogs. Some are not aligned for the entire U.S. 2-meter band, many lack thermal protection circuitry for over voltage, overdrive or high VWSR or simply have an inadequate heat sink and will overheat and quit.

<PAUSE for the Repeater to reset >

OK, this concludes "Emergency Operations and your HT." Are there any questions?

The Effects of VSWR on Transmitted Power

By James G. Lee, W6VAT

No matter how long you have been a ham, sooner of later you will be involved in at least one discussion of something called the Voltage Standing Wave Ratio, or VSWR, of an antenna system. There is a lot of good information available on VSWR as well as a lot misconceptions about what it is and what it signifies. Probably the most often misconception is that your VSWR should be as close to 1:1 as possible, otherwise " you won't get out very well." A 1:1 VSWR implies a perfect match between all elements of the antenna system. The only problem is that it is possible to have a low VSWR and still have some very serious things wrong with your antenna system. Other misconceptions such as a high VSWR causing television interference, or other unwanted problems are often heard and can cause unnecessary worry. The concept of VSWR is easy to grasp and its importance in an antenna system does not require an engineering degree to understand.

WHY VSWR EXISTS

Early in electronics you learned that to get maximum power into a load required that the load impedance match the generator impedance. Any difference, or mismatching, of these impedance would not produce maximum power transfer. This is true of antennas and transmitters as well but, except for handie-talkies, most antennas are not connected directly to a transmitter. The antenna is usually located some difference from the transmitter and requires a feedline to transfer power between the two. If the feedline has no loss, and matches BOTH the transmitter output impedance AND the antenna input impedance, then - and only - then will maximum power be delivered to the antenna. In this case the VSWR will be 1:1 and the voltage and current will be constant over the whole length of the feedline. Any deviation from this situation will cause a "standing wave" of voltage and current to exist on the line.

There are a number of ways VSWR or its effects can be described and measured. Different terms such as reflection coefficient, return loss, reflected power, and transmitted power loss are but a few. They are not difficult concepts to understand, since in most instances the are different ways of saying the same thing. The proportion of incident (or forward) power which is reflected back toward the transmitter by a mismatched antenna is called reflected power and is determined by the reflection coefficient at the antenna. The reflection coefficient "p" is simply a measure of this mismatch seen at the antenna by the feedline and is equal to:

$$P = (Z1 - Z_0)/(Z_1 + Z_0)$$

Here $\mathbf{Z_1}$ is the antenna impedance and $\mathbf{Z_0}$ is the feedline impedance. Both $\mathbf{Z_1}$ and $\mathbf{Z_0}$ are complex numbers so "p" is also a complex number.

You remember from elementary AC mathematics that a complex number has a "phase angle" associated with it. The phase of the reflected signal will be advanced or delayed depending upon whether the antenna appears inductive or capacitive to the feedline. If the antenna appears inductive the voltage will be advanced in phase, and if the antenna is capacitive, the voltage will be retarded. The reflective signal travels back to the transmitter and adds to the incident signal at that point.

Thus, any mismatch at the antenna gives rise to a second 'travelling wave' which goes in the opposite direction from the incident wave. When $\mathbf{Z_1 = Z_0}$ the reflection coefficient is zero and there is no reflected signal. IN this case all power is accepted by the antenna and this is the ideal situation where VSWR is concerned. The problem is that this condition is rarely, if ever, achieved and so "p" will have a value different from zero. Note that "p" can have negative values, but in calculating VSWR from the reflection coefficient, only the "absolute value" is used - which is a positive value lying between 0 and 1.

As the two travelling waves pass each other in opposite directions, they set up an interference pattern called a "standing wave". At certain places on the feedline the voltages will add producing a voltage maximum, and at others their relative phase difference will cause a voltage minimum to exist on the feedline. These maximum and minimum points occur 1/4 wavelength apart. In the days when open-wire feedlines were used these points could easily be measured with simple indicators. Coax cable however presents another problem since the "inside" of the cable is not readily available for measurements. Consequently, VSWR measurements on coax are usually made at the transmitter end of the feedline. Therefore you are presented with the VSWR of the entire system which includes all losses associated with the entire system.

INTERPRETING WHAT YOU HAVE READ

Many VSWR meters are calibrated to read FORWARD power as well as REFLECTED power. They may actually be measuring voltage,

and simply have the scales calibrated in power. The important point is to understand what the meter is actually telling you. Assuming for the moment that the VSWR meter contributes no errors, the FORWARD reading is the SUM of the forward power and the reflected power. As a result, it is greater than your actual power output. The REFLECTED power reading is that amount of power which was not initially absorbed by the antenna and has been sent back down the feedline. At the transmitter end it encounters the transmitter output circuitry and is re-reflected back towards the antenna. This happens because you do, in fact, have a VSWR greater than 1:1 as seen by the transmitter. When the re-reflected power encounters the antenna, a portion of it is absorbed and the whole process starts over again.

Ultimately then, most of your signal is eventually absorbed by the antenna. You might be tempted to think that all of this bouncing back and forth would cause "smearing or blurring " of your signal but this is not so. The average transmitted signal appears as a "steady-state" signal to the feedline and antenna. Remember your signal is travelling at a significant fraction of the speed of light. For instance, the velocity of propagation of RG-8/A is 0.66 or 2/3 the speed of light. The speed of light is close to 1000 feet per microsecond, and a dot or voice peak takes milliseconds to complete. If the speed of light were 20 miles-per-hour then the situation would be completely different and we probably wouldn't have radio transmission at all. (Ed. Note, it would be as fast as the mail then.)

Given the reality then that almost all power launched down a feedline reaches and absorbed by the antenna, one has to wonder why VSWR is all that important. The importance is due to the fact that feedlines have losses and, antennas have something called radiation efficiency. They are what make proper interpretation of VSWR important. Power is lost due to feedline attenuation and this loss goes up as the VSWR goes up. The efficiency of an antenna is determined by the ratio of its "radiation resistance" to its "loss resistance". Antenna efficiency can simply described by the following equation:

$$\% \text{ Efficiency} = [R_a/(R_a+R_{loss})] \times 100$$

The radiation resistance is $\mathbf{R_a}$, and $\mathbf{R_{loss}}$ is made up of any associated losses of the antenna such as loading coils and ground systems. How well you "get out" therefore depends more on low losses and efficient antennas than on what your actual VSWR is as the following example will show.

THE EFFECTS OF ATTENUATION ON VSWR

Early in this discussion the statement was made that your VSWR may appear to be very low and yet there could be serious things wrong with your antenna system. Figure 1 shows how this can happen. The curves in the figure represent the forward and the reflected voltage on an antenna which has a feedline loss of 3 dB. and a reflection coefficient of p=0.5. In this example the actual value of voltage is inconsequential and can be considered to be "E". We are only interested in relative values of "E" in any case. The length of the feedline is also arbitrary since we are only concerned with its total loss between transmitter and antenna.

Figure 1

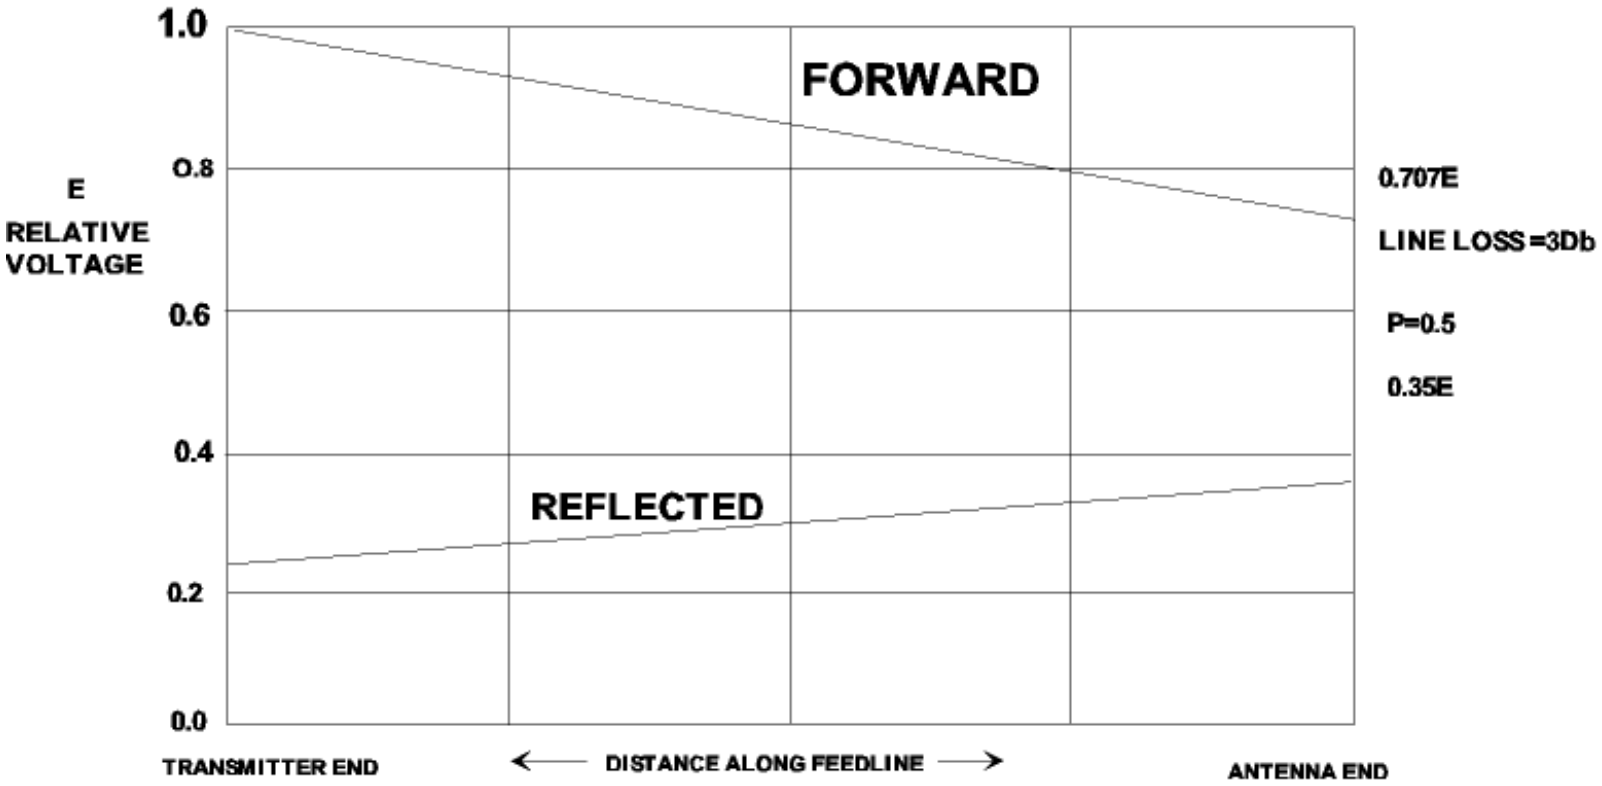

FIGURE 1: EFFECT OF LINE LOSS ON SIGNAL AMPLITUDE

The signal voltage "E" starts out at full value -1.0 E - on the feed line and is attenuated at a 3-dB rate. This means that the voltage will only be 71% - or 0.707E - when it reaches the antenna terminals. Remember that while 3-dB is a factor of two for power considerations, power is proportional to E-squared, consequently E will be only 0.71e when it arrives at the antenna input. The top curve in Figure 1 shows the FORWARD voltage decay as it travels down the feedline to the antenna input.

Since the antenna in this example has a reflection coefficient of 0.5, this means that 1/2 of the incident voltage will be reflected back down the feedline. This value is (0.5 X o.71E) or 0.35E volts. The feedline has no way of knowing which way signals are traveling, so this reflected voltage will suffer the same 3-dB attenuation on the return trip. When it arrives back at the transmitter end of the feedline its value is only (0.71 X 0.35E) or 0.25 volts. The VSWR meter sees this value and since

$$\mathbf{VSWR=(E_{fwd} + E_{ref})/(E_{fwd} - E_{ref})}$$

the VSWR meter will read 1.67:1

That value of VSWR is guaranteed is to make almost everyone happy, but your antenna system is not very good. The 3-dB loss down the feedline means only 1/2 of your output power reaches the antenna, and if your antenna has significant losses, something less than 1/2 of your power will be radiated depending upon how bad the losses really are. If for instance, the loss resistance equals your radiation resistance, the antenna is only 50% efficient meaning only 1/4 of your output power is actually radiated. Yet that reading of 1.67:1 looks fine. A reflection coefficient of p =0.5 means your antenna is not well matched to the feedline. VSWR can be calculated from the reflection coefficient by the following:

$$\mathbf{VSWR = (1+p)/(1-p)}$$

Using this formula shows your VSWR at the antenna is 3:1, quite a different value than your VSWR meter reads. The difference in the input and output VSWR values is due to the loss introduced by the feedline. Figure 2 shows how this loss can cause you to get a different VSWR depending upon where you measure VSWR in a feedline. You can measure VSWR at the antenna end of the feedline, but it is usually impractical to do.

Figure 2

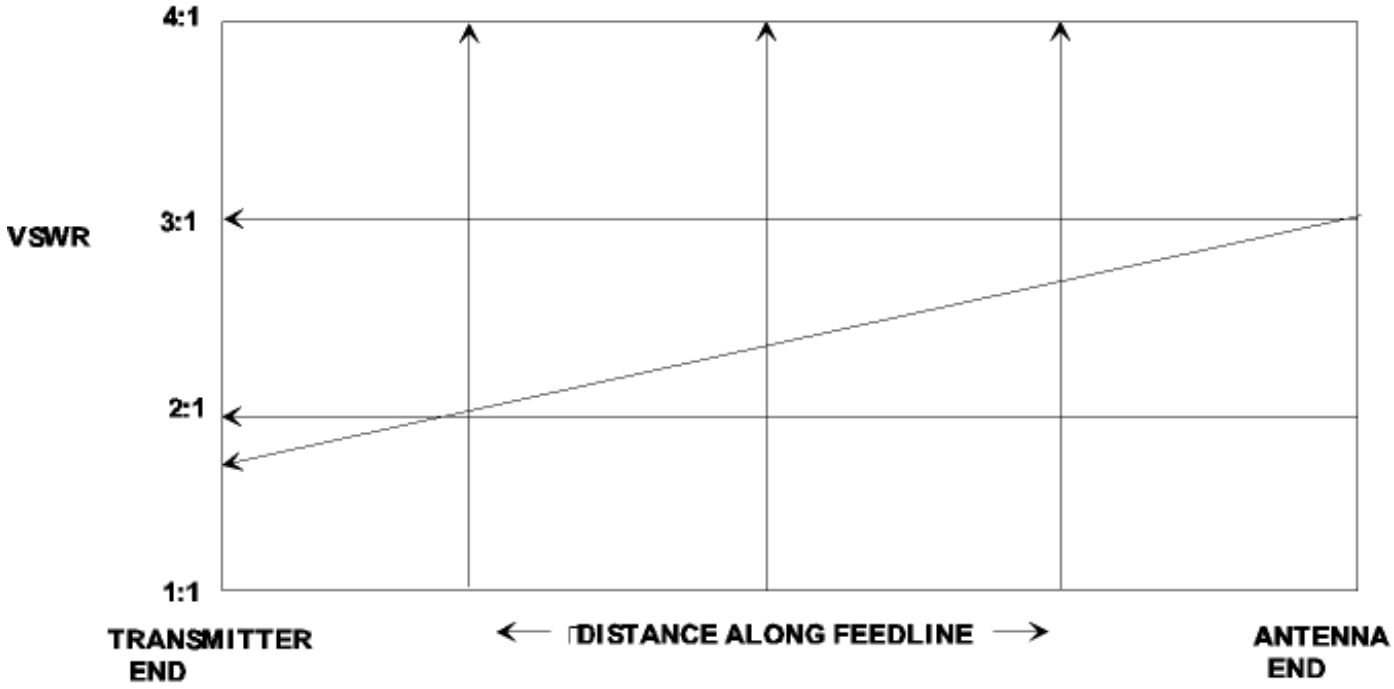

FIGURE 2 EFFECT OF LINE LOSS ON VSWR

You can use 1/2 wavelengths of coax between your VSWR meter and the antenna because a 1/2 wavelength of cable repeats the impedance it sees. The only problem is that you are introducing other possible elements into your measurements. But let's assume that your VSWR measurement at the feedline is reasonably close to what is actually occurring on the feed line, and that your feedline losses are not great. The burning question still is "how good or bad is the VSWR reading?"

VSWR AND TRANSMITTED POWER

Let's assume you have an efficient antenna, fed with a low-loss feedline so that the VSWR meter at the transmitter gives you a true reading of 1.65:1. There is no real reason to try to lower it, in fact the same would hold true if the reading were 2:1. Figure 3 is a chart showing the equivalence of VSWR to RETURN LOSS(dB), REFLECTED POWER(%) and TRANSMISSION LOSS(dB). Return loss is related to reflection coefficient by the equation:

$$\textbf{Return Loss} = -20\log_{10}(p)$$

It is just another way of measuring VSWR. For example, with a perfect 1:1 VSWR there would be no reflected power consequently the return loss on the feedline would appear to be infinite. A short or open circuit at the antenna is the worst case scenario since the reflection coefficient would be p =1.0. All incident power would be reflected, and with a lossless feedline the return loss would be 0-dB. this is what the RETURN LOSS (dB) column refers to

The most informative columns in Figure 3 are the REFLECTED POWER(%) and the TRANSMISSION LOSS(dB) columns since they provide an answer to our question of whether further reduction of VSWR is worthwhile. Figure 3 shows that for a VSWR of 1.65:1 the reflected power is only 6.2% of the incident power, and the transmission loss is only 0.27 dB. In more familiar terms, if you count an S-unit as 6 dB, then the 0.27 dB loss is only 1/22 of an S-unit. A reduction of the VSWR to 1.5:1 would provide only a 0.09 dB reduction in transmission loss. This is not worth the effort it would take to achieve such a miniscule increase in power.

Figure 3

VSWR	Return Loss (dB)	Reflected Power (%)	Transmiss. Loss (dB)	VSWR	Return Loss (dB)	Reflected Power (%)	Transmiss. Loss (dB)

1.37	16.1	2.44	0.106	6.00	02.9	50.8	3.08

Further examination of the chart shows that a VSWR of 2.6:1 results in only about 1 dB of transmission loss. A high VSWR of 6:1 shows just a 3 dB transmission loss, but this is 1/2 an S-unit. You will still be getting out but this is becoming a significant loss. Your feedline will be dissipating more power than it should, and there may be other serious things wrong with your antenna system.

Throughout this article you've noticed the use of the term "antenna system". The word "system" means you must pay attention to other things besides just the VSWR and your power output. Each component of your antenna system must be optimized to get the best results. Many factors must be considered such as operating frequencies, bandwidth requirements of the antenna system, heights, and directivity, all of which affect its efficiency. Since the height of your antenna, and your operating frequency determine both the length of the feedline and its losses the interfaces become very important. So there are a number of trade-offs which must be considered when you contemplate putting up a good antenna system, but these are tales for other times.

You can build or buy your own VSWR meter, but make sure that you understand what it is measuring and what it is really telling you. Then once you are satisfied that you have put up a really efficient antenna, fed with a low loss feedline, you can sleep well knowing that to try to reach the ultimate 1:1 VSWR is only an ego trip. As a rule of thumb, any accurate VSWR reading under 2:1 is probably not worth the effort to achieve if the other elements of your antenna system are the best you can make them. In fact you might be surprised to find that you really do have a low VSWR when you put up the best antenna and feedline you can. There is an old saying in ham radio that "a dime in the antenna is worth a dollar in the transmitter any day". Try it and see if you don't agree. **-30-**

Editors note:

W6VAT has a lot of good points, and careful attention should be paid to what is covered in his article, as it can make a difference in your signal. A case in point involves a ham club that I belonged to many years ago. They had just gotten the license for their repeater, and the only antenna that was available was a commercial antenna fed with ancient heliax. The antenna had only a small amount of reflected power and it seemed to get out well. Everyone was happy, and all was well with the world.

Until my boss who was a ham and I took the liberty of checking out the repeater with the equipment from the two-way shop. When I disconnected the RG-8A pigtail, water poured from the heliax for about 5 minutes. But the Bird showed no reflected power with a 10 watt element and 50 watts forward. This was met with extreme disbelief when the club members were told of the water cooled coax. No one wanted to spend the money to replace the antenna and coax. However, since we had a very heavy rain just before the meeting, duplication of the waterfall was easily achieved.

To the extreme displeasure of the older members who wanted to "patch the feedline and connections" a motion to spend the money to replace the old antenna and coax with new everything. After the purchase of a Ringo and some 1" heliax and the installation of same, the repeater range was tripled. The grumblers did not like the Ringo, as "it was not good enough". And, after I had left the area, they spent nearly two hundred dollars for a commercial antenna cut for the frequency, which they purchased from a club member who ran a two way shop and was adamant that the Ringo was no good. They were totally destroyed to find out that the high dollar antenna gave them no more range than the Ringo.

The moral to this story is things are not always as they seem, especially when it comes to VSWR, coax, and antennas that seem to work on frequencies that they shouldn't. Never take anything for granted, especially when it is your RF going up the flue. -30- *K5CNF*.

Antenna Projects

ARRL Technical Information Service page · TIS Menu page

Introduction

QST, through the years, has had more articles on antennas than any other subject. This is probably because your antenna, although it can be the least expensive, easiest to construct component of your station, can have the greatest effect on performance.

The main feature here is a menu of antenna pages divided into type and use. There are all kinds of antenna projects you can build for home, portable and mobile use, HF and VHF. Go to the Technical Information Antenna Projects Menu to find what you need. For the new-comer there is a special Beginners Section covering both HF and VHF antennas.

Additional resources

The ARRL Antenna Book
ARRL's Wire Antenna Classics
More Wire Antenna Classics Volume 2
Vertical Antenna Classics
Antenna Compendium Vol's 1 through 6
QST Magazine

The ARRL has an extensive catalog of books and materials related to Amateur Radio.

ARRL Products: Interference/DF
(More)

AC Power Interference Handbook -- New insights into the causes, effects, locating and correction of power-line and electrical interference. 2nd Edition.

The ARRL RFI Book -- Practical Cures for Radio Frequency Interference.

Transmitter Hunting -- Radio Direction Finding Simplified

The RSGB Guide to EMC -- Tackle RF interference problems and understand the underlying causes.

Information for HF and VHF beginners

General Antenna Info Articles:

- HF Amplifiers versus Antennas--One Ham's Opinion (39,999 bytes, PDF file)
  QST November 1998, pp. 54-56
  The solution to "getting out better" is not necessarily "more power".
- Low Power, Crummy Antenna (293,108 bytes, PDF file)
  QST December 1998, pp. 57-59
  A major part of the fun of amateur radio is putting together a station that works from stuff you have just laying around. Antennas lend themselves to this practice nicely.
- Antenna and Tower Safety (15,694 bytes, PDF file)
  QST June 2001, p. 91
- "What's Up Top"
  QST June 1960, pp. 38-40
  Crud and rust can be a real detriment to the performance of your antenna. Here are some procedures to make it look (and work) like new again.
- Stacking Yagi Antennas
  By what distance should stacked Yagi's be separated?
- Beam Talk for the Layman (263,249 bytes, PDF file) MEMBERS ONLY
  QST July 1958, pp.35-37
  Step-by-step tuning of a gamma matched Yagi antenna and other thoughts on installation.
- Sound-Card Antenna Measurements and Other Useful Techniques (1,560,065 bytes, PDF file) MEMBERS ONLY
  QEX Jan/Feb 2002, pp. 33-46
  Measure antenna and receiver performance and record results, even when you are not present, using your computer's sound card.
- Tower and Antenna Wind Loading as a Function of Height (192,267 bytes, PDF file)
  QEX July/August 2001, pp. 23-33
- A Low-Loss VHF/UHF Bias Tee (279,405 bytes, PDF file) MEMBERS ONLY
  QEX May/June 2002, pp. 52-54
  A simple circuit that lets you superimpose DC control voltage onto the transmission line without altering the RF characteristics.
- Tower and Antenna Wind Loading as a Function of Height (192,267 bytes, PDF file)

QEX July/August 2001, pp. 23-33

- An Inexpensive External GPS Antenna (253,745 bytes, PDF file)
  QST October 2002, pp. 36-39
  An easy to build antenna for your GPS unit for better reception.

40 meter half square $29.95

eHobbies has remote control plains, cars, rockets, helicopters and much more.

All about baluns

Theory and construction

Srewdriver moble antenna mount

A very nice mount from K9ROY

DX dual dipole

A wire yagi

VHF/UHF Long Yagi Workshop

Designs for VHF/UHF yagis

Quickie Vertical

---

7 ELEMENT LOGCELL YAGI

Claimed to be better than a regular yagi but on a shorter boom

---

Fractal quad for 10 meters

It's small, high performance, and unencumbered by electronic parts, transformers, discrete loads, and so on. And a 50 ohm feed

---

Rotatable Dipoles

6 meters, 20 meters and multiband

NB6ZEP antenna

A modified 20 meter Extended Double Zep, 40 thru 10 meters (with tuner)

Cubicle quad antenna calculator

This page makes calculates all dimentions for quad antennas, just enter the frequency. With detailed plans.

1270Mhz Yagi Antenna

Build your own antenna for the 23cm band (1250Mhz - 1280Mc) using some aluminium and this simple design

---

2 EL. Quad for 10-12-15 meters

Simple disign useing bamboo poles, of course fiberglass, pvc, etc could be used.

---

80 METER FRAME ANTENNA

A nice antenna for limited space

ANTENNA ROUND UP

ANTENNA'S FOR 6, 10 AND 2 METERS

K1TTT Technical Reference

Links to antenna resourses

Grounding is key to good reception

Discussion on grounding.

An Attic Coaxial-Cable Trap Dipole for 10, 15, 20, 30, 40, and 80 Meters

A good antenna for HF operation on 6 amateur bands at a QTH with restrictive covenants that prohibit outside antennas.

Clif's Ham Radio Page

Summary of experience with restricted space antennas.

No tuner required

Amateur Radio

Amateur Radio is a communications service consisting of operators licensed and regulated in the United States by the Federal Communications Commission. Amateur radio operators, by regulation engage in emergency and other public service communications, maintain technical skills, and foster international good will via communications.

My personal interest in amateur radio focuses on research into and education about antennas and antenna modeling. The listings on this page link to some past and present research (and to some past research updated before posting on these pages). Since these are essentially working notebooks and not polished articles (for the most part), they may contain typos, misspellings, and a few grammatical infelicities. Moreover, they are subject to revision and updating whenever I discover something more accurate, more useful, or more interesting.

Tales and Technicals:
A Little History and a Lot of Antennas

From time-to-time, I shall post some yarns, mostly taken from my collection of old books, manuals, magazines, and handbooks. I shall also occasionally post from the pages of my notebooks some technical information that may be of use to fellow and prospective hams. To keep this index from being too long to use, I have placed many items in collected groups. So be sure to check the listings that appear collect items together from time to time for additions. Since these are notes and some reprints of casual articles, there will be considerable overlap in places--and many large gaps in other areas. Nevertheless, let's begin with these items:

A Little History, a Little Humor, and a Little Seriousness

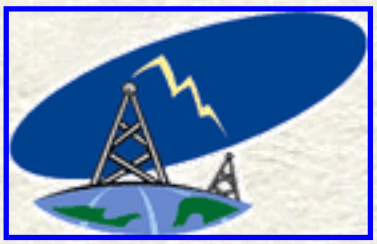
Continuing Series

- **An-Ten-Ten-nas**: a series of articles for *10-10 News* on antenna basics having special relevance to 10-meter operation.
- **Antennas From the Ground Up**: a series of articles on antenna basics for *Low Down*, the journal of the Colorado QRP Club. The emphasis will be largely on lower HF and wire techniques.
- **Antenna Modeling**: a series of articles on antenna modeling specially prepared for *AntenneX*. The series aim is to help antenna modelers get the most benefit and least anguish from their programs.
- **Amateur Radio Continuing Education**: a series of articles prepared over several years for the annual *Proceedings of the ARRL National Education Workshop*. The pieces range in scope from a full-scale proposal for a technical education series down to using a blackboard more effectively in the classroom. There are also links to some other educational sites.

HAMCALC: A Special Note. Numerous articles refer to HAMCALC, a suite of utility calculation programs developed for hams by George Murphy, VE3ERP. The information in the articles gives Murph's address for obtaining the current version on CDROM. Due to a bout of ill-health, HAMCALC is no longer available on CDROM. However, you can obtain **HAMCALC** from this link to the CQ Magazine site and download the current version of the suite in Zipped format. The site provides instructions for installation and use.

-- -- SEARCH -- --

Because the collection of material at the site has grown to fair proportions, I have added a search capability. Clicking on the "Search" button will lead you to a page containing a search engine. You need only enter in a key word (or words) of interest to get nearly instantaneous returns of links to articles containing the term (or terms). Not all articles will be of equal interest relative to your desired term, so use the search engine in conjunction with a scan of the article titles to isolate the items most likely to be useful to you.



Links to Other Antenna Information

These links carry a lot of valuable information and ideas, ranging from antenna fundamentals to advanced topics in antenna design, modeling, feeding, and building. In addition, some provide links to other sites.

Commercial Antenna Manufacturers and Vendors: A collection on known sources, offered because these pages often contain educational as well as commercial information.

Other Amateur Radio Links: A small collection of links to organizations and linkage sites to help you find other good sources of information.

A Final Note

You will note an absence of reviews, analyses, and evaluations of commercially made antennas in the notes at this site. It would be inappropriate for me to remark on such antennas without having the antennas at hand and the appropriate range and equipment for testing them. These notes relate to antenna types and designs over which I have design control and are generally aimed to assist you to understand their operation. Even specific designs are not intended for uncritical replication, although a number of them have been successfully built and used. Still, the goal is not to produce a compendium of antennas for you to build. Rather, the object is to assist you to understand the antennas that you do build, use, or simply think about.

Please do not attempt to download the entire site using software designed for blind downloading. If you wish a record of the entire site, *antenneX* periodically produces a CDROM with the entire site on it. However, I have kept most (but, alas, not all) of the items at the site short enough to read at a single sitting. Pick something of interest, read, and digest. Then pick something else. Let your wandering interests be your guide. If you wish to read more on a subject, by all means, select a related item. Or, look in other good sources for information on the subject. This site is collection of items cast at an intermediate level. Hence, it is far from the last word on any subject, whether you think of basic theory underlying a matter or about very practical construction aspects of an antenna or system.

When you begin to track the items at this site, you become a companion down the path of antenna explorations that I have followed. Be certain that you are ever alert to pathways that are a function of your own interests. This pathway is not the only one, and it is far from the perfect one. But it has been and continues to be both a good and interesting one.

It has been my high pleasure to receive e-mail and regular mail that suggests these materials are of educational and technical service to a broad spectrum of individuals, both in the United States and around the world. Numerous items have appeared in the newsletters and other publications of amateur radio groups. The formal and informal distribution of some of the material, both as written and in translation, in areas where bound publications are unavailable or prohibitively expensive suggests that the energies used to develop and place some of the notes has been productive. So much to learn and so little time to learn it, but always time to share what I have learned along the way--lest it be lost.

Tales & Technicals: the CDROM

As a convenience to those who may pay for on-line time by the minute, have long-distance phone charges, or who have run out of paper downloading items, the site is now available on CD-ROM. The cut-off date for the recently updated Version 4.0 is December 1, 2003. The CD-ROM is available from AntenneX in the "Shopping Shack."

Other information will be made available on these pages as time goes by. For now,

Amateur Radio Station

G4FGQ's Software

Original, high-quality, radio engineering/modelling programs.

Not freeware -- just free gifts -- please help yourself -- no catch.

Download in a few seconds -- not zipped-up -- run immediately -- user friendly.

There *ARE* such things as free lunches after all.

Click on Index now.

##

Occasionally programs may be amended. Minor changes such as correction of spelling errors, a more covenient arrangement in the display of results, a change in the number of decimal places, will not result in a change of program name. Only the date of issue will change as shown on a program's introductory screen when a program is run.

When significant changes, improvements or corrections are made in mathematical modelling the program name will be changed and the original program may no longer be available from this site. An announcement of a new name may be made on appropriate Internet newsgroups

and on the "Late-News" page of this website. When a serious error or bug is discovered in a program an explanatory note will appear in the "Program Bugs" page. See Index.

About this Site

There are few purely decorative features on these pages. No wallpaper, no pictures, decent or otherwise, no voices-off, and absolutely no adverts to distract the serious visitor. Consequently this text and the programs themselves will very quickly download themselves.

The site has been produced by Reg Edwards, UK Amateur Radio Station G4FGQ, for the benefit of the many Radio Amateurs world-wide who make friends and obtain satifaction not only from operating a radio station but also from building and testing it. However, much construction consists of copying or adapting the work of others. But without a quantitative as well as a qualitative appreciation of radio basics the opportunities for innovative work are necessarily severely limited. Refer to Lord Kelvin's pertinent remarks and the great revolutionary work of the self-taught amateur Oliver Heaviside in the "Quotations" page.

Therefore, the primary purpose of this website is to freely distribute computer programs, composed by G4FGQ himself, which mathematically model the behaviour of components, circuits, power amplifiers, transmission lines, aerials, earth electrodes, radio propagation paths, etc. 'Working models' allow experimenters to examine quantitatively how the various input data interact and affect performance. They will relieve the hobbyist of some of the labour, the costs and the disappointments of constructing unsuccessful prototypes. Also of tedious arithmetic. He/she will gain further insight and will better appreciate the finer points of design. Opportunities for original contributions to this truly international hobby will be broadened.

Download Pascal Source Code from here

For various (some dishonest) reasons I have been asked on numerous occasions to release the source code of programs available free from this website. To satisfy the genuine curiosity of those people who have asked for "the 'formula' for .... ", here are a few source code examples. Anyone who considers he understands the contents of these *.pas files is hereby granted permission to make full use of the information contained therein. If any future products result no reference shall be made to the author who is unable to provide any assistance in such matters.

Files are best read in non-proportionally-spaced text such as displayed by the mini word processor "NotePad".

To download a file click on underlined program name.

GRNDWAV3.pas * Groundwave propagation vs frequency, distance and terrain.

TOPHAT2.pas * Performance of top-capacitance loaded vertical.

PADMATCH.pas * T and Pi resistive-matching and minimum loss pads.

Index

Program Size, Reliability and Accidents

The number of possible ways in which a computer program can misbehave increases enormously with its size in bytes. A very large program is virtually certain to contain defects or bugs if only because of the impossibility of identifying and testing every one of these many ways. Debugging operations themselves are likely to introduce further defects. The importance of individual defects is uniformly distributed randomly between trivial and catastrophic.

A smaller program is a more reliable one. Unnecessary elaboration must be removed. Simplicity of source-code structure and understandability is the ultimate target. Small programs are better understood by both the programmer and during later maintenance. Testing will be more thorough and 'bugs' far less likely to remain. Consequently large programs must be composed of a number of small, independent, testable modules whose functions are precisely, unambiguously defined beforehand. Each module is then itself a complete small program.

The size of a complete program can greatly increase due to built-in precautions to protect itself, the computer and its user from the consequences of accidental entry of 'illegal' data. For example, illegal data might result in the maths processor being asked to calculate the square root of a negative quantity. To omit protection might result in the program 'crashing', sieze-up of the computer's operating system and the need to press the re-set button. The number of possible ways in which illegal data can be entered is also very large. To lay traps, deal safely with them all and inform the user, is impractical and will itself increase the liklihood of bugs

remaining in the finished product.

In G4FGQ's programs a bare minimum of protection is provided against entry of impossible data. Inevitably the user will make mistakes especially when unfamiliar with a new program. Mistakes are most likely to occur when entering numerical values. They fall into categories of incorrect measurement units, impossible physical proportions, ie, wire diameter greater than wire pitch, inclusion of non-numerical characters and using a comma for a decimal point. Obvious errors can be corrected, of course, by inspecting the data before pressing the Enter or (cr) key.

If you are running one of these programs in DOS where you have arrived from Windows, and it aborts, the system may not automatically switch you back into Windows. To return to Windows from DOS type EXIT (cr) against the DOS prompt. No harm is likely to come either to the computer or to the program as a result of being unceremoniously dumped back into the system.

To re-start a program which has just aborted while in DOS, from the same directory as the program is filed, just type the program's name against the DOS prompt followed by (cr). The .exe ending may be omitted. If you are not in the same directory then the name of the program must be preceded by the directory path to the program, the several items being separated by backslashes. Or you could change the current directory to that where the program is installed and then enter the program's name.

To Q(uit) or E(xit) from within a program do so by pressing the key indicated on the menu bar (Q or E) at the bottom of the screen. The option to quit is available only when the menu bar is visible. Pressing the quit key when the option is not available, if followed by the (cr) key, may indeed cause the program to close down but not in a very graceful manner.

Index

What kind of programs are they?

The source-code language of G4FGQ programs is Turbo Pascal. Unlike BASIC and various spreadsheet calculators, when compiled into a stand-alone program, as they all are, the Pascal source text is inaccessible and cannot be modified. Programs can be run only as the author intended. Integrity and authenticity are preserved.

Subject matters are technical and are necessarily dealt with quantitatively. At the heart of each program is a set of mathematical functions and procedures. Properties of the 'parts' used to construct the model are stored within the program. Other procedures accept from the experimenter the details specifying the model. The program then proceeds with its analysis and its conclusions are displayed. Advice or warnings may be given to the experimenter as appropriate.

Entry of numerical input data obliges the experimenter to clearly visualise the system modelled and approach it logically. He will learn to ask himself the right questions. The relative importance of the various factors affecting behaviour of the system will be better appreciated. This conforms with one of the purposes of amateur radio activities: self-teaching in the art of radio communication.

But before the amateur who takes pride in being purely practical and ignorant of theoretical matters now leaves, don't go, these programs have been written with you in mind.

To use these programs you need no more than the ability to estimate the number of rolls of wallpaper required to decorate your shack. That's not maths - it's only arithmetic. Authors of articles published in radio magazines often confuse these activities.

Programs are intended to relieve the user of the labour and tedium not only of mathematics but of arithmetic too. But the quantitative visualisation of a model cannot be avoided.

If you have not yet mastered the sizes of enamelled copper wire in terms of milli-metres and still work in 'thou of an inch', or 'mils' you will be at a slight disadvantage - all the programs are in metric units. But down-load a program anyway and let me know how you get on with it. You'll be back.

Actually, most of my programs are more than 10 years old. Most of the basic research had been done and the mathematical procedures had been developed by then. Recent work has been to extend their range of application, to combine related subjects into single programs, to generally tidy up loose ends, and to make programs presentable and user-friendly.

At present, several more are in their final testing stages, being cross-checked for mathematical inconsistencies, bugs, etc. More effort is spent on later quality-control than on producing the first useable version of a program.

It's good practice to put a supposedly finished program on the shelf for a month or so, allow one's mind to forget it, concentrate on something else such as producing this web site, even spending some time on the 'bands'. It is surprising how previously unnoticed defects then become obvious. However, these discoveries do not improve one's self-confidence - how many other hidden boobs remain?

Until recently I have never actually finished a computer program. The self discipline of saying "It's done. Date it. Archive it. Make it available on the Net" has not come easily.

Index

What if . . . . ?

All programs ask for a set of numerical values which describe or define the matter in hand. Often the data are physical dimensions plus a choice of operating conditions. This initial array of input data is always on view at the top of the screen.

When a set of results has been computed it is displayed in the lower part of the screen. It is now a simple matter to select and change any one of the initial values while asking "What if I set it to this particular value . . . ?" Immediately the question is answered. A similar question can then be asked about any other input parameter.

Later programs, on the press of a key, have the facility to sweep input parameters slowly in fine increments over wide ranges while immediately observing the effects on output data.

There is no need to go back to the begining and re-enter a complete set of initial values although that particular option is available when needed. The response or behaviour of complicated systems when subjected to changes in inputs can be analysed and appreciated very quickly. Not only will programs be of practical use - by encouraging the user to become familiar with magnitudes and ranges of the essential factors they will also be of educational value.

Copying and Re-distribution of Software Programs available from this Website

There are no restrictions on copying and re-distribution of self-produced software programs available free from this website, via any electronic, magnetic or optical means, by any individual or organisation, except that no copies shall be made, distributed or sold for commercial or financial gain.

With due regard to the foregoing I retain the Copy and Intellectual Property Rights for all programs. To preserve program integrity the source code of these programs is not normally available.

RAISING WIRE ANTENNAS

Wire antennas deliver the most bang for the buck, but they require a little work to put up. The most common way to put one up is to use the biological towers in your yard: the trees! To make this work, you need to install ropes to hold up the antennas. Here's a description of my favorite technique for getting those ropes up there:

SETTING ROPES IN TREES FOR WIRE ANTENNAS

ANTENNA PROJECT SELECTOR

VHF ANTENNAS	
2 meter HT Handipole	Add some gain over your 'rubber dummy load' with this full size dipole on your HT.
2 meter rollup J-pole	Compact portable companion for travel or temporary operation. Hang it up anywhere.
2 meter 4 element, portable yagi	This yagi breaks right down and the elements store right inside the boom. The boom and mast can be used for walking sticks. Can be used as a base, as a portable or for foxhunting.
2 meter, 4 element quad	Rugged, yet lightweight powerhouse is great for base or portable and is especially *excellent* for foxhunting. It can also be constructed to break down for compact storage.

2 meter Bicycle whip antenna	This 1/2 wave, end-fed vertical with compact feed is built right onto a 1/4" fiberglass bicycle flag whip and *requires no ground plane nor radials*!. Excellent for bikes, boats, RV's, etc., or anywhere a compact vertical is desired.
MONOBAND HF ANTENNAS	
10 meter wire J-pole	This end-fed half wave radiator is simple to make and even simpler to put up with a single rope. Can also be strung horizontally from your shack's window with a single rope to another support.
10 meter wire collinear 'super' J-pole	Yeah! More gain! Two 5/8 wave, phased radiators. Can be strung vertically for omnidirectional gain. This is a great omnidirectional gain antenna!
20 meter wire J-pole	This end-fed half wave radiator is simple to make and even simpler to put up with a single rope. Can also be strung horizontally from your shack's window with a single rope to another support.
40 meter wire J-pole	UNDER DEVELOPMENT
MULTIBAND HF ANTENNAS	
80-10 meter doublet with open wire feed	Arguably the most popular 80-10 multiband antenna ever! Certainly, the most bang for the buck!. If you only build one, this should be it. Ultra simple to build and no pruning required. Good lobes of serious gain on the higher bands and low loss. Requires an outboard tuner with open wire terminals for best performance or you can use your rig's built-in tuner and a remote balun to match most bands. This antenna has the most gain when strung as a horizontal, flat-top, but it is versatile and can be strung as a sloper, or inverted vee.
80-10 meter mobile vertical	My latest project, and the results of 9 months of experimenting after putting an HF rig in my car. The signal reports have been excellent! This is, essentially, a homebrew version of a Texas Bugcatcher, except that the capacity hat is up at the top of the whip where it belongs for maximum efficiency. And, it's a lot cheaper!

Good luck and have fun with your antenna project!

--...MARK_N1LO...--

These antenna plan files are in Adobe Acrobat Portable Document Format (*.PDF files), the emerging standard for downloadable documents of all types on the web. To read or print the item, just click on it to download the file, then open it using the free Adobe Acrobat reader program, which you must have installed on your computer. Typically, Acrobat will open automatically and display your goodie. Follow the link below to get Acrobat if you don't already have it.

Webmasters note:
I Apologize for this very cluttered page!
This web site has grown so fast that I cannot keep it mowed. The weeds are getting very tall in places and the grass needs cutting just about every other day!
Broken antenna elements are scattered all over, bent towers, burned out baluns, loose connectors and lots of spiders, useless bits of wire of all sizes and the accumulation of SWR is getting awful!
Please be patient.....
We plan to use weed, grass killer and insect spray so the page should be much neater in the future! **73** N4UJW.

Antenna Magic

by

Ray Jurgens

KQ6RH

(C) 1998, 1999, 2000

Updated 2/25/2000

This page is devoted to light weight wire beams and quad antennas. Most of these antennas are low profile wire beams constructed with fiberglass rods and tubes supported with central hubs. Each of these has been designed to give significant gain over a dipole but require much less space. All are self supported and able to be rotated with low cost TV antenna rotators. This site provides construction details as well as information about where specific materials can be found. We also offer some materials that are difficult to find or make.

Philosophy

You may wonder what the motivation is to try to build antennas with super-light weight structures when larger and heavier structures are readily available. Some might say that this is equivalent to buying into the minimalist movement which, for ham radio, is the same faction as the QRP movement. However, there are many reasons for developing light weight systems for portable and emergency situations as well as relatively stealth applications in controlled spaces such as apartment and town house developments. A few general principles that we have tried to abide by are that each antenna must be self supporting, must be sufficiently light in weight that a single person can easily assemble it and erect it, and that if at all possible, it should be able to give significant gain over a simple dipole. Why settle for less? This is not exactly minimalism, this more in the line of optimism.

Content

This page currently discusses quad-loops, cubic quads, Pfeiffer quads, VK2ABQ wire beams, Reflected M beams, Half Squares, X-Beams and a few simple antennas including a rotatable dipole. The Reflected M beam is a variant of both the VK2ABQ beam and the X-Beam. For a given wavelength, the Reflected M beam is the smallest of all. To compare these, I'll consider the length of the spreader required for a 15 meter antenna cut for 21.2 MHz. Though these differences are small, they are significant in that the bending of the spreader increases as length cubed for an applied force. Thus, the bending of the Reflected M spreader is reduced to 60% of that of a quad loop for a similar wire loading. The Reflected M beam is planar, takes less space to construct and can be designed with performance nearly equal to that of the two element quad. For example, a two element optimized quad might have about 7.5 dBi gain with a F/B ratio of 17 dB. The optimized Reflected M has 6.0 dBi gain with an F/B ratio of near 20 dB, though the actual rear lobes are about 2 dB poorer. The reflected M beam can be assembled and erected in about a half hour. Try that with any quad. I also give the performance of the X-Beam which is similar to and has similar performance as the Reflected M. Though the X-Beam has a good front to back ratio, the front to side lobe ratio is much poorer than that of the Reflected M. Still, the X-Beam is a great antenna that uses aluminum tubing for the radial elements and folded back wires to complete the element lengths rather than using fiberglass and wire, but the Reflected M is better in most respects.

These pages carry a copyright notice. You may make a copy of this web page for your personal use, but you may not distribute it in entirety or any part of it to others without written permission form the owner. You may, of course, pass the URL to others.

Comparing Antennas

The table below give some idea of how each antenna compares to the others. The sizes given are for a 15 meter version of each antenna. The size reported is the required length of the spreader. The impedance of some antennas depends upon several parameters, but the typical values are given below for both free space and ground mounted cases. In the case of the cubic quad, only the two element version is considered in the table. The elevation and peak gain reported are for the first or lowest lobe above an flat earth ground with average properties. For the elevation data, all antennas have their centers set at one half wave length above the ground or about 24.5 feet except for the Quick Vertical which is mounted 3 feet above the ground. The Quick Vertical uses a Hustler whip fed against a counterpoise. The Half Square antenna is actually better at suppressing high angle radiation if it is set at about 18 feet above the ground, but the data given in Table 1 is for 24.5 ft.

Antenna Type	Size ft	Z Ohms	Gain dBi fspc	F/B ratio	Elev. degrees	Peak Gain dB
Quad Loop	8.38	130, 125	3.2	0 dB (bi-dir)	24	7.8
Cubic Quad	8.38	110, 117	7.4	17.7	24	11.4

VK2ABQ beam	8.45	146, 200	3.8	12.6	26	9.8
Reflected M	7.46	38, 47	4.7	11.8	26	9.8
Reflected M	7.40	22, 24	5.8	21.8	26	10.6
Half Square	11.8	48, 50	4.4	0 dB (bi-dir)	14	3.3
Quick Vertical	8.0	24, 34	0.7	0 dB (omni-dir)	24	-0.9
X-Beam	9.3	34, 33	5.7	22.9 (deceptive)	26	10.5
Dipole	11.2	71, 65	2.1	0dB (bi-dir)	26	7.6

Table 1

Properties of Various Antennas in Free Space and Elevated a Half Wavelength

Inspection of the table gives some interesting insights:

1. The Reflected M beam has the smaller turning radius and size
2. The only antennas with good matches to 50 Ohm line are the Reflected M and the Half Square
3. The Cubic Quad has the highest free space gain followed by the Reflected M and X-Beam
4. The Reflected M and the Cubic Quad have the best F/B ratios
5. The Half Square wins the low launch angle by a large margin
6. The Cubic Quad has the highest ground mounted gain followed closely by the Reflected M and X-Beam

All of these antennas have respectable performance, and all can be designed with light weight fiberglass construction. So, take a look at these, and pick a winner for your application.

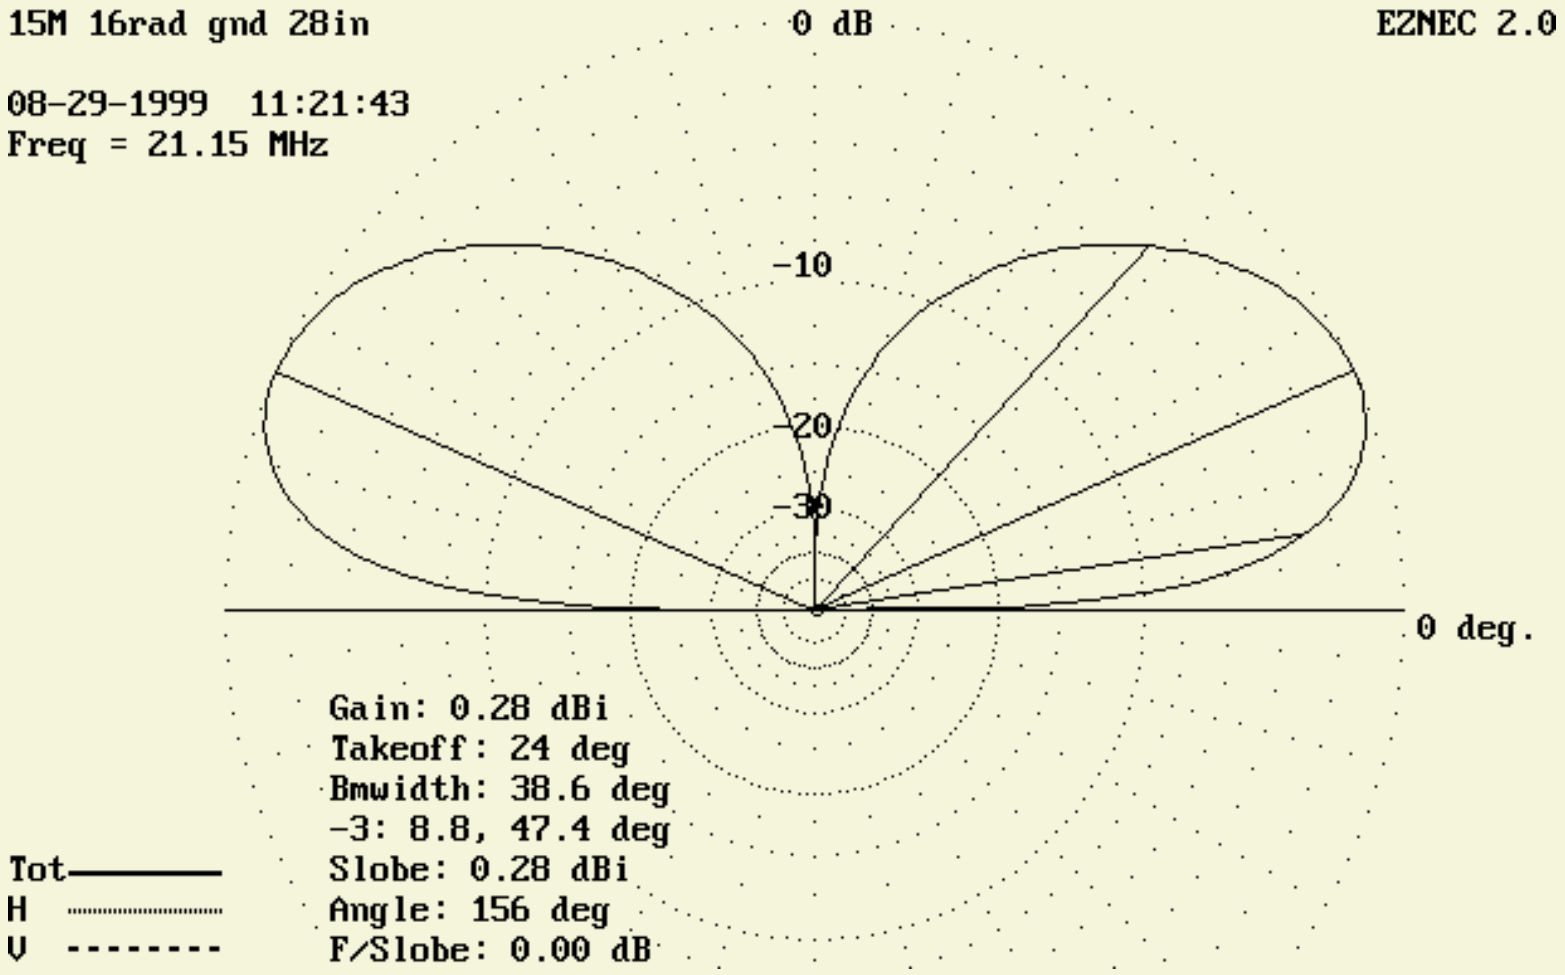
Common Antennas For Portable Use

Lots of speculation goes into antennas for portable use. There are conflicts. On the one hand you need to cart all the stuff with you so there is a definite "less is more" attitude here. On the other hand, putting up a "dummy load" does no one any good. As it turns out, height of the pole or poles available in wavelength determines just about everything in the selection process.

Several basic types are compared here using EZnec software. One is a very highly optimized vertical. It uses 16 elevated radials 28 inches off the ground. It uses lots of segments and is carefully matched to the EZnec model to make as certain as possible that it is free of computational artifacts.

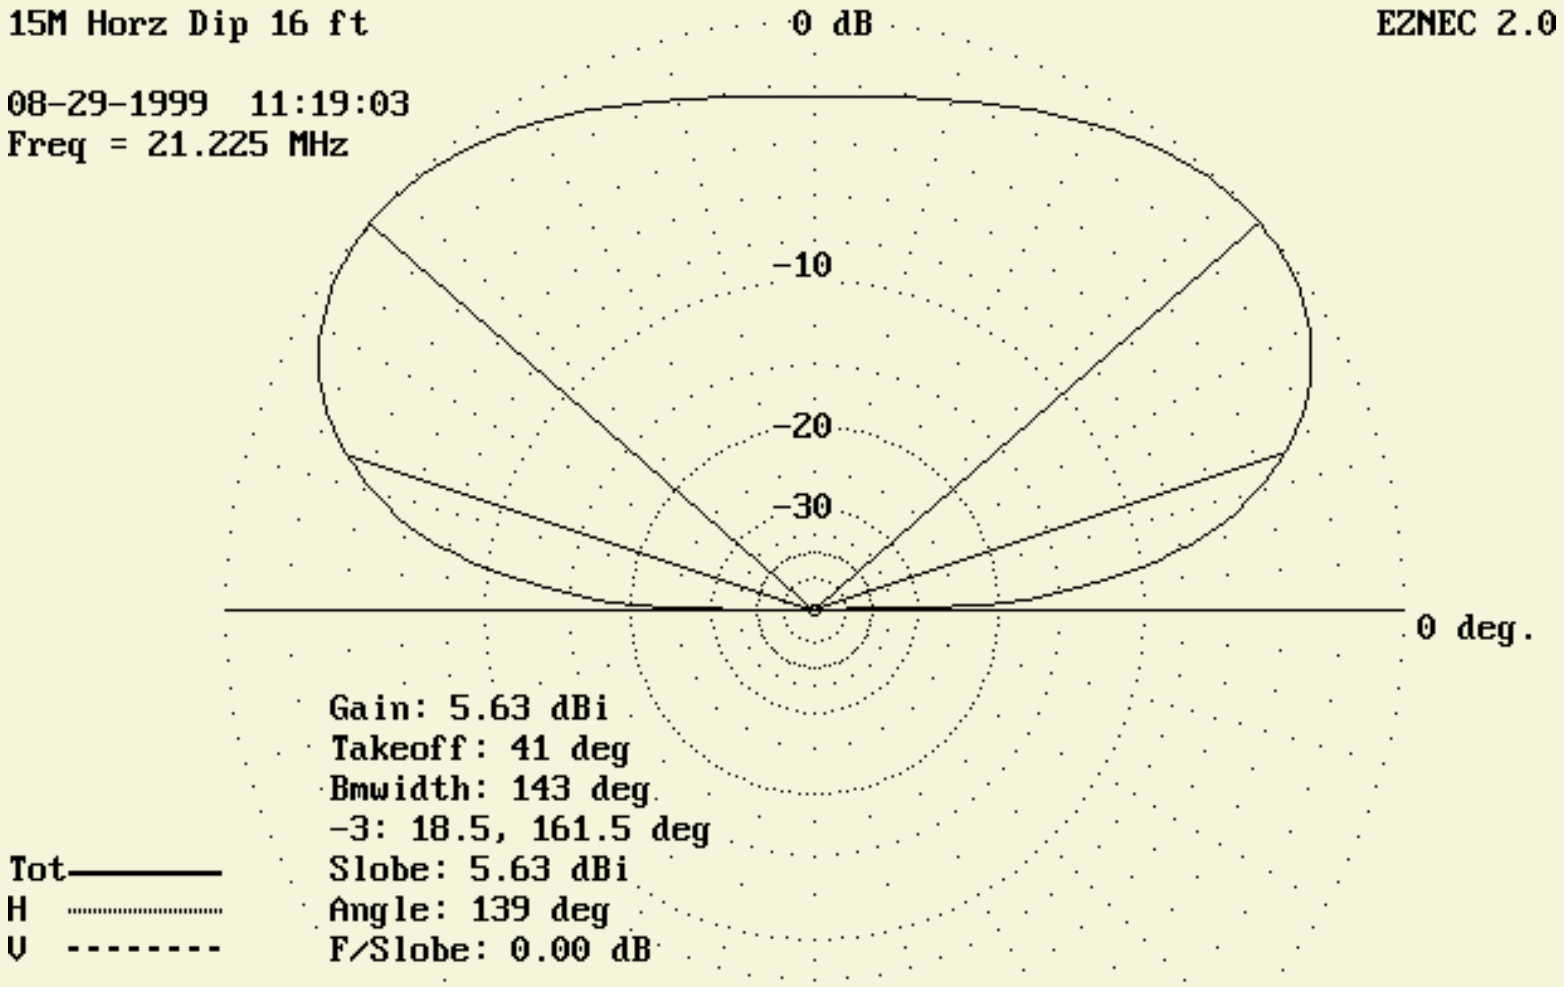
The second is a classic dipole erected using about the maximum length of pole that can be easily packed or taken on an airplane, a pair of multi-segment 16 foot poles. The third is a classic inverted V with an apex angle of 90 degrees. Another was modeled with an apex angle of 120 degrees but it had a large footprint due to the long guy wires. It was a tiny bit better at the flatter angle. The final one was an interesting fan dipole with triangular wire elements that were 24 inches wide at the far end. All used the same pole height.

The shock was the vertical. First look at the great pattern!:



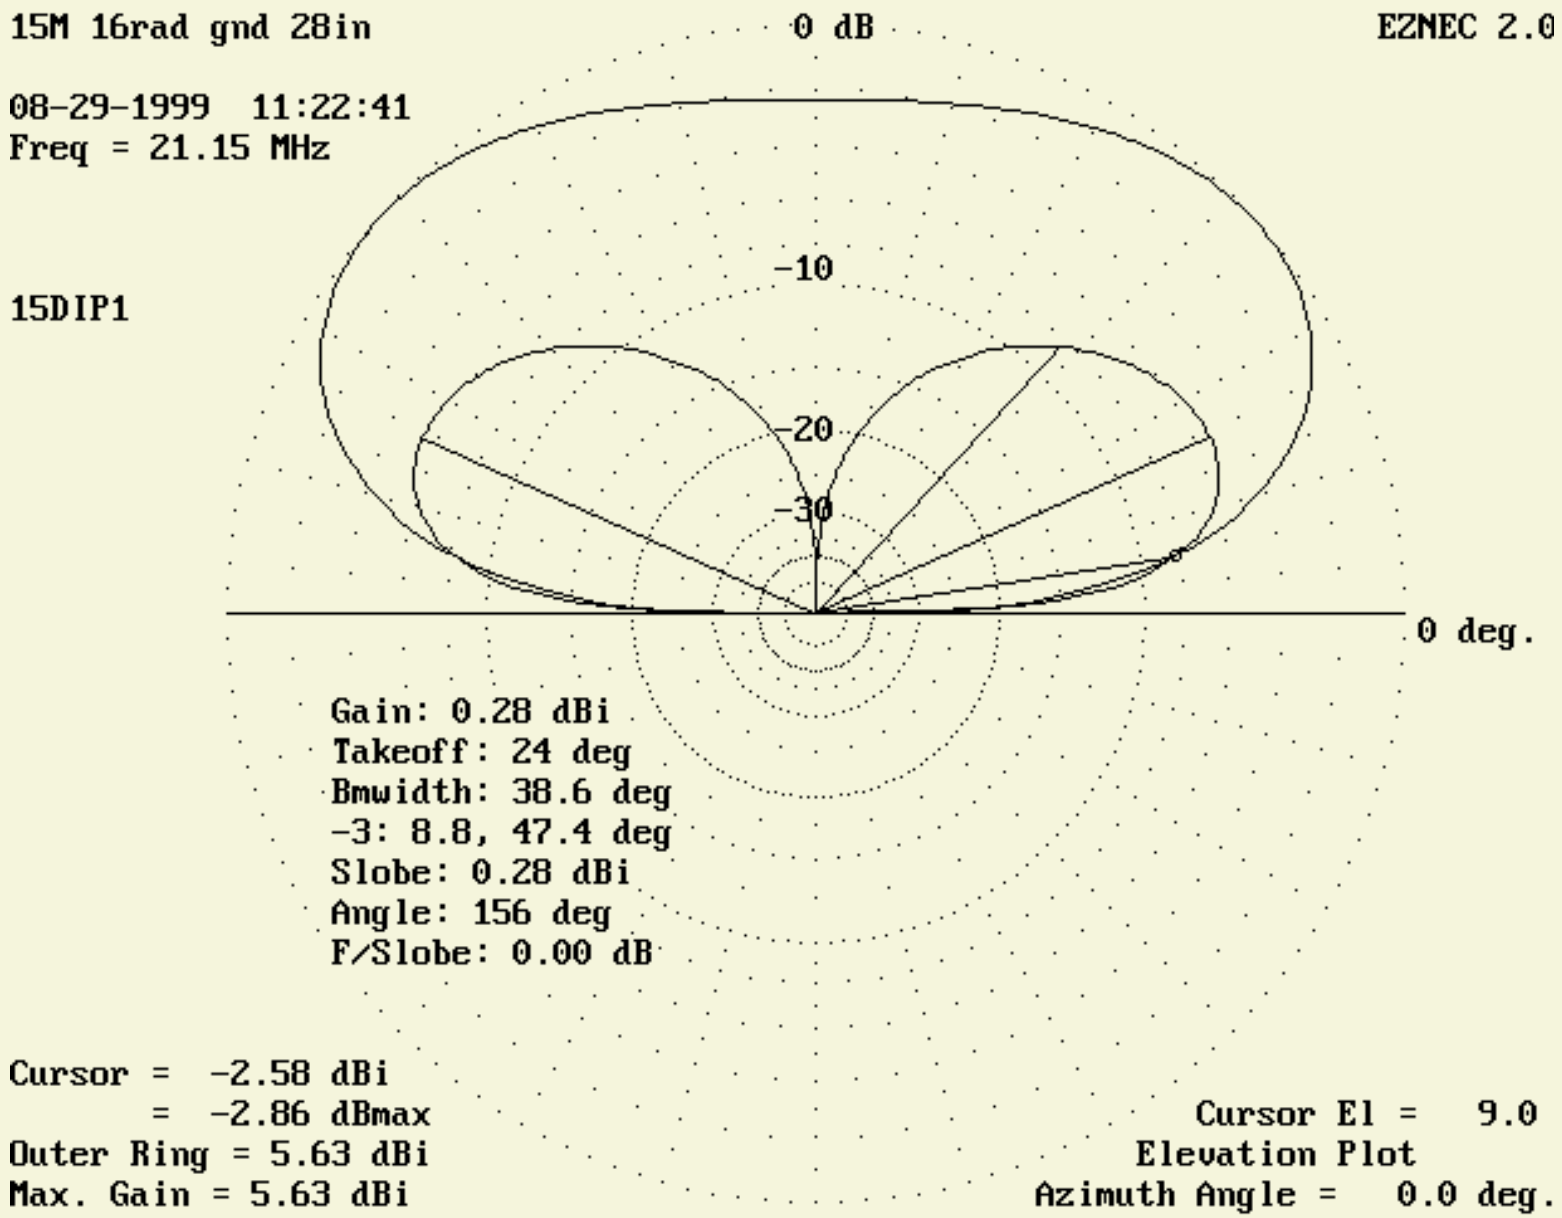
This looks **REALLY** good. It should. Everything that can be done has been done. This design brings along 16 additional stakes each about 3 feet long, to hold up the 16 elevated radials, but it is self supporting and needs no guy wires other than those on the 16 stakes for the elevated radials. Look at the nice concentration of power in the low angles, something a vertical is famous for. This one is getting close to the pattern over perfect ground.

Let's look at the pattern of the dipole. Who in their right mind would cart along two 16 foot poles instead of the above antenna. You could even get away with not elevating the above radials and laying them out on the ground as long as you used 16 or more of them, and still get much the same performance as above. But here is the dipole pattern:



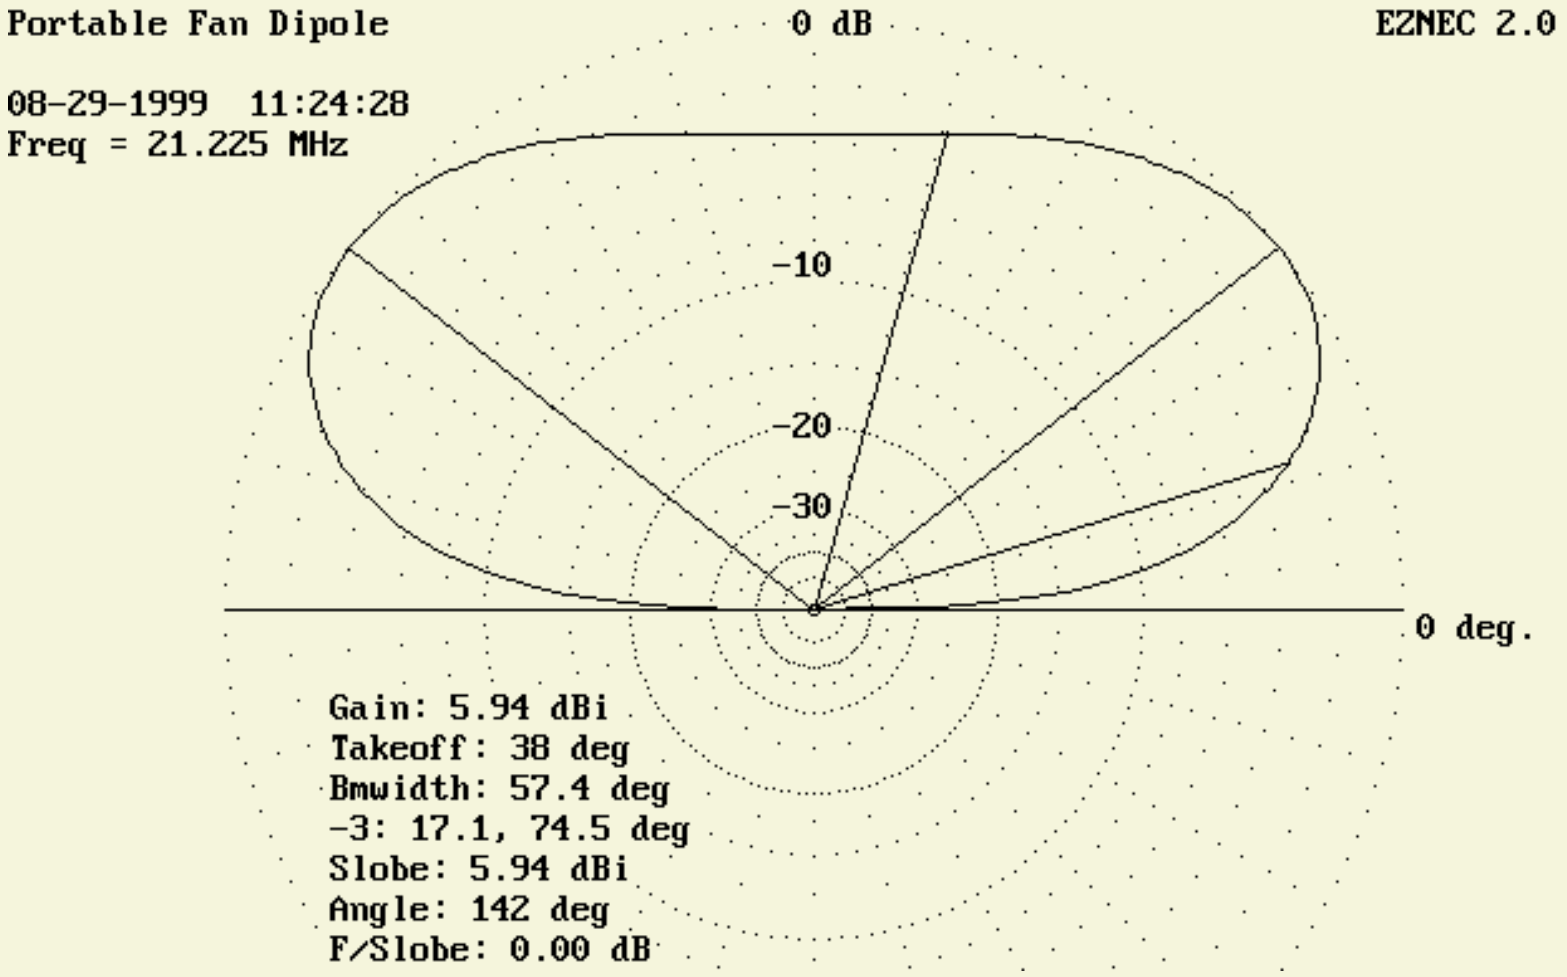
Not much to look at compared to the beautiful vertical pattern above. But there is something to look very very carefully at here. The absolute values. All of these antennas were modeled on 5 millisiemen ground and in each case the support poles were modeled as well as grounded metal poles. Note that the presence of the poles made only a slight difference in the patterns and gain figures. All antennas were carefully resonated at the test frequency.

So what is wrong? Let's have a look at the two patterns scaled and plotted on top of each other:



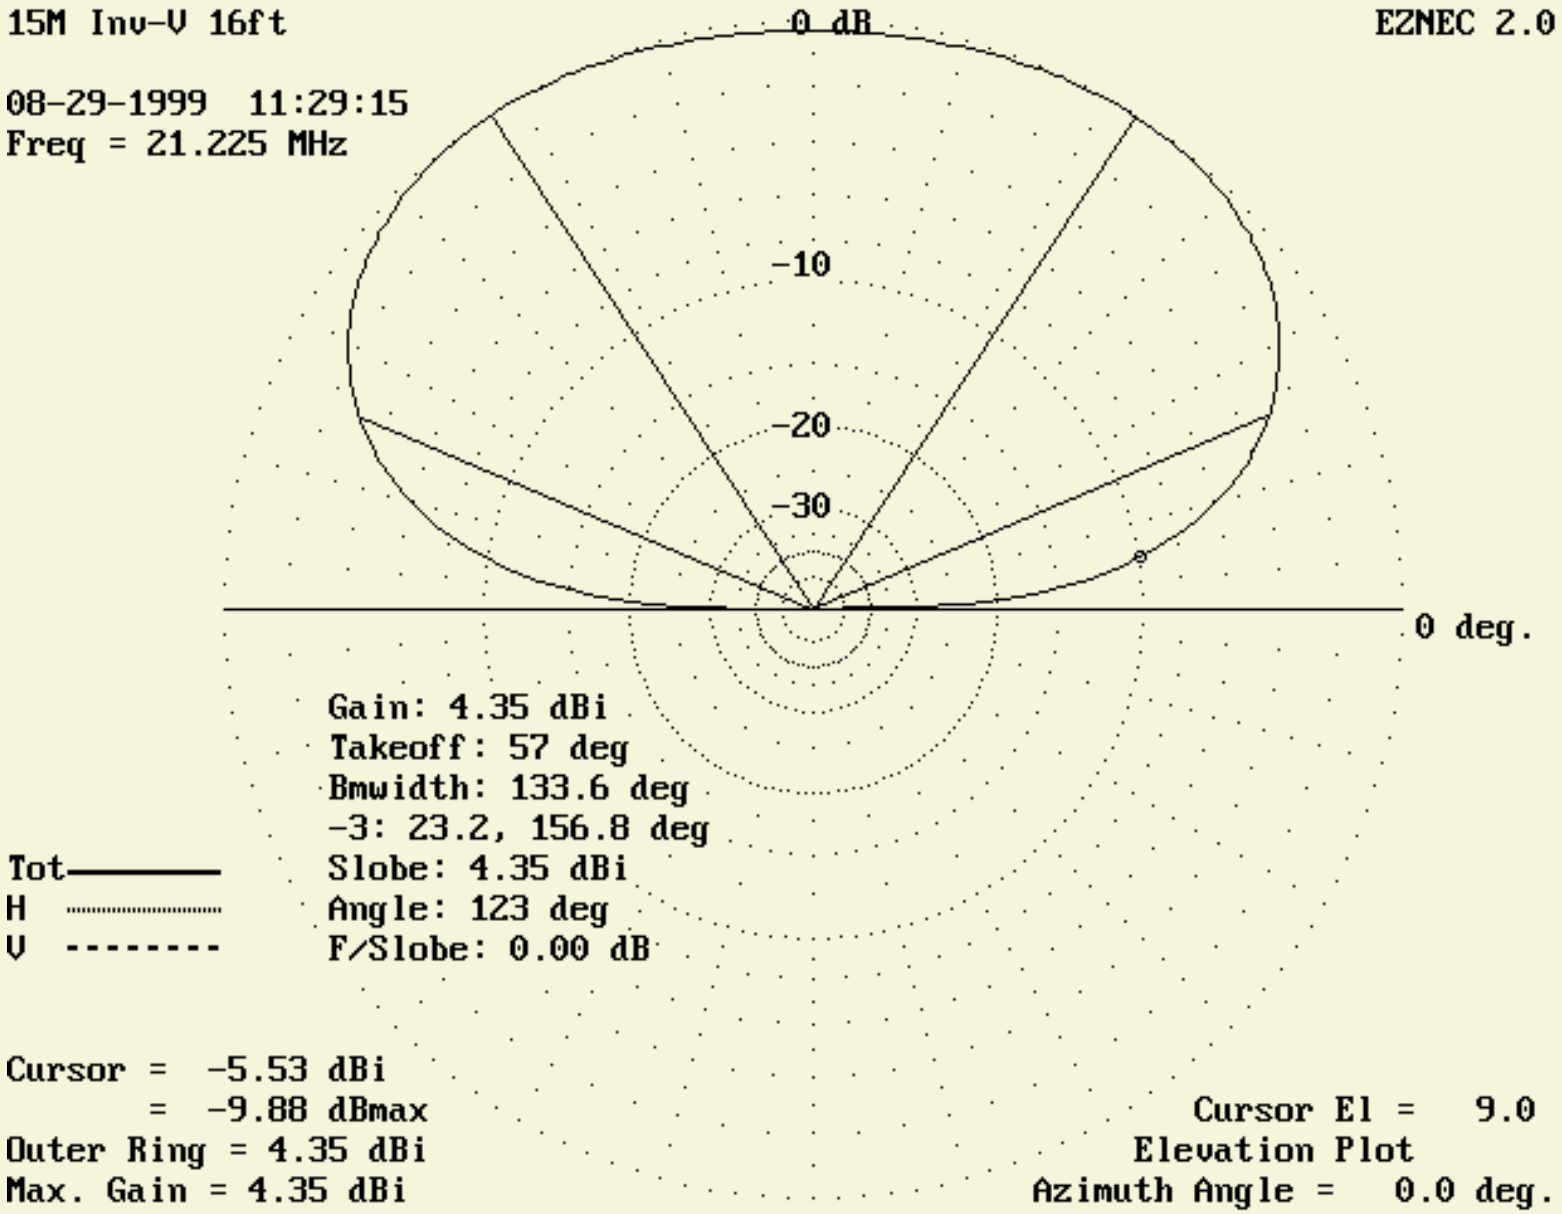
Oops. Suddenly the dipole does not look so bad. In fact, there is only a very tiny portion of the patterns, below 9 degrees, where the vertical is better than the dipole and there only by the smallest of fractions of a db. The vertical pattern is a subset of the dipole pattern. At angles like 15 degrees, a solid DX angle, the dipole is considerably better. And this dipole is only mounted about 3/8th wave above the ground.

The fan dipole was fun. It was of course shorter between poles than the regular dipole and seemed to have a slightly better gain figure vs. the dipole. Perhaps it had a bit bigger capture area:

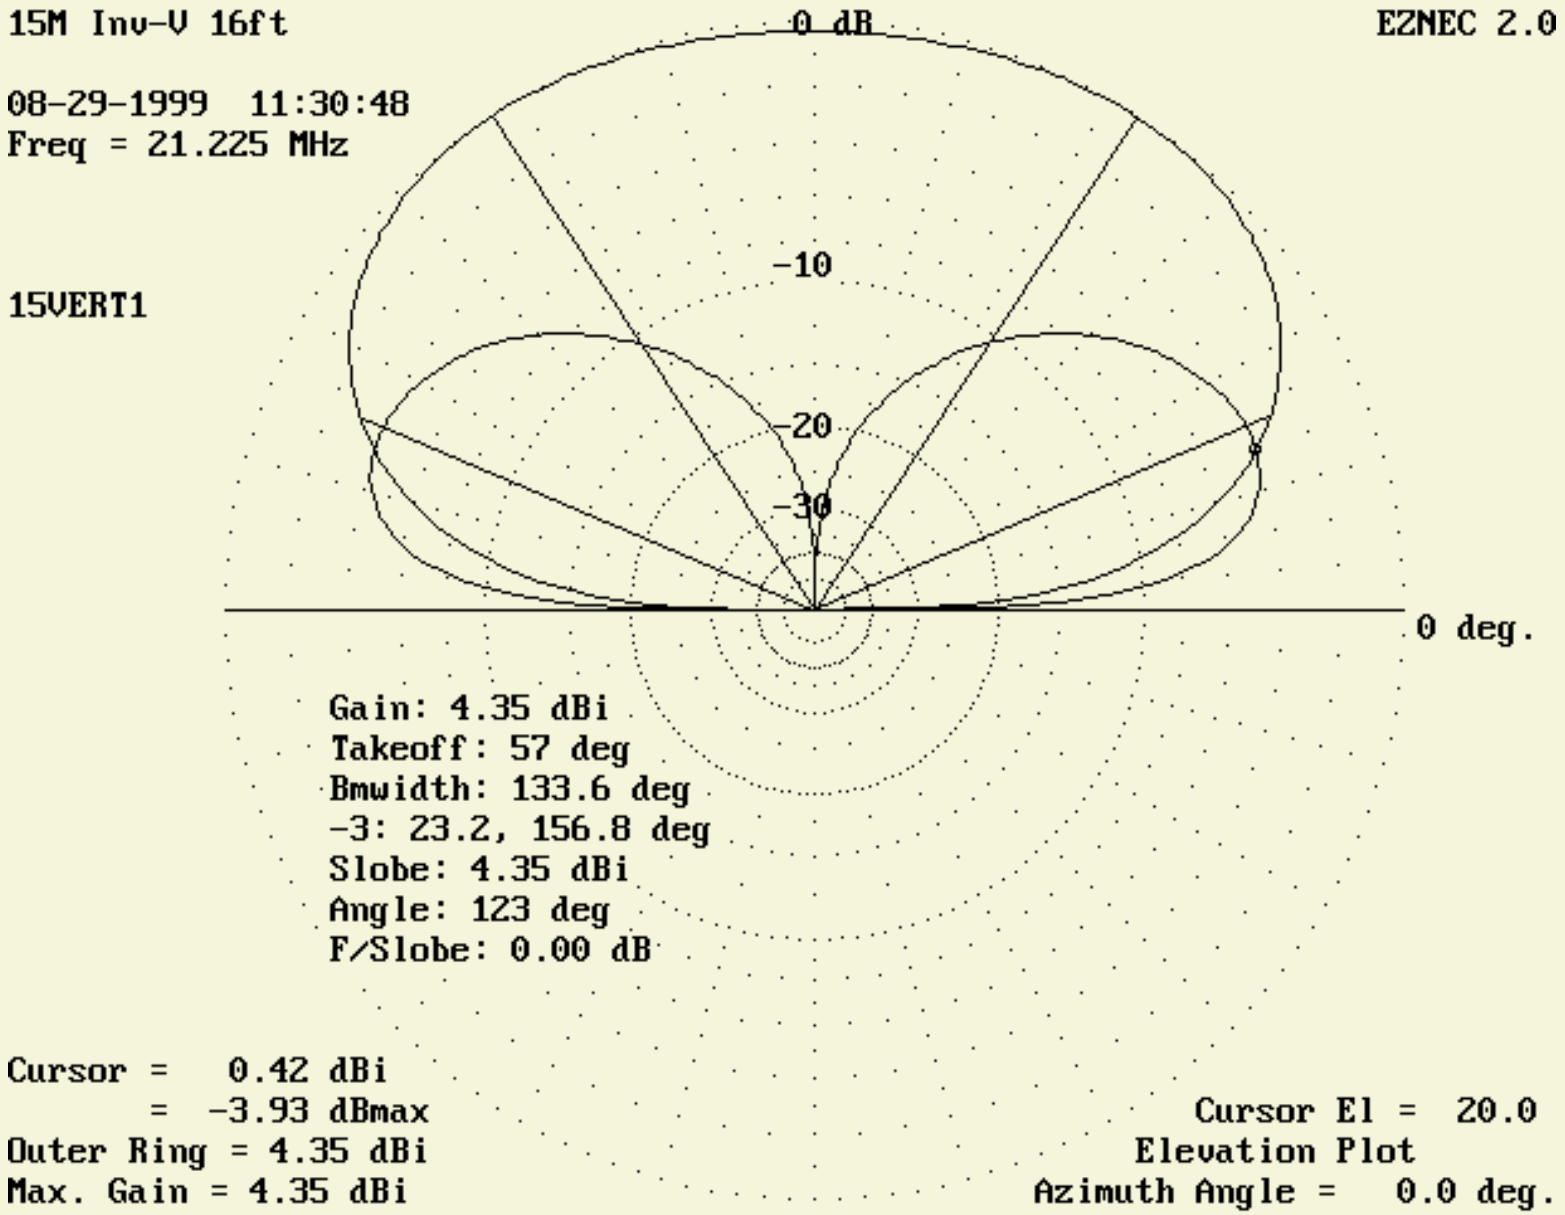


But notice the great similarity to the regular dipole. This is a cute antenna. It has one advantage. Since it assumes a slight droop in the upper wire, it supports the coax better than the regular dipole. The regular dipole was modeled with a droop due to coax or feed line weight. With an upward angle of 5 degrees on each side if center. This made a slight improvement in the pattern of the regular dipole.

So we decided to simplify things. With an inverted V you only need one support. Half the things to drag along. But there is a serious problem. As soon as the dipole started to droop a significant amount downwards at the ends, cancellation attacked. The sad truth is the inverted V is probably a bit worse than the vertical:



Let's compare the two on the same scale on the same plot:



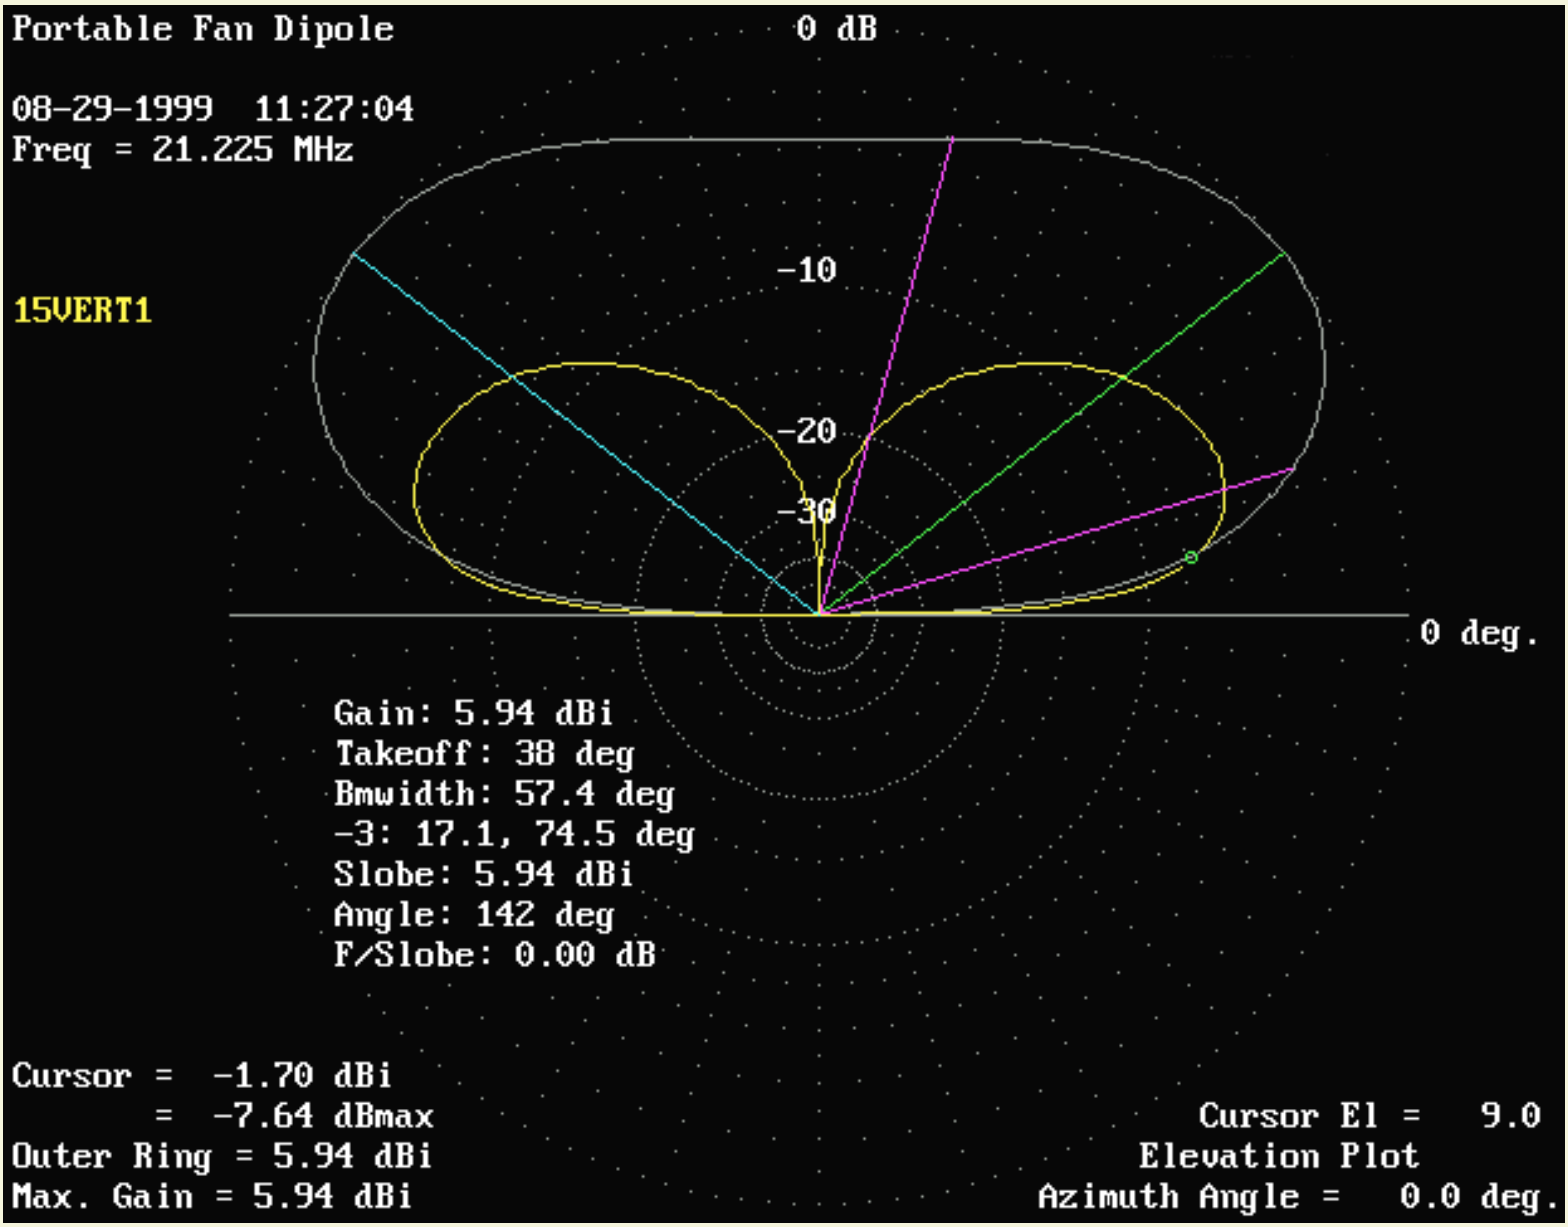
Note that below 20 degrees the vertical is better, enough better to call it significant perhaps. So, the sorry truth is that in spite of how pretty the vertical pattern is, and how nice it looks, and how primitive the old center fed dipole is with its simplicity, the dipole appears to be the best selection.

So why the great reputation of the vertical as a DX antenna? Probably for what it throws away. The pattern of the vertical will make it reject signals coming via NVI and high angle skip. This means it will reject signals from 50 miles to 400 or so miles out. If you live in California this means that lots of DX signals buried in local QRM might suddenly become readable as the vertical rejects the local stuff in favor of the low angle signals.

The vertical with ground laid radials is easy to set up and self supporting. When done this way it is a compact antenna to take along. The problem comes when you try to do better. You can use a pair of verticals and phase them. But then you have the same double hardware of the two poles supporting the dipole. The final sorry result is that phasing verticals is a bit tricky for best gain, you need lots of radials under both verticals to get them to work well and you might get about 3 dbi gain. The dipole is very easy to set up and tune and get the predicted performance out of. And it may well outperform your fancy two phased verticals unless you get them just right.

The support poles can be quite light, of nesting aluminum, relying on small guy wires. The dipole itself can be designed to be a light as possible as well to reduce strain on the poles. 16 feet should be quite manageable with careful design, making a bundle short enough to qualify as "fishing rods" a category recognized by airlines.

Finally, one last look, this time at the Fan Dipole vs. the optimized 1/4 wave vertical with 16 elevated radials. The cursor is placed at the intersection of the two figures and the lower left hand corner has the gain at that point:



In summary:

At one half wave above ground, a simple resonant dipole will significantly outperform the best installed 1/4 or 5/8 wave vertical.

At one quarter wave above ground, A simple resonant dipole will outperform a quarter wave vertical for NVI or local communication. The vertical if well installed over a decent ground structure, will outperform the dipole

for radiation angles less than 30 degrees.

Below one quarter wave above ground, the simple resonanat dipole will suffer significant loses, but still outperform a quarter wave vertical for NVI operation. Even a shortened loaded vertical, well installed, will outperform this low mounted dipole for radiation angles below 30 degrees.

An inverted V has both problems, the self cancelation of a vertical and the low mount pattern distortion of a dipole. But at 1/4 wave center mounting height it would be a good compromise between a quarter wave vertical and a horizontal resonant dipole. It would be much easier to make efficient if one is not judicious about the ground screen creation for the vertical.

Thus selection depends entirely on the height available and the number of supports. With two supports 1/2 wave tall, a resonant dipole, especially a fan dipole, will outperform the vertical in all cases.

With less than 1/2 wave of support/vertical pole, a carefully installed vertical will outperform the dipole for DX, but be much less useful for local NVI communications.

The inverted V includes the worst of everything, and is thus generally useful with a single 1/4 to 1/2 wave center support.

Antenna System Evaluator

This JavaScript program evaluates the performance of your antenna system, computing the consequences of SWR and feedline loss. 73 de Ron

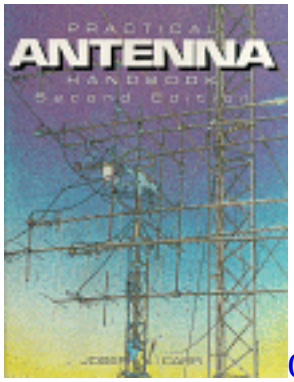
JavaScript PROGRAM by n6ach@comcast.net
original program concept done in CPM basic by KC6A and N6NB.

Translate this page automatically.

power from xmitter in watts	-1VSWR @ xmitter
feed line loss in db(must be in line with other values)	Antenna gain in dBi: Enter 2.2 for dipoles; add 2.2 for antennas rated in dBd

---

reverse power at xmitter	-1VSWR @ antenna
forward power in watts at antenna	reflected power in watts from the antenna
true power in watts into antenna	power in watts lost in feed line
db line loss including vswr effects	EIRP in watts



Order *Practical Antenna Handbook by Joseph J. Carr* Today!

Order *Antenna Theory and Design:*
A book on principles and development techniques for examining and designing antenna systems. Emphasis is on basic topics and applications, and much material does not rely heavily on mathematics.

Read Our Monthly Columns!

Antenna Modeling

This is a regular and popular monthly column by L.B. Cebik, W4RNL Because computerized antenna modeling has become widespread, and its popularity as a design tool continues to increase, this series is devoted to helping readers get the most from the design software used. The articles focus upon the use of NEC and MININEC, along with useful adjunct software as well.

From The Shack

This column is primarily for "Guest Editorials" to provide a podium for our readers to voice their opinions to the rest of the world too. This is a chance for readers to get on their "soapbox" and speak about antenna and radio-related subjects. Don't miss these interesting views about anything and everything about radio and antenna systems! Now, what have YOU to say??

Ham WorkShop

Ham WorkShop, is also another regular monthly column filled with a variety of "RADIO-STUFF" of value to almost everyone in amateur radio from Novice to Extra and those just beginning to take up this special hobby. This includes subjects, but not limited to: VHF, choosing the right antenna, coax cable, small to mid-scale construction projects in a practical manner, use of test equipment, etc. It is also meant to help readers become more familiar with the technical jargon *and* the fun side of radio.

Stone's Throw!

***Stone' Throw!* a monthly column by *antenneX* publisher, Jack L. Stone, among other things, is to keep the readers informed about our progress, new developments, plans for the future, and to introduce the authors and their subjects each month. Also, our main slogan around here is "we aim to please", so this serves as a place for the readers to tell the publisher what is wanted or at least make suggestions. Just remember, the publisher is only a *Stone's Throw* away! Go in for a visit and read this month's column.**

Propagation

***Propagation* another monthly column by Marcel H. De Canck, ON5AU of Belgium. Signal propagation is a subject that is one of the most basic ingredients of radio and is something everyone in radio should know about in order to maximize communications in the most effective way. It's not enough to have the best equipment and the best antenna if you are trying to send out a signal against a brick wall. Conversely, one may possess a very crude rig, running low power, but yet transmit/receive a signal to great distances with ease, simply by making use of a thorough knowledge about how signal propagation works within the environment. Follow this column and learn more about propagation!**

Extending the 2-Meter OWA Family
Part 3: Increasing OWA Gain
vs. Preserving Sidelobe Suppression

By L.B. Cebik, W4RNL

In our preceding discussion, we developed tentative answers to two out of our three inquires that emerged from the extension of the OWA 2-meter family to 20 elements. By way of quick review, the low gain but high sidelobe suppression of the 20-element version of the array left us with these questions.

- **1. Which of the two OWA design concepts--the core or the method of adding new elements--has the dominant effect on side-lobe development?**
- **2. Is there a method of obtaining more gain from the OWA series without sacrificing sidelobe suppression and attenuation?**
- **3. What role does element population play in sidelobe attenuation?**

Building a CCD Antenna

By Joel C. Hungerford, KB1EGI

This month, I continue looking at a thing I recently heard about on the antenna discussion list — a so-called CCD antenna. CCD stands for "Controlled Current Distribution." It consists of a string of series tuned circuits and short bits of wire between them. The circuits are all tuned to the lowest frequency to be used. The current at each circuit can be set by the reactance of the inductor and capacitor. It seems a natural for the combination of the interlaced wire capacitor I used to tune the loop, and small coils, all wound on a long PVC pipe. What if one used a modest number of tuned sections, say 5 to 10, and increased the reactance as one progressed from the feed to the end of the pipe, following an approximate tangent curve. Could this simulate the current in a vertical, but in a shorter distance? Would it radiate? Just how does the tuning behave if I string together several sections all tuned to the same frequency, but with a different L/C ratio in each section?

So, this month I set out to build a CCD antenna, consisting of several series tuned circuits all resonant at the same frequency, but with each section L/C ratio varying along the antenna to mimic the effective impedance of a dipole: high impedance at the open end, and low impedance at the center.

Yagi-Uda 2-Meter 12-Element Beam Design

By Fred M. Griffee, N4FG (EE Retired)

In this article, a 2-meter 12-element Yagi antenna will be designed using optimization in lieu of the Optimized Wideband Antenna (OWA) approach (Ref 1, 2, 3). The optimization approach I shall use follows the conjugate-gradient optimizer type found in many programs such as YO by K6STI. However, the more interesting approach may be the generic optimization approach, but to date I find it to be overly lengthy, cryptic, very time consuming, and difficult to implement. I find the conjugate-gradient approach creates designs through its progression that follows user defined gain, SWR, impedance, F/R ratio weighting, and element characteristics (diameter, wall thickness, material, etc..). Any of the mentioned characteristics can be altered where the azimuth coverage is assigned with respect to 180 degrees (N – 180 degrees). The DL6WU-gg program, for example, creates side lobes that start at 45 and 315 degree E-plane azimuth so the range will be assigned 45-180 degrees.

THE BILOOP – A LOOP TUNABLE WITHOUT THE USE OF CAPACITORS

By Claudio Re, I1RFQ

Recently, on the *antenneX* antenna discussion list, several contributors expressed interest in learning more about improving the performance of compact loops. This was prompted, in part, by the introduction of some new antenna concepts based on recent articles on the "Cubes Family."

The most common question seemed to be, "What techniques are available to significantly improve the performance of compact loops?" Over the last few years, the author has spent quite a lot of time reviewing this subject from the point of view of the amateur radio operator. This article contains some of the results of these studies.

THE GROUNDED HORIZONTAL LOOP
A single antenna from 10 to 160m
Or, the TTT: Top-Band Top-Fed Top-Cap Antenna
J.M. Bourdereau, MD, F5LCI of France

Author J.M. Bourdereau says the "horizontal loop antenna" has many advantages, when there is enough area. Grounding at a voltage node does not affect its characteristics, allows static drain, and allows its use as a top-loaded top-fed vertical for lower frequencies. This idea seems confirmed by computer modeling. Thus, we have (at least) two antennas in one.

ORTHOGONAL CURRENTS
&
TANGENTIAL MAGNETIC FIELDS
Experimental Evidence
By William Miller & Werner Hödlmayr

In the 1860's, James Clark Maxwell postulated the existence of Displacement Current as the mechanism whereby Alternating Current (AC) flows through a capacitor. It forms the keystone in a series of equations — often called Maxwell's Equations — that are the basis of all Electromagnetic theory.

About a year ago, *antenneX* published the author's 2-part article called, "Displacement Current Does Not Exist." The article was prompted by the apparent failures to perform as claimed found in two classes of antennas — the CFA (Cross Field Antenna) and the EH. The inventors of both antenna types claim that they "use" displacement current as an integral part of the radiation process.

July's issue of antenneX (July 2004) featured an article by William Miller entitled, "How A Capacitor Really Works." In this article, Mr. Miller postulated an alternate explanation for Maxwell's "Displacement Current." Displacement Current is the key ingredient in the equation set that relates the total Magnetic Field from an AC conductor to the magnetic field generated by current flow and electric field.

In his pursuit of working proof, Bill has recruited the very able assistance of Werner Hödlmayr, well known for his previous work on the MicroVert, TeslaVert, Fractals and others. The latest of Werner's TeslaVert versions was chosen for some experiments while applying Bill's theories. This month's joint article discusses Bill and Werner's initial experiments and the early evidence realized from them.

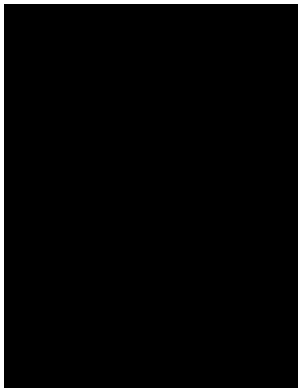
Professional RF Network Designer: A Short Review

SOLUTIONS

? need a compact antenna?
? have signal problems either transmitting or receiving
? can't choose between a vertical or horizontal antenna
? want to learn about antenna modeling
? want to design an antenna, but don't want to redo the wheel
? need a program for antenna design and antenna plotting
? don't know what antenna is best for hamsats or others
? have a busy mobile signal on all bands
? need an inexpensive directional antenna for 10 meters
? need a low-noise antenna for 160 meters
? want to know if someone else has solved your problem
? need a disguised mobile antenna for the vehicle
? just want to know more about antennas

Then you *need* to subscribe to *antenneX*© ONLINE! ... but take a good look at our info page About antenneX , some preview articles, and pricing pages before you decide to subscribe. Be



sure to read our monthly editorial page which is always posted outside the Library for all to see. Please visit our many Discussion Boards and talk to the Editor or others about your ideas. This board also serves as our Letters to the Editor section.

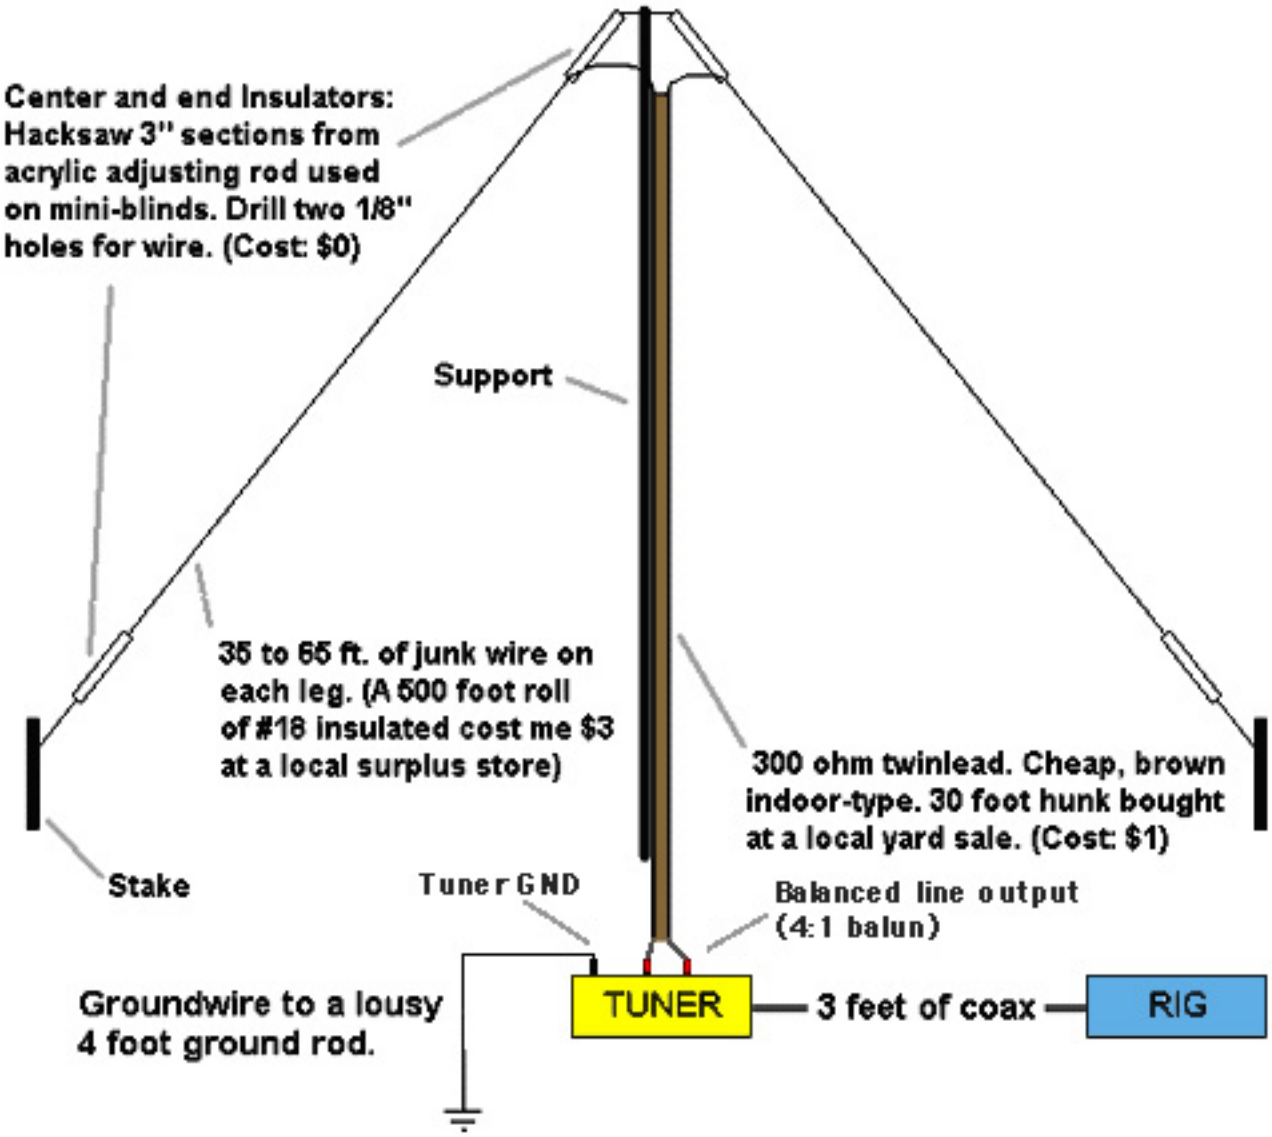
THE $4 SPECIAL

by Joe Tyburczy, W1GFH

Sure, you can find "all-band wire antennas" for sale in the back pages of Ham magazines costing $150 or more. But beware: *Marconi spins in his grave everytime a ham buys an aerial instead of building it!* Look, the plain and simple truth is that wire antennas for the HF bands were intended to be *hand-made* and not store-bought. Untold generations of intrepid Radio Hams have fashioned their own equipment out of spit and baling wire. In this world of microprocessor controlled micro-rigs, this may be your only chance to build something and actually see it work on the air. Think about it.

Another bonus of "rolling your own" antenna is that it costs you next to nothing. Don't be intimidated by SWR, either. Your rig will not blow up and kill you. Most modern rigs will politely refuse to transmit into a really bad match. A perfect 1:1 SWR is for sissies, anyway. All *real* hams have conducted perfectly good QSO's at 3:1, and even 10:1 at some time or another. Anyhow, I recommend a tuner. This, you can buy over the counter with a clear conscience.

I am a big believer in balanced line vs. coax. The basic "W1GFH $4 SPECIAL" shown below is a variation of the type of exceptional skyhook I've been using for years.



I've tried the commercial 450-ohm ladder line, but prefer 300-ohm TV twinlead, and the cheaper the better.Forget all that crap about impedance, wavelength, and velocity factor. What you really need to concentrate on is getting an interesting set of *antenna insulators*.

Back during the disco era when I first got on the air, I got a pair of really cool antique *pyrex antenna insulators* from a flea market table in Derry, NH for 25 cents each. They looked like the kind Hiram Percy Maxim used in 1910, and seemed able to pull in exotic DX all by themselves. The other day I

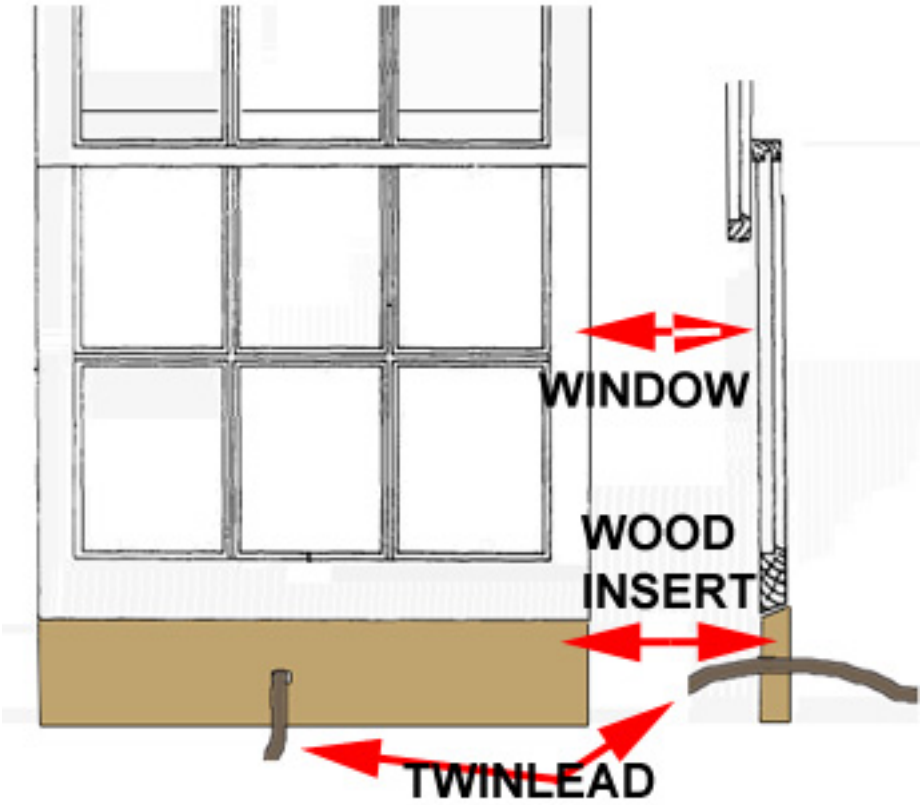
found out that Radio Shack wants $5 apiece for insulators made from some kind of white plastic crap. So I improvised my own by sawing up pieces of an acrylic adjusting rod from a discarded miniblind. I think Hiram would've been proud of me.

The tuner was an MFJ-949C I got at a swap meet for $15 a long time ago and has connections for balanced lines on the back. A link-coupled balanced tuner arrangement like the Johnson Matchbox would be better, but use what you have. The idea is to *get on the air with a decent signal for cheap*, just like they did in the early days of ham radio!

I had a 65ft. per leg version of this antenna working in Massachusetts, and it'd tune up on all bands 80-10. At my Burbank, California QTH, I used a 35 ft. per leg version, and it tuned up on 40-10. By the way, you'll notice it's an inverted vee --- a real advantage if you don't have room for a full-on dipole in your yard. If you still don't have room, bend and angle the legs to fit the space you've got. Antennas gently bent into Z-shapes still work fine!

THE *MAGIC* OF TWINLEAD

The feedline comes straight in thru a window sash. The nice thing about the 300 ohm twinlead is that the small stuff only needs about 2" separation from metal objects in its path. (OK, so TV Twinlead won't take a kilowatt, but the 450 ohm stuff you can obtain at ham stores will. You just need to be more careful with routing it)



You can get a 4:1 balun to make the transition from the balanced line to a length of coax, so you can bring the coax into the house via a properly sealed-up feedthough hole to avoid winter drafts if you'd like. If you really want to get nutty, try using 110VAC lamp cord ("zip" cord) as a feedline. Yeah, it'll work as a crude balanced line, believe it or not. Impedance varies, but is usually "close enough" to work. *Improvise. Experiment.* Take notes of what works and what doesn't. This is what ham radio is all about.

Many of you will recognize this antenna as the venerable "double zepp" aerial, a variation of the "end-fed Zepp" -- the skyhook responsible for the dramatic Hindenberg tragedy in Lakehurst, NJ. It seems the blimp's radio op decided to work a little DX while waiting for landing clearance. He sent out a few CQ's. Unknown to him, the ladder line had twisted in the breeze, shorting the bare conductors. A brilliant spark flared

up, and....well, that's another story altogether.

To see an "end-fed Zepp" version of the $4 Special, click here.

Alas, I never had the height to make this antenna perform the way it should. The one in Mass. was up 50 ft. and worked terrific DX. The one I have now is only up 30 ft. and gets average results. It won't outdo a yagi at 100 feet, but what will?

And for $4....who can complain?!

ADDENDUM: November, 2002

Since writing this article, I've gotten a lot of questions. Many are curious about the end-fed Zepp. I suggest you go to L.Cebik's fine page on this subject for an explanation of the practicalities of such an antenna:

http://www.cebik.com/gup/gup12.html

The other question deals with feedline lengths. Is there any 'ideal' length? Yes and no. Some feedline lengths will

present an extremely high impedance to the tuner on certain bands. Each installation is different, but here are some rough guidelines that may help:

Start by trying a feedline listed in the lengths below. It may take some trimming or adding of feedline to work well on the range of bands you want to cover. The worst possible feedline lengths are shown in brackets:

If Ant is 120 ft per leg it will cover 160 thru 10 meters. Feedline of 40-70 or 150- 190 feet suggested. [Avoid lines around 120 or 240 ft]

If Ant is 65 ft per leg it will cover 80 thru 10 meters. Feedline of 25-40, 80-100 or 140-160 feet suggested. [Avoid lines around 60, 120, or 180 ft]

If Ant is 33 ft per leg it will cover 40 thru 10 meters. Feedline of 40-50, 70-80, 100-110 or 130-140 feet suggested. [Avoid 30, 60, 90, 120 ft]

Page Eight, Miscellaneous Aerial Antenna Information

.....

For now, the QTH is Singapore.

The call is 9V1GO.

My name is Bob, and I have been an amateur radio operator since 1962. My activity on Top Band goes back 20 years.

Now, I am living and working in Singapore. This past season (2003-2004) 91 DXCC entities and 30 zones were worked on Top Band. Now there are 92 DXCC countries in the 9V log,

thanks 4X4DK. Conditions have been getting better the past few weeks, and it is nice to know that the new season is not too far away.

If you think you have worked me from **9V1GO**, you can check the log at **http://dx.qsl.net/logs/index.html** and look under my call for the logs from here.

The 160 metre transmit antenna is a half sloper at 40 metres. I have one receive antenna that has out performed pennants and flags. It is a full sized half wave dipole two metres off of the roof of the 13 floor apartment building. I also have a tuned co-ax loop that occasionally out performs both the low RX dipole and the TX sloper, depending on conditions. Watch for Top Band activity from Singapore on 1814.5 and 1822.0 at my sunrise and sunset. In addition, CW on 80, 40, and 30 metres will get a lot of attention as the S9 QRN on 160m in Singapore is hard. Up to more than 100 DXCC on all the rest of the bands but 10 and 12 metres. Email me for a sked if you need 9V on any of the low bands. **Please QSL DIRECT ONLY to my manager OK1DOT -** Petr. His address is on the QRZ.COM web page.

Now, for a little about G4VGO at home:

In "G" land, Top Band is my O-N-L-Y band, and I have been active in Europe since 1984 on 160 meters. Shortly after coming to the UK in 1980 I was issued the reciprocal call G5EPD. A few years later it was changed to **G4VGO**. That has been my call in the UK since then. In 1985, I managed to confirm 102 countries and received 160 Meter DXCC Certificate #269. Since then the total has increased to 224 with 39 zones. The entire country total has been on CW.

I am now fortunate enough to live on a piece of land with wide-open space (when I get home). The farm is in the middle of countryside, not far from the North Sea coast and with more than enough room for beverages, and tall masts. Although the necessity for kite and balloon lifted antennas is not so acute with space in every direction and no neighbours to worry about, I still really enjoy putting the wire high up in the air. The chances of increasing your score in a Top Band contest or pushing the country total higher go up by about the square of the height of the antenna on 160.

My job is a telecommunications consultant and I work mainly with mobile networks. This profession has taken me all over the world. I have deployed networks on all continents but Antarctica and came close to there when we put a site in very southern Argentina. It is fortunate that my hobby and my work both involve radio and I enjoy both very much.

In 1997, I was **EI7IU** in Naas in county Kildare, just outside of Dublin. In seven months I managed to work more than a hundred countries on Top Band including Myanmar and a few other rare ones with 150 watts and a 14 metre 'T' antenna.

For about eight months in 1999 I was **LU/KY0C** in Buenos Aires while working there. Conditions were terrible in the noisy city environment, but regular QSO's with W8JI and other USA big guns were the norm. It was good to get back to the UK, to low noise and better propagation.

In 2001 I spent five months in Israel as **4X/G4VGO** and with 25 watts to a full sized 160 metre sloper and two Pennant receive antennas managed to work more than fifty countries including the USA and Canada. Again, Israel was a very noisy location with poor summertime propagation.

I left **SM Land (SM0/G4VGO)** after about six months there in the last half of 2002. While staying in Kista near Stockholm I worked 42 countries with a marginal antenna and very low power. I didn't have such good antenna possibilities, but as the nights got longer, DX picked up a bit.

.....

The Home Shack

This is the home QTH operating position. I have tried every top end transceiver in the world, and for several years used FT1000Ds as the mainstay. For a while, I used an FT1000MP, but went back to the 1000D. I also bought an ICOM IC746Pro to try, and after exhaustive trials on Top Band, sold one of my FT1000D's and opted for the 746Pro. It was a good transceiver, but then I had a chance to try the Ten Tec Omni VI. After a few nights on 160m CW, I decided I should have gone with the Omni VI years ago....it is AWESOME on CW receive. For CW, I use the Omni VI, but for SSB, the D104 and the TS830S are a very good combination. The old Kenwood has done well in many SSB contests on Top Band.

My latest purchase here in Singapore was a Elecraft K2/100. With the latest firmware and keying mod it is rapidly becoming a contender for my main radio. (Although the Icom 756 Pro II I am also using does have a pretty good receiver on the low bands. However there are no

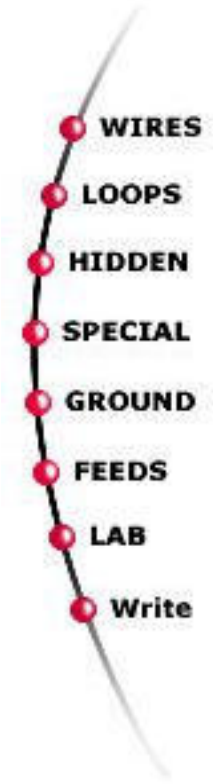
strong signals nearby to contend with at my 9V QTH) European Top Band activity is a challenge for any receiver, so the K2 may be the new rig of choice upon the return to G4VGO.

The Dreaded Key Clicks

Most stations I hear on CW have key clicks. After participating in many contests on CW and suffering the clicks, I decided to get rid of all of my Yaesu radios and change to the Omni VI and the trusty old Kenwood TS830S. The TS830S has **NO clicks** or phase noise**,** and the RF speech processing in the 830 makes it one of the best rigs for that mode ever made. The Omni VI has had the key click mod, so it is a lot better than anything I have used in the recent past. All of the transceivers I am using now do NOT cause the obnoxious and very broad key clicks that the Yaesu FT1000 series (**ALL of the FT1000 series**) cause. In a pile up, the un-modified Yaesu rigs sound like a convention of castanets clicking up and down the band several tens of KHz. Really rotten keying. Add several tens of dB of phase noise and you have a proper mess on Top Band.

There is an excellent "must read" article by Tom W8JI on CW Key Click's (Spurious Emissions) caused by Yaesu Top-of-The-Line FT-1000 Series HF Rigs. This includes, the FT-1000MP, the Mk 5, the MK 5 Field and FT-1000D Models. The receivers may be mostly OK, but the CW transmitters are ***CRAP***!!!!!! I see more and more of the FT1000 variants for sale used now so maybe someone is listening. Or, maybe they are tired of hearing complaints about their terrible keying from those they clobber with the clicks. Anyway, it is clear that Yaesu has "zero" concern about good engineering practices, customer service, quality control and spectrum management. We should all think twice before buying one. Can Yaesu say "Lost Revenue Stream"? The new Icom radios have variable keying rise times, as does the new Ten Tec Orion, why can't Yaesu make a good CW transmitter?

I use Beverage and Pennant antennas for receive. An east Beverage on Asia and the Pacific one and a half wavelengths long on 160.... a pair of phased end-fire Beverages to the northwest on North America, one and a half wavelengths long and a south Beverage one wavelength long take care of the main DX directions. The Pennant receive antennas look southeast and northeast as 'gap fillers' on Africa and deep Asia. Beverages and Pennants at this quiet location have given me a whole new level of weak signal capability that I had forgotten existed. They also give me a front to back ratio that gets rid of the European key clicks that can drive you nuts.



Balloon or kite antenna? Why not

- First thick nylon line, then copper wire

- Excellent supports for LF antennas

First thick nylon line, then copper wire

From: Hugo Caron (hugo@infobahnos.com)
Date: Nov 4, 1996
Original source: Usenet's rec.radio.shortwave

Last month there was a discussion about balloon antennas, mainly about using 2 balloons instead of one for a vertical antenna.
Two persons mentioned their concerns after having read articles on the subject relating about wind-induced static shock hazard and reception high noise level.
One participant replied that if one would shunt the antenna with carbon resistor (~4.7k-22k) to local ground, high enough not to upset antenna caracteristics but still, low enough to discharge the beginning of charge buildup, one would be able to cope with this problem.

On the same subject, a second participant with actual balloon and kite antenna experience (300 ft - 100 meter) did report the reality of shock hasard, but eventualy got around the problem by shunting an antenna tuner inductor to ground or shunting the antenna directly with a 100k resistor. He reported that in these conditions, he was able to get signals that sounded great. Also in light wind conditions, he said that static was not much of a problem.

On the structural aspect, for security reasons, personally I would't try to tie a thin copper wire directly to the balloon, as some may have suggested. I'd rather use high strenght nylon or alike line (fishing line type for exp., I've seen some with 40 lbs capacity) to cary the all strain the holding line may be subject to in presence of higher ds than expect winds. The thin wire copper line would only be ' brought along ' for its antenna role. To avoid any wobbling of the 2 lines, I would knot, using short lenght of holding wire (trimmed after knotting), every 5 feet or so. For example, if one want to jack a 300 feet vertical up and chooses a

nylon line of 20 lb capacity (lets say it's 2000 feet/lb (.0005 lb/foot) and AWG #28 copper wire at 2081 feet/lb (again, ~.0005 lb/foot) and 65 ohms/1000 feet (ARRL handbook), one would end up with a line at .001 lb/foot for a total payload of .3 lb. So the balloon would need, at least, this 'net' boyancy (preferably a bit more let say .4 lb). By net boyancy I mean the payload the balloon can handle, after lifting its own weight. A 3.5 to 4 feet diameter ballon should be able to handle this charge, depending on its enveloppe weight.

The balloon envelope material quality his also something one should consider before attempting any lift off. If not, one may experience a short lived project.
We've all air blew party rubber balloons to their max, just to realize that the next day they had shrinked to half their size. The reason being that, due to pressure differential between inside and outside of the streched enveloppe, air will just sift through it. Rubber is an elastomeric material build around long organic molecular chain attatched one to the other through ramifications (something like a tree), and there are 'holes' between these chain elements. Air (that is, molecular oxygen, nitrogen (and carbon dioxide if you blew the balloons yourself... pfiew!!)) eventualy finds its way through. So if molecular elements like O2 and N2, that are many time the size of atomic helium (He) can do that, you can imagine how helium would act considering the wide open barn doors these 'holes' are, relative to its size. I dont think one would be able to retain it for more than a couple of hours. So not any off the shelf stock will suffice.

I've done a few phone calls, a couple of weeks ago to see what's available, mentioning I was looking for a balloon to be inflated with helium, that was able to retain its content for at least a couple of days. The only source I found was the Party Decoration retailers. I eventualy found someone that told me they had 42 inches size balloons, the enveloppe of wich is made of unstreachable material (vynil???) made for that purpose (helium inflating) for $5. They would inflate them for $5 each. One can also get pressured helium portable refill thanks, good for ~25(?) of these balloons, at $60. They were not able to specify the enveloppe weight or the ' net boyancy '.
Another retailer told me the he could supply me with a 7 feet balloon (that's 9 times the volume of 42" diam.), again the unstreachable kind used for outside advertizing, hence relativaly long lasting, with a 4 lb lifting capacity for CAN$342 + helium...
Ooops, this time *my* budget was blown!

Be extremely careful about static

From: Jake Brodsky frussle@erols.com
Date: Nov 6, 1996
Original source: Usenet's rec.radio.shortwave

First: Hugh Caron's post concerning static charges on the balloon wire are accurate. I was one of the guys he spoke about and, yes, when flying kites with a wire antenna, one must be extremely careful to bleed off the static charge. My friend Tony, was practically thrown across the deck of his boat when he touched the ungrounded wire on one of our kite- antenna experiments.

Two: Helium is much easier to buy and transport than hydrogen. It may not be cheaper, but at least you don't get anything close to the HAZMAT paperwork you'd get if it were hydrogen.

Three: Although latex balloons do deflate more readily than, say, mylar balloons, the surface area to size ratio of an eight foot weather balloon will guarantee that it will stay up for quite a while.

Four: The FAA's relevant regulation on this subject of tethered kites and balloons is Part 105. When I last read it three years ago, it said that anything with a total weight of under five pounds empty is exempt from most regulations.

You do have to know where the airports are, and don't fly your kite or balloon where it may get in the way. A call to the local Flight Standards District Office (in the United States) will go a long way toward clarifying whether the place and altitudes you wish to fly the antenna are appropriate. Even if you might fly it so high that it could interfere, they'd be more than willing to accomodate you by issuing a NOTAM, or NOtice To AirMen, with adequate notice, and then issue you a permit for a certain time and place.

My balloon and kite antenna system

From: Jake Brodsky frussle@erols.com
Date: Nov 7, 1996
Original source: Usenet's rec.radio.shortwave

Since the discussion is going this way I'll go in to more detail as to how I handled the Balloon and Kite antenna systems.
First, all flights were made from a boat, a few miles south of the Middle River in the Chesapeake Bay. All lines were 400' or less.
The kites and balloons all had empty weights of under five pounds (thus not requiring notification under part 105). Prior to conducting these tests, I contacted the Baltimore Flight Standards District Office for advice on how to proceed.

We thought briefly about using a strobe light. The problem was two fold: first, the strobe itself sometimes put us over the part 105 weight limit (depending on which kite we used). Second, the strobe light could easily have been mistaken for a life-vest strobe light on the water

(because that's what it was). We decided to keep the line to about 200' instead, and to forget the strobe light.

There are few standards for this sort of activity. Kites and tethered balloons are usually not a problem for most aircraft, especially those over open water. I caution you, however, to know the area where the airports are, to know where the instrument approaches are and to avoid those places. This is something I'm already aware of, since I am an instrument rated pilot.

In any case, low flying aircraft don't often go over open water, so the risk of collision is low (the big sky, small target theory).
Obviously, these details are things you should consider well before purchasing that kite or balloon...

Kite antenna - watch out!

From: Glen Leinweber leinwebe@mcmail.cis.mcmaster.ca
Date: Dec 12, 1994
Original source: Usenet's rec.radio.shortwave

Using a kite, or balloon, to launch a long-wire antenna is a risky business, even on a clear day with no clouds around. The danger arises from the electric field between the earth and ionosphere. This field is about one hundred volts per meter (in the vertical direction), and is always present. Any antenna launched into the clear blue yonder will aquire a charge large enough to wipe out a final transistor, or a receiver front end.

So what's the difference between ordinary outdoor antennas and one attached to a kite?
Earth's electric field is easily distorted by objects attached to ground, like a tree, or mast, or house (your tower doesn't have a few kilovolts between top and bottom). A kite-bourne antenna protrudes into wide open spaces, where it very likely gets charged up. Your earth-bound antenna is attached to a mast or tree or house, where earth's electric field is greatly reduced.

Here are some precautions for kite experimenters, or anyone who uses temporary outdoor antennas:

Add a choke coil to the antenna connector between centre pin and ground. This will leak away any charge that tries to accumulate. I see that most modern rigs don't provide a D.C. discharge path from antenna connector to ground - this is dangerous to your equipment.

This choke won't save you if you connect a charged antenna to your rig after you've put it up: either discharge the antenna to ground or connect

the rig to antenna **before** putting it up.

A few years ago I put up a two-meter 1/4 wave antenna on top of my tower. The coax snaked thru the window had no connector. When it started snowing, I noticed a snapping sound every twenty seconds or so. The end of the coax was arcing over from the charge accumulating in the coax capacitance. That cable was being charged five or ten kilovolts in only twenty seconds!

Balloon antennas - a theoretical approach

From: Hugo Caron (hugo@infobahnos.com)
Date: Oct 27, 1996
Original source: Usenet's rec.radio.shortwave

The discussion about the possibility of erecting a balloon supported long vertical and/or inverted L type thin wire antennas has raised concerns about potential shock hasards and high noise levels resulting from wind-induced static. Solution replies were proposed, through the use of bleading resistor (and/or inductor) to a good ground, high enouph to discharge the static buildup at adequate rate while preserving electrical caracteristics of the antenna. r > 4700 ohms. inductor = ?

Concern was also raised about the trouble of putting up a 2 balloon setup over a single one as high (or even higher) vertical, on the base that inverted L would behave as top loaded vertical, which is omnidirectional by nature. On this, I replied it *may* and *would* only be worth the trouble *if*, considering the multiple wavelenght in hight and lenght for a large part of the SW band, such a setup would show *directivity* caracteristics that would approach that of a long wire. As I could't answer this question myself, I left it open for comment. If there were any, I have not seen them, yet.

Lastly, concerns were also expressed about the physical (structural) ' reality ' and security of such a setup. To this I brought the idea it should take the shape of a trapezoidal figure (as seen from the side). I also stated that I will try to determine through mathematical (mecanical) equations, proper sizing of such a setup along with constrains the wiring would be submit under different wind loads.
This is what will now follow.

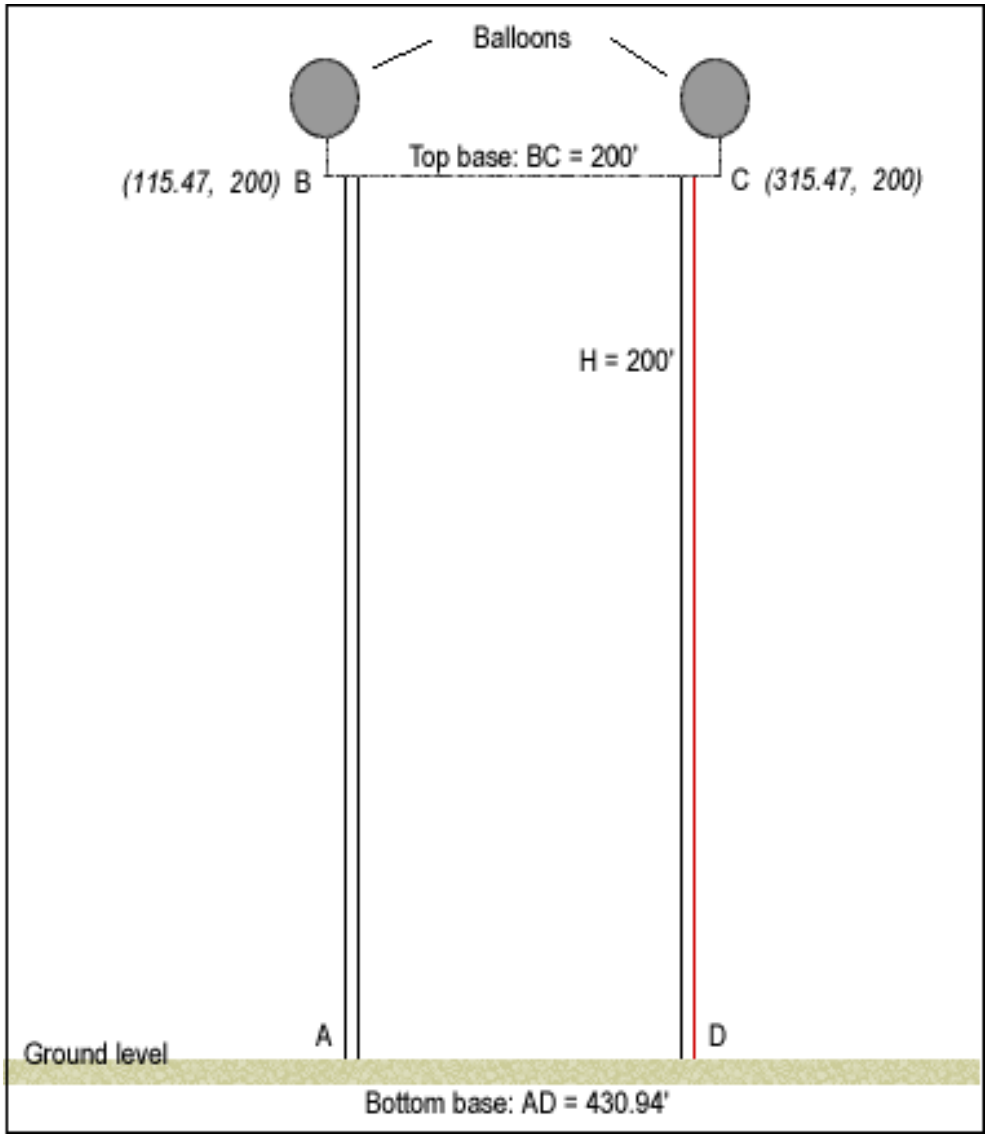
Sizing for still-air conditions

Material specification.
Thin copper wire: AWG 28 : 2081f/lb (.0005 lb/f); 65.31ohm/1000' (source ARRL Hbk.) about $12 for a 1500 feet spool at Mouser Electronics

Support wire: fishing line type 20+ lb at .0005 lb/f (conservative estimate).

I choosed to evaluate a 200'H x 200'L feet trapezoidal setup, ABCD c.c.w. with base angle at A and D = 60 deg.

XY locations



Sides: AB = CD = 230.94'
Top base: BC = 200'
Bottom base: AD = 430.94' Actual side **line AB** is made of 2 lines of support cable, thus 40 lb strain capacity and unit lenght weight of .001 lb. Reasons for doubling this lenght will be brought later.
Lines BC and **CD** are made of 1 support line and 1 thin copper wire for, again, a unit lenght weight of .001 lb, and strain capacity of 20 lb (only the support wire will bear any constrain, the copper wire only brought along on support wire, for it's antenna function. So only the support wire would be attached to the ground and the balloons.

A cable or wire suspended between to horizontal points, such as points

B and C in the above figure is called a ' Catenary ' in a Mathematical and Mechanical sense. A cable or wire such the ones that links A and B or C and D (sides) is more simply call a ' Flexible Cable Suspended from Two Differents Levels ', at least in the Mechanical engineering texbook I refered. (1952 ed., but the logic still good, even after iron curtain fall ;-))

I will limit here the results resolution of the proposed equations brought, in the case of this problem. I would suggest to those interested by the details of these equations to refer to similar book as mentionned above. They are long, dry and require the use of minimal graphic support, beyond the limit of this media, to have any meaningfull sense. I will just mention they are of the recursive type, that one can resolve with a spreadsheet such as Excel with relative ease.

The resulting figures were found to be:

Top section BC (Catenary):

Actual wire lenght:	202.97'
Sag	15.0'
Tension at B and C	.3508 lb at 16.82 deg with horizontal axe
	.3358 lb along x axis
	.1015 lb along y axis (down)
Side sections AB and CD	
Actual wire lenght:	231.22' *(to compare with 230.94' above, thus very little sag on those)*
Tension at B and C	.7790 lb at 64.47 deg with horizontal axis
	.3358 lb along x axis
	.7030 along y axis (down)
Tension at A and D	.5790 lb at 54.55 deg with horizontal axis
	.3358 lb along x axis
	.4717 along y axis (up)

At B and C vertical down force combine .1015 + .7030 to give .8045 lb which is the vertical upward force (net boyancy) that is required by the balloons, at each site, to maintain the setup aloft at desired location.

The Baloons

As per Archimede's principle, the upward force developped by a balloon is related to the weight of the displaced air by the balloon volume.
Actually the balloons shall be sized to carry this net boyancy (.8045lb) + the weight of the helium (s.g. = .1308 that of air) it carries + the weight of the balloon envelope.
For exp., someone wants, on 500' ASL (at sea level) site put a 200' high (= 700' ASL) balloon able to procure sufficient lift for a .8045 lb payload.

Let suppose that a 40 inches (3.33') diameter of .5 lb envelope weights is available.

Density of air at 500' ASL = .0754 lb/pi3, at 700 ASL = .0750 lb/pi3

Volume = .5236 x d3 = 19.39 pi3

At 700' ASL ; Weight of air = 19.39 x .0750 = 1.454 lb
At 500' ASL ; Weight of helium = 19.39 x .0754 x .1308 = .191 lb

Net boyancy at 700' ASL = 1.454 - .191 - .4 = .863 lb

In this case, 2 of these balloons would be ok for the proposed setup. The top part would be a bit flatter (but, not by much) than calculated

Effects of the wind

In fluid mechanics textbooks, one can find formulas to determine the drag force applied by moving air upon stationary spherical object. (the balloons) :
Fd = Cd p V2 A / 2

Fd : drag force (lb) Cd : drag coefficient (no dimension)
V2 : Velocity of the wind squared (f2/sec2)
A : Center area of the sphere (f2)

Cd = .4 for Re (Reynold number) < 350,000
Cd = .2 for Re > 350,000

Re = D V / u

D diametre of the spere (feet)
V Speed of the wind (feet/sec)
u (nu) Kinematic viscosity of air = ~.00016 (f2/sec)

Below a table that shows the evolution of horizontal pressure (in ponds) induced by various wind velocities (mph) on various balloon diameter

(feet)

Table 1.
Horizontal wind-induced pressures on a spherical balloon: Fd (pounds)

V (mph)	3'	3.33'	4'	5'	6'	Diam
10	.71	.88	.66	1.02	1.5	
15	.83	1.03	1.5	10.7	15.4	
20	1.5	1.83	2.63	4.1	5.9	
30	3.33	4.1	5.9	9.2	13.3	
40	5.9	7.3	10.5	16.5	23.7	

Here, I will limit the analysis to a worst case senario, where I will use only common sense to evaluate resulting strain on support wire AB. Examining the trapezoidal shape of the proposed setup, one can observe that a wind blowing from the left would induce the highest strain on line AB, resulting from the combine effect of the pressure on balloon C 'added' to the one on balloon B through wire BC.
To get these 'exact' values one would have to develop some kind of program that would require to first compute the relative reposi- tionning of each balloon wit varying wind condition and then apply vector computation to get this value. Developping such a program would be time consuming.

Common sense evaluation should suffice to get acceptable ballpark values. One can see that wind blowing from the left will tend 'push' balloon B along a circonference of radius AB, thus going down. At the same time, balloon C would be ' forced ' to travel up along the circonference of radius DC. Those 2 opposite forces would tend to oppose, resulting in reduced displacement of point B as to compare to a single vertical balloon. In any case one can see that balloon B moves at all, the effect will be to reduce the angle at A.

Hence, If one directly adds the horizontal wind induced pressure on B and C balloons (or doubles the value at B) and divide the result by cosine 60 deg, one would get a value of the strain induced in wire AB higher than reality, but still representative for evaluation purpose. I did that to Table 1 above to generate Table 2 below. Let's keep in mind these values are somewhat on the overestimated side.

Table 2.
Estimated side wind-induced strain on wire AB: T (pounds)

V (mph)	3'	3.33'	4'	5'	6'	Diam
10	3.9	4.1	3.1	4.7	6.9	Safe zone
15	3.9	4.8	7.0	10.7	15.4	
20	7.0	8.5	12.2	19.0	27.4	
30	15.4	19.0	27.4	42.7	61.8	Risk zone
40	27.4	33.9	48.8	76.7	110.	

One last table (some useful physical properties of air)

Altitude(ASL) feet	Air pressure lb/f2	Air density lb/f3	Air viscosity f2/sec
0	2116.2	.0765	.000156
1000	2040.9	.0743	.000162
2000	1967.7	.0720	.000164

Well those are my findings. I hope those infos will be of some help for anyone who would like to tackle (or proceed) with the idea of erecting some kind of balloon antenna.

A Skyhook for the '90s

By: Don Daso, K4ZA
Date: May, 1997
Original source: QST May 97, pp. 31-33

Balloons, shaped like small blimps, are in relatively common use for advertising purposes. Such a blimp, of 10- to 12-foot (3.3 to 3.7 m.) length and 3- to 4-foot (0.9 to 1.2 m.) diameter can easily be used to support a vertical antenna for temporary use, such as in Field Days. K4ZA has successfully used them, and in this article, offers the benefit of his experiences for others who might want to follow his example.

A balloon of such size, when filled with helium, will provide a lift of about two pounds, ample for a quarter-wavelength wire on the 160-meter band. The balloon should be tethered in the center of an open space of such size that the perimeter is at least as far in all directions from the tether as the length of the antenna. For safety and good results, one should select an area of relatively flat ground with no buildings, towers, trees, fences, or overhead wires within it.
The balloons are commonly made of polyurethane film of 2- or 3-mil (50- to 75-micron) thickness. The film is relatively strong but must be

protected from puncture. The author suggests laying a 20- by 20-foot (6- by 6-m.) tarpaulin around the tether where the blimp will be inflated, to protect it from twigs or sharp weeds.

The tethering line should be 100-pound test fishing line or 1/8-inch (3-mm.) nylon rope. Stranded wire or aluminum welding wire is light and amply strong for the radiator. A good quality ball-bearing swivel should be used to attach the tether to the balloon's halter, since the wind will cause it to turn, pitch, and roll in all directions. Gloves should always be worn when the blimp is being launched and retrieved. In all cases, one should avoid dangerous situations, such as operating near power lines, in wet or stormy weather, or near airports or areas congested with people. Do not attempt to use heights greater than a simple quarter-wave monopole. Finally, remember that an adequate ground system is at least as important as the antenna; use either four elevated, or up to 60 ground radials for best results.

Two suppliers of these inflatable blimps are:
Toy-Tex Novelty Company, 7315 N. Linder, Skokie, IL 60077, tel (847) 673-6600;
The Blimp Works, 156 Barnes Airship Drive, Statesville, NC 28677, tel (704) 876-6705; web http://www.msmall.com/blimp.

Mail PI4CC

Here is a description of shortened 160 meter vertical. The Battle Creek Special is worked out here.

This is a copy from an article in QST December 1974.

Mobile operators and those who reside on property of city-lot size should find the author's treatment of physically shortened 160-meter vertical antennas of considerable interest. Construction details are given here for making his Minooka Special from readily available inexpensive materials. Performance is reported to be excellent with both the mobile and fixed-station versions of his design. Data are given also on basic antenna types in use by some of the leading "top band " DXers.

THE MAIN ACTIVITY at W9UCW for the past 10 years has centered on 160-meter operation. The focus has been on antennas. Much of the study has been directed toward comparing the performance of vertical and horizontal antennas for various objectives. A further study has been made on portable, mobile, and small-lot antennas, including suitable antennas for use at DX locations. Three trips by the author to HK0 and HK1 locations motivated further investigations of portable antennas for use on 160 meters. Improved mobile operation was sought also, seeking solutions to the problerres of efficiency, durability, bandwidth, ease of construction, and cost.

Inspiration for the design offered here resulted in past from the author's survey of antennas in use by 160 meter operators, worldwide. An extensive report was compited. It filled a loose-

leaf notebook! A boil-down of the most useful information resulted in an 11-page report which was made available to numerous amateurs. Subsequently, the writer was encouraged to submit some of the data for publication. Approximately 60 operators were polled, The following information from that inqury should be of interest to those who are curious about "preferred"antennas for topband use. Question if you could put up any antenna for 160, what would it be? Result: 60% favored verticals, 30% said horizontals, and 10%. indicated mixedfeelings. (The term "vertical includes various configurations 1/4, 1/2, and 5/8 wavelength, vertical arrays, and inverted Ls.) Questions 2: "Comparing antennas that an average ham could build, do you prefer verticals or horizontals for 160? Result: 70% said vertical, 17% favored horizontal, 5% inverted L, 2% horizontal and vertical 2% inverted V and 3% had no opinion. Reason; given for the responses were, "Because of signal comparisons and past experience. A backyard-compatible vertical is more effective than a back-yard-compatible horizontal." Question 3: "Do you operate mobile on 160? If so, what is the antenna used?" Result: 3 used base-loaded verticals 8 used center-loaded ones and one employed a Heliwhip. Some of the operators used capacitance hats. Other questions in the surrey dealt with receiving antennas, types of soil and terrain, besides requesting complete details of the present transmitting antenna.

The Minooka Special

The following is a description of an effective vertical antenna for 160 meters, designed with these objectives in mind.

1) Highly effective for 160-meter DX and local work. 2) Easy to build and adjust. 3) Very economical. 4) Fits neatly into back yard. 5) Reasonable bandwidth. 6) Good for portable and I)Xpedition work. 7) Can be scaled down for mobile operation.

The resultant antenna (Fig. 1) is top loaded inductively and can be built by anyone from readily available material. Only a dip meter and SWR indicator are needed for tune-up Man versions were built and tested, ranging from 7- foot mobile types to 60-foot backyard or DXpedition models. They have been used with good results from 20 foot- wide backyards in cluttered Chicago,

to vast beaches on Carribean islands, and in South America. The fixed-tuned bandwidths vary from 10 kHz for mobile versions, to 50 kHz for the larger fixed-station models (SWR 2:1 or better).

Fig. 1 Electrical details of the Minooka special.
Table 2 gives specific information concerning dimetions X, Y and Z L2 may vary in size from 1 to 20 turns, and L3 will contain between 5 and 10 turns, typically. L2 and L3 are made from No.18 wire spaced 1/8 inch between turns. The coil diameter is 1-1/2 inches. Refer to text for tuning instructions.

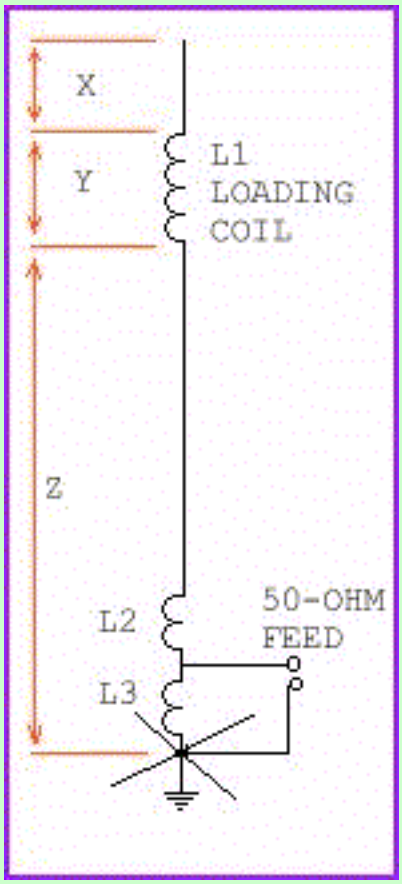

Table 2

X	5 ft	8 ft	4 ft	4 ft	19 ft	3 ft 3 in
Y	2 ft	15 in	3 ft 6 in	4 ft	11 ft	3 ft
Z	*	*	*	*	*	*
Wire size	No 20	No 19	No 18	No 16	No 19	No 22

* mean as long as possible

Construction

The physical layout of the antenna is centered around the use of 3/4-inch-diameter rigid PVC water pipe. This sturdy tubing has an outside diameter of 1.038 inches. The inner diameter provides an "interference fit" for 1/2-inch EMT conduit (thinwall). A 3/8-24 nut is driven into a 5-inch length of conduit, then aligned and braized into position. Next, the conduit is taper-ground and polished on the opposite end, then driven into the PVC tubing (see table of dimensions).

In the construction of mobile antennas another piece of conduit is driven into the bottom of the PVC coil form and a 3/8 - 24 bolt is brazed into the bottom end The bolt will mate with standard mobile antenna mounts. For larger versions of the antenna the PVC material can be mounted in TV wasting, or whatever. A standard 8-foot stainlesssteel whip between 3 and 8 feet in length can be screwed into the top section. For home-installed versions of the antenna a three- or four-foot piece of thin-wall tubing can be used in place of the whip. This will save on the cost of materials, and will eliminate the need to have brazing done. The coil wire should be soldered to the conduit to assure a good electrical connection.

Adjustment

Pick a set of dimensions from the table which suits your application, but add a few inches more of coil turns (all turns close wound) than are recommended This will allow leeway for pruning the system to resonance.

To simplify adjustment it is suggested that the system be assembled first with only the coil and top section (no base section). Place the antenna where it is in the clear (on the car or fixed-station site), and where it can be tuned against the proposed ground system - car body or ground radials.

A three-turn link should be connected temporarily between the lower end of the coil and the ground system. This will permit rough tuning of the system to resonance by inserting a dipper

coil into the link and adjusting the coil turns on the antenna until a dip is noted in the desired part of the band. Upon completion of the pruning the constructor can, if he wishes, cover the coil with weatherproof tape or shrink tubing. The antenna should be tuned for roughly 2000 kHz if the entire band is to be used. Adjust the resonance for 1850 kHz if only the low segment will be utilized.

Erect the antenna with all of its parts - coil, top and bottom sections - and insert inductors L2 and L3 of Fig. 3 as shown. With L3 temporarily out of the system, adjust L2 for the lowest value of SWR obtainable at the desired operating frequency. Then, place L3 back in the circuit and adjust it for an SWR reading of 1. Addition of the base section later on will not affect the resonant frequency of the overall system materially, provided the base section does not exceed, say, 60 feet.

The foregoing steps are used also in adjusting the mobile version of the antenna. However, because of the small size it is possible to adjust the antenna in completely assembled form. Only L3 of Fig. 3 is needed for mobile antennas. The main coil, L1, is adjusted for resonance, then L3 is set for lowest SWR. L3 can be mounted inside the trunk or under the bumper in a weatherproof enclosure.

For fixed-station operation it is recommended that a good ground system be employed. One should use at least 10 radials oft say, No. 18 or larger wire, 10 to 50 feet in length. If you can manage 40 radials, 60 feet in length, all the better.

Concluding Comments

Three fixed-station versions of the Minooka Special have been tested and used at W9UCW. Each was compared against the regular antenna, which is a one-quarter wavelength vertical (130 feet high), and operates against a radial system that contains 12,000 feet of wire. The short verticals were always inferior to the big antenna by approximately 5 dB.

Using version No. 4 from the table (4-foot base section), the author worked Wls through W6s from the mobile setup. The rig

was an HW-18 transceiver. Contacts were also made with VP9 and KV4 stations from the car.

While DXing from San Andres (HK0) reports were received of signal strengths exceeding S9 plus 20 dB from Maine to Washington. Good reports were received from Europe also.

Because the loading coil acts as an rf choke at 3.5 MHz and above, several versions of the antenna have been used successfully from 160 through 20 meters with an appropriate L-network matching section installed at the base of the system.

Acknowledgements

The author wishes to express his gratitude to all who helped make this article possible particularly K9SKX, WA9EYY, and W9YYS, who assisted with the initial experiments on the Minooka Special. The participants in the antenna survey (a list too large to include here) deserve considerable thanks for their help as well.

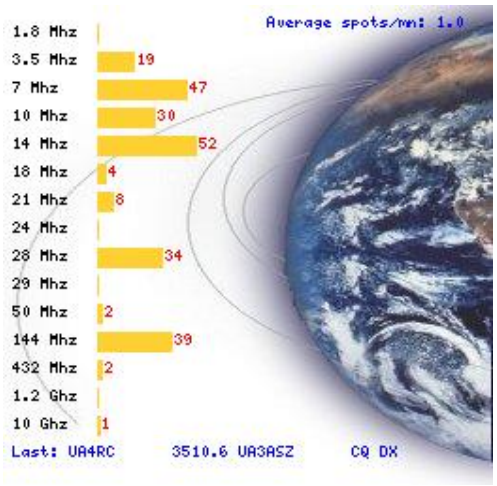
The bands just now



Welcome

This page is devoted exclusively to Amateur radio. You may find here some stuff concerning DX, CW and contesting.

If you have any great suggestions, feel free to **email me,** and I'll probably feel free to ignore you.

How to use the 'The bands just now' chart?

This bar chart is based on the 250 lasts spots from the OH2AQ web cluster (fantastic tool!).

For each band a bar chart is drawn proportionally to the number of spotted DX informations. The absolute number of spots is noted in blue at the end of each bar. To see more spots from a particular band, click on the band indicator.

The last spot posted on the cluster is noted in blue at the bottom of the graph.

The Average spot/minute indicator is a calculated stamp, based on the 25 lasts spots.

PLC (Power Line Carrier) or PLT (Power Line Technology) - the end of Short Wave Bands?

They will use HF and VHF broadband systems. The outdoor power wires will serve as antennas, typically producing directivity and hugely strong increases in background noise for ham reception. ARRL did a study and included it in Comments in the FCC docket. Also, consumers will have equipment potentially susceptible to the ham signals. FCC rejected access to the 136 kHz band because of the risk of interference at 3mV/m, whereas the ham signals in HF/VHF will be at 30mV/m. ... **Download and read the set of basic documents.**

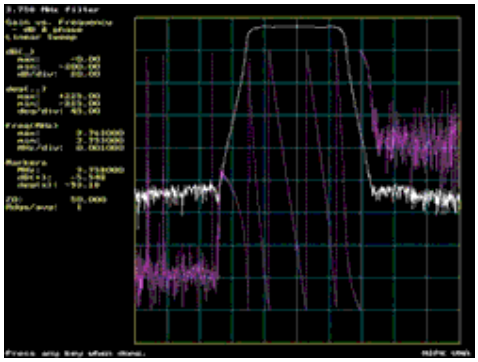
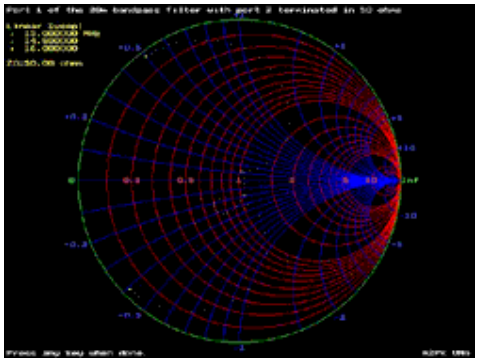
VNA - The Vector Network Analyzer by N2PK

Not satisfied with your MFJ-259B, Autek RF-1 or AEA CIA HF? Impossible to spend some 2 kilobucks for an advanced vector impedance analyzer? Do you want a highly interesting home brew project? Then visit **Greg Ordy's (W8WWV)** and **Paul Kiciak's (N2PK)** web sites and learn more about the VNA - Vector Network Analyzer built and developed by N2PK. This is a homebrew VNA capable of both transmission and reflection measurements from 0.05 to 60 MHz, with about 0.035 Hz frequency resolution and over **110 dB of dynamic range**. Its transmission measurement capabilities include gain/loss magnitude, phase, and group delay.





(click on images to enlarge)

Its reflection measurement capabilities include complex impedance & admittance, complex reflection coefficient, VSWR, and return loss. Unlike other impedance measuring instruments that infer the sign of the reactance (sometimes incorrectly) from impedance trends with frequency, a VNA is able to make this determination from data at a single frequency. This is a direct result of measuring the phase as well as the magnitude of an RF signal at each test frequency.

With optional narrowband extensions, this VNA can function through 500 MHz with some degradation in performance. Its custom software operates on DOS and Windows based IBM compatible PCs and communicates with the VNA through a parallel port. It is aimed at the serious experimenter with, at least, a basic understanding of transmission lines.

A sad story of the stolen name of the HSC

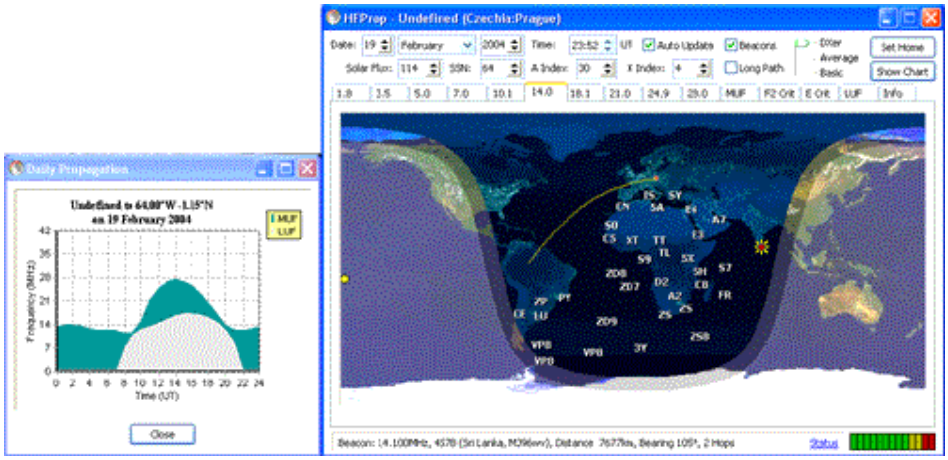
The new version is still in process which take some time. My apologies for this inconvenience. If you want to read some news, **click here**.

Software news

Software is like sex: it's better when it's free.

Linus Torvalds

- **HFProp** by Julian Moss, G4ILO is very nice hard-to-beat software. It employs Solar Flux or SSN value and both A and K displaying a particular propagation prediction chart to any point on any band at a glance. Many other programs are hard to use because it cost a significant effort to prepare a prediction to single point. HFProp combines a powerful beacon tracker with very good propagation calculator dusplying the results on a Mercator world map. Julian says that it employs "a quite simplistic algorithm" but I can witness that it works at least in the same way as many of the highly priced programs. You can also directly compare the results with beacon availability, therefore confirm the prediction accuracy.



- **CT by K1EA** (DOS version) is **now free!** There are many new features including paddle support. Look for regular updates at the CT home site.

- **Swisslog** by Walter Baur, HB9BJS for DOS is another addition to high value **free** programs. The latest DOS version 3D8a is probably the best logger for DOS which beats many known and expensive Windows logging programs.

- **4nec2** by Arie - a top grade **FREE** antenna analysis software based on true NEC2. Generates very nice color 3D patterm models, Smith chart, can optimize your antenna design and works up to 11000 segments, based on the RAM capability of your machine. The only disadvantage is that it uses NEC cards, you need a bit of experience with this ancient method. I believe this is the BEST antenna software!

- **NEC2 for MMANA** by Dimitry Fedorov, UA3AVR- a supplement to the famous MININEC implementation allowing NEC2 antenna analysis up to 3000 segments. Calculates also structures made of dielectric coated wires. Works with .maa files which can be prepared in the MMANA. There is a way to convert a MMANA file to the NEC card file (see above), simply rename the **Indata.txo** file generated by this program to a file with .nec suffix. An ideal companion to MMANA and 4nec2!

- **VUSC** (**V**HF - **U**HF - **S**HF **C**ontest) by OK1DIX/N1GA is a TR-like contesting freeware with many advanced features. Visit the **author's web site** to obtain the most fresh version. The new **version** features:

  - Both modes on-line (during the contest) and off-line (evaluation after the contest) possible
  - Free log data editor
  - Multiband support (up to 8 VHF/UHF bands simultaneously on one computer)
  - Very high memory capacity (several thousands QSOs, all databases in RAM)
  - High data security in case of hardware/system failure

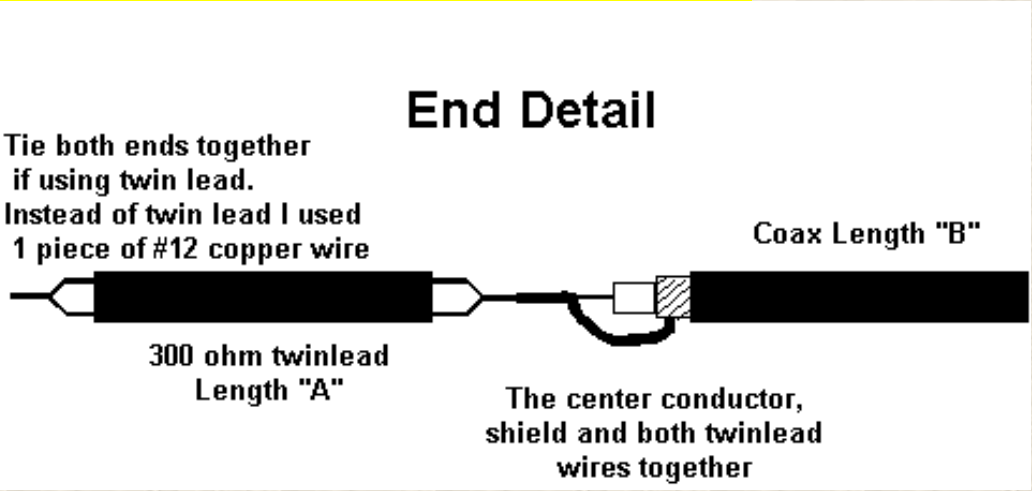
THE DOUBLE BAZOOKA



HAM UNIVERSE

SET YOUR SIGHTS ON BETTER QSO'S

Notes on Assembly:

On the cable ends you do not need to use twin lead. You can make these antennas using a single piece of 12 gauge copper wire for each end,, you can also use ladder line etc. I would advise using heavy end wires for strength purposes. To prevent the joints from breaking especially for long lengths, I picked up some 1/2 inch PVC pipe and end caps. I cut the PVC so it would overlap a few inches on the joints. I then glued the end caps on. Place the PVC between the joints and secure with regular screw hose clamps. Put the clamps close to the end caps and it will give a strong joint. Do this for the center also.

About The Antenna

The Double Bazooka Dipole is a very efficient **single band antenna** which is very quite,and does not require the use of a balun. This antenna consists of coax (RG58) with the shield split at the center and the feedline attached to the open ends. **Do not break the center conductor.**
With the feedline attached directly to the two open ends this acts as a half wave dipole along with the open wire end sections. This antenna can be cut for any operating frequency and is broad banded. It can be mounted as a flat top or an inverted vee and will handle the legal limit.
As with all antenna projects, you may have to tune length for best swr and select materials that are easily obtainable.
EXPERIMENT! EXPERIMENT! EXPERIMENT!.

AN EXAMPLE ANTENNA

75 METER GENERAL BAND CENTER (3.925 mhz)
LENGTH "B" = 325/freqmhz = 82.8 FEET (aprox 82 feet 9 1/2 inches)
LENGTH "A" = 460/freqmhz = 117.20 feet 2 1/2 inches minus length "b" (82.8feet) = 34.4 feet divided by 2 = 17.2 feet
TOTAL ANTENNA LENGTH = 117.2 feet 2 1/2 inches (aprox)

Introduction

The Beverage (or "wave") antenna was invented in the early 1920s by Dr. Harold H. Beverage. It was first discussed in a paper titled "The Wave Antenna - A New Type of Highly Directive Antenna" written by Beverage, Chester W. Rice and and Edward W. Kellogg for the journal of the American Institute of Electrical Engineers (Volume 42, 1923). The paper discusses testing longwave antennas (7,000 to 25,000 meters; 12-43 kHz) that were 7 miles (11 km) long. This work was done at Riverhead, Long Island, NY, and mentions "shortwave" tests around 450 meters (665 kHz) as a practical upper limit in subsequent experiments. While others have since written about the antenna, if you can find a reprint of this original work in a research library, you'll find the paper is fascinating reading.

In 1938, the Radio Institute of America presented Dr. Beverage with its Armstrong Medal for his work in the development of antenna systems. The Beverage antenna, the citation said, was "the precursor of wave antennas of all types." Dr. Harold Henry Beverage, Stony Brook, NY, USA, passed away on January 27, 1993 (at age 99).

A classic Beverage receiving antenna requires a lot of space. It is a long wire, one or more wavelengths long, mounted near to the ground and oriented in the direction of the desired reception. A nominal 9:1 balun is required at the juncture of the wire and 50- or 75-Ohm coaxial feedline.The far end is terminated with a nominal 600-ohm resistance. (When available land will not permit the installation of a "full length" Beverage, some people install "short" Beverages, ranging in length from about 300 feet up to 600 feet or so.)

The Beverage antenna is highly directional, responsive to low-angle signals, has little noise pick-up, and produces excellent signal to noise ratios. Some say the frequency range suitable for Beverage antennas ranges (from an Amateur Radio viewpoint) from 1.8 MHz on up to about 7 MHz or so...
However, consider the following from Frank, W3LPL:

Subject: Beverage antennas effective on entire HF range
From: Frank Donovan (donovanf@jekyll.sgate.com)
Date: October 22, 1995
Organization: (Usenet's) rec.radio.shortwave

Properly designed Beverage receiving antennas are very effective across the entire HF frequency range. At the W3LPL DX contest station we use Beverages from 1.8 to 14 MHz, and during the sunspot maximum we used them up to 28 MHz!
Beverage arrays (multiple Beverages designed to operate as a phased array) are even more effective on HF. I've seen Beverage arrays with as many as 128 individual Beverage elements, each 220 feet long and 4 feet high.

"How To" articles:

An original article by KB1GW: "Beverage Notes"
(Note: This article originally appeared in the YCCC newsletter: "Scuttlebutt;" April 1997.)

And, another Beverage article by KB1GW (with guest, K4VX):
"More Beverage Notes" -- Copyright: August, 1997.
(Note: This article originally appeared in the YCCC newsletter: "Scuttlebutt;" October 1997.)

An article by K5ZD: "A $50 Beverage"
(Note: This article originally appeared in the YCCC newsletter: "Scuttlebutt;" October 1995 .)

"Frank Donavan, W3LPL, discusses beverages on the CQ-Contest reflector.
This is a reprint of Frank's message," along with a nice picture of W3LPL's QSL card!

Contest-reflector postings from W3LPL on Beverages:
Close-spaced Beverages

Phased Pair of Beverages

Terminating / Sloping Ends of Beverages

Minimum and Optimum Lengths for Beverages

New! W3LPL Receiving Filters...
"These filters have several applications:

Preventing interference -- or receiver damage -- from strong nearby signals in a multi-transmitter contest station (or field day, etc.), or to reduce interference in the 160M band from nearby AM broadcast stations operating below 1500 kHz."

"Sharing an antenna among up to four receivers on separate ham bands; specifically a diplexer (constructed from two 'LPL filters) is used when you want two receivers -- on separate bands -- to share a common antenna, any multi-radio contest station can benefit from sharing Beverages among radios with less loss than the typical 3 dB power splitter."

A link to a 1968 interview with Dr. Harold H. Beverage
"Dr. Beverage was formerly director of radio research for RCA Laboratories and also was vice-president in charge of research and development for RCA Communications. During the interview, Dr. H.O. Peterson came in and joined the interview. Dr. Peterson was formerly in charge of the Reception Laboratory at Riverhead. The first RCA Laboratory was established by Beverage and Carter in a tent at Riverhead [NY] in 1919. The interview describes the events leading up to the formation of RCA in the autumn of 1919, the invention of the wave antenna, and first diversity reception. It also describes Dr. Hansel's development of the first crystal controlled transmitter and the first 15 meter transmitter. Some of the personal characteristics of Marconi, Dr. Alexanderson, Roy Wegan, Dr. Hansel, Major Armstrong, President Wilson, and others are discussed."

And, a link to a 1992 interview with Dr. Beverage.

ICE offers a Model 180A matching box for $39 (plus $4.50 for shipping). The 180A has taps to select 50 or 75-Ohm coax feedlines; and taps to match 300/450/600 or 800-Ohm Beverage antenna loads. The 180A has dc blocking capacitors and a gas-discharge lightning protection system. ICE also sells a Model 181A ($39), which allows you to apply a dc voltage into your Beverage for remote switching. Like the 180A, the '181A has a gas-discharge protection system. Finally, they offer a Model 185A "resistive load" to terminate your Beverage with. It has same high-impedance taps as the Model 180A and it costs $34. These units are rated for 10 W of continuous RF and 100 W on peaks. (I was told that these ratings are not specified for transmitting into the boxes. Rather, they are what the boxes can withstand when your Beverage picks up energy from nearby transmitting antennas.) All of these boxes are made of 1/8-inch extruded aluminum (milled and tapped). And, if you're looking to buy American, they're all made in the USA.

A link to: ByteMark Corporation in Orlando, FL; tel: (800) 679-3184 (They sell Amidon stuff.)

Among other things, they offer high power ununs designed by Dr. Jerry Sevick, W2FMI...

Features:

- Broad Bandwidth (1 MHz up to 50 MHz)
- Low energy loss (<0.2 dB)
- Aluminum casing with SO-239 connectors on inputs and outputs
- Dimensions: 4 inches x 2 inches x 2.8 inches (same for all models)

Typical Applications: Matching unbalanced 50 ohm coaxial cable to:

- Ground fed antennas - shortened verticals, vertical beams, slopers and inverted L's

- use 4:1 HCU50, 1.78:1 HDU50, etc.
- Shunt fed towers performing as verticals - use 1.56:1 HDU50
- Beverage antennas - use W2FMI-BEV

"The unun should find some important applications. Until recently, they have been literally impossible to obtain. But now they can be designed to match 50-ohm cable to loads as small as 3.125 ohms and as high as 800 ohms (both unbalanced loads). They can come in low-power and high-power versions as well as

multimatch designs. An important application for ununs is to match 50 ohm cable to the input impedance of ground-fed antennas such as verticals, slopers, inverted L's and towers performing as verticals. Since ground losses play a large role with these systems, a knowledge of the input impedance of the antenna as well as the ground loss is important in determining the optimum impedance ratio. Also, a high impedance, multimatch unun can be easily designed to match 50 ohm cable to the input impedance of Beverage antennas."

"Baluns (balanced to unbalanced transformers) and ununs (unbalanced to unbalanced transformers) belong to a class of matching devices known as transmission line transformers. They transmit the energy from input to output by a transmission line mode instead of by flux linkages as in the case of conventional transformers. When properly designed, they can have extremely high efficiencies and very broad bandwidths."

A 2:1 unun is a good choice for feeding a 1/4-wavelength "Inverted L" type antenna. For example:
One 2:1 unun they offer has 22/25-Ohm taps on one side, and a 50-Ohm tap on the other side.
This aluminum cased model (HDU100) has female SO-239 connectors at each end, too.

C&S Engineering
9229 Goldenrod Drive
Fort Wayne, IN 46835
Phone Orders: (219) 485-1458

E-mail: Chuck, N8BYI

Web: **C&S Engineering**

C&S Engineering offers several products, including their "Front End Saver (FES)," available as a kit ($22.95); pre-populated curcuit board ($29.95); or built, tested and cased ($49.95), plus shipping costs. The FES "protects your receiver when you operate on the aux. (RX) antenna. A must for 80m and 160m operators." (The FES was described in *CQ* Magazine, February 1997, p 32.)

In addition, C&S offers a "160 Meter Preamp," (also available for 80 meters). Single-band preamps are available, in kit form ($29.95); built, tested, and cased ($59.95); or for 80 *and* 160--switchable--($99.95). These preamps offer tuned inputs and outputs. "Amplify sig not noise. Over 25 dB gain, lo noise, gain control. A must for Beverage and loop antennas." (The 160-meter preamp was featured in the October 1989 issue of *Ham Radio* Magazine, in an article by Gary Nichols, KD9SV.)

Here's an ad I saw in the "Ham Ads" in the back of *QST* Magazine:

"BEVERAGE matching transformer kits, 160/80/40 DX reception.

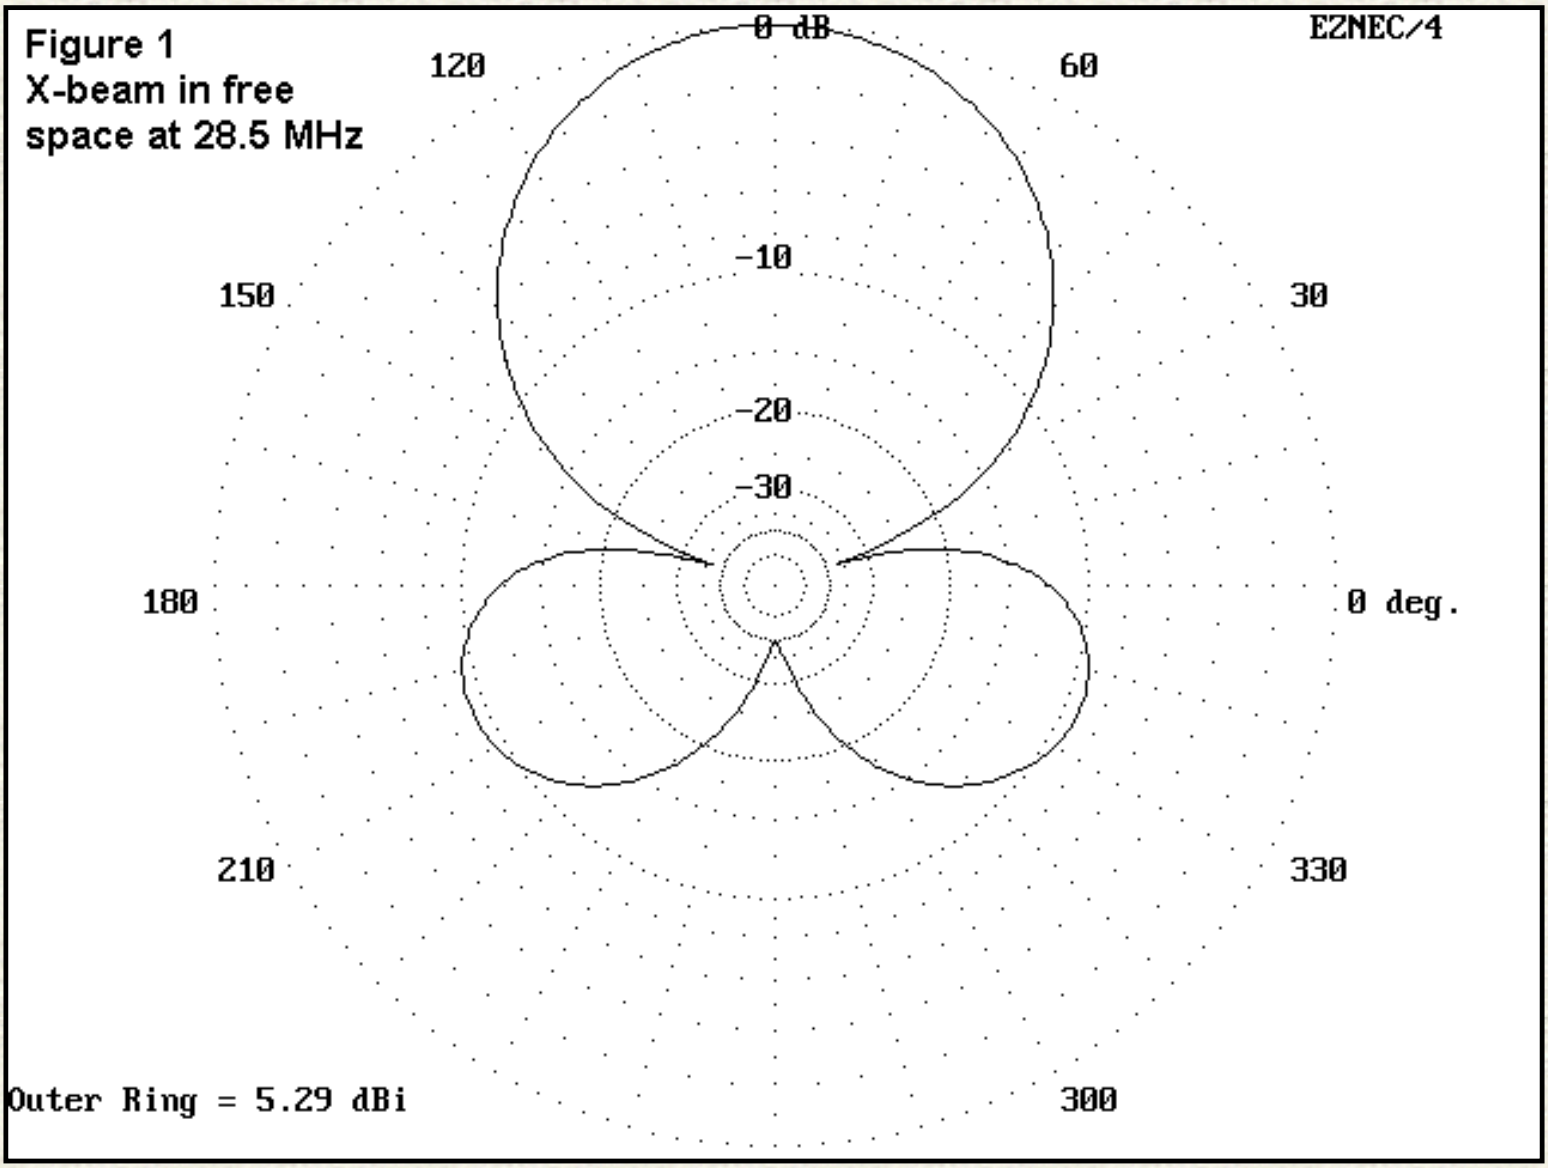
The Birdcage Antenna

L. B. Cebik, W4RNL

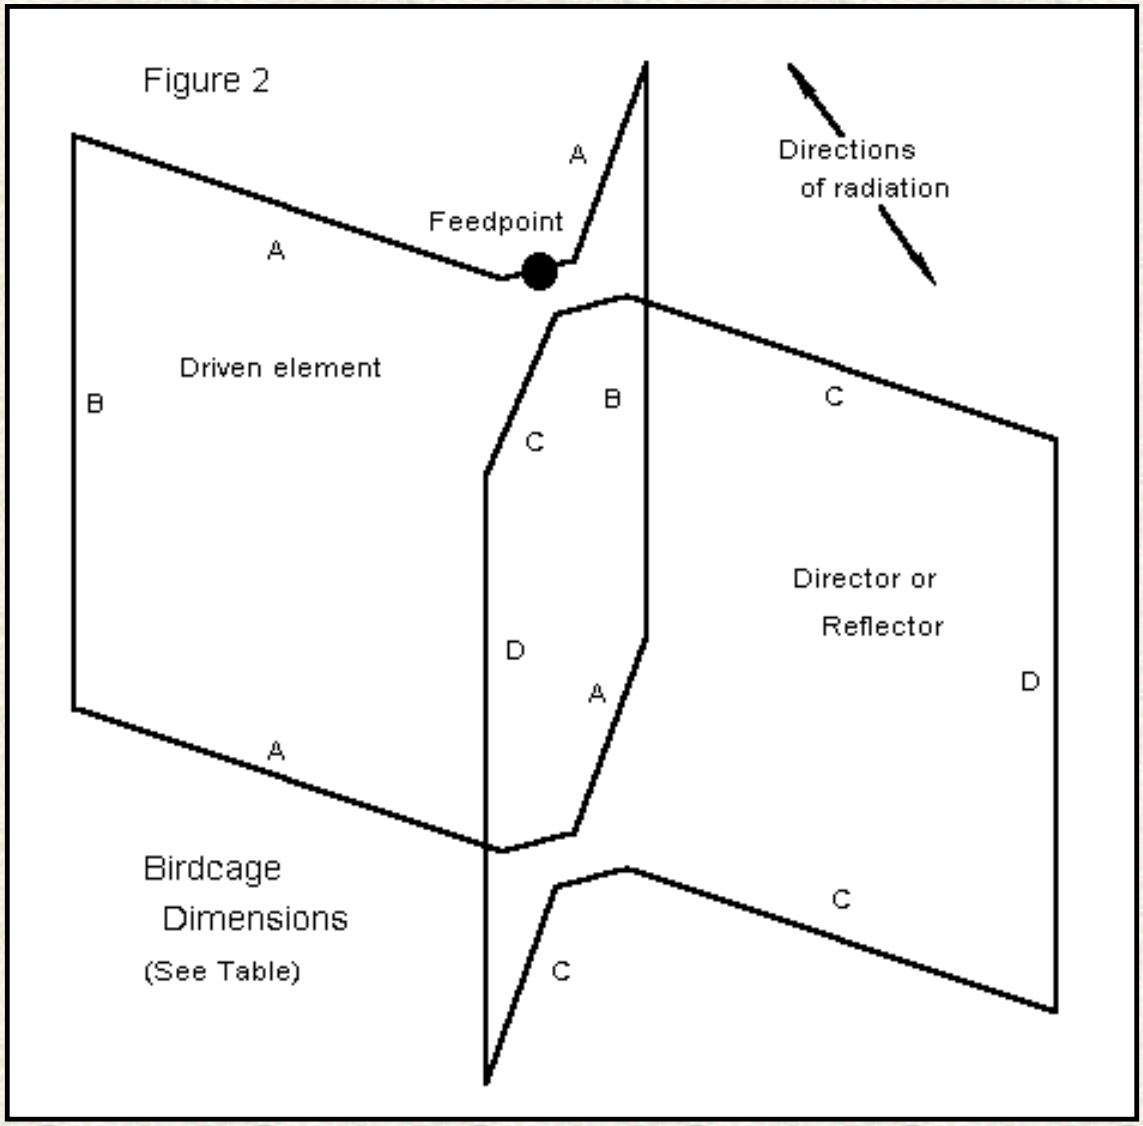
The folded X-beam derives its existence from the G4ZU Birdcage antenna. W2EEY viewed the X-beam as half a Birdcage.(1) Although this is historical fact, the logic of antennas goes the other way round: the Birdcage is a double folded X-beam. For reference, Figure 1 provides a free space pattern of an X-beam tuned for maximum front-to-back ratio.



We may legitimately ask, how much better does the whole Birdcage work compared to an X-beam? When Dick Bird,

G4ZU, published his work in 1960, he made some fairly extravagant claims for the antenna, claims that led him to patent it.(2) At this distance and with the calculating power made available by NEC and its offspring, we may decide that the claims for his antenna (and those of many hams who built one) reflect more accurately the low state of home-brew Yagi and quad construction of the time than they do contemporary comparative performance. Models of the Birdcage show little advantage over the X-beam and exaggerate some of its limitations.

Bird graphically demonstrated what he took to be the principles of the Birdcage by beginning with the bidirectional pattern of the dipole. Folded into a Vee, the antenna would show, according to his sketches, a strong lobe out the open end and a weak lobe off the apex. Add a Vee reflector (pointed the other way to make an X), double the assembly a quarter wave above or below, bend the X-arms vertically to meet each other as phasing lines, and the Birdcage is born. Figure 2 shows the outline of the Birdcage, with identification of each relevant dimension.



Unfortunately, the seeming flaw in the reasoning begins with the Vee itself. Short Vees do not cancel the radiation off the backsides of the elements (the outsides of the V). Thus are born the uneliminable quartering lobes of the X-beam and even larger lobes for the Birdcage.

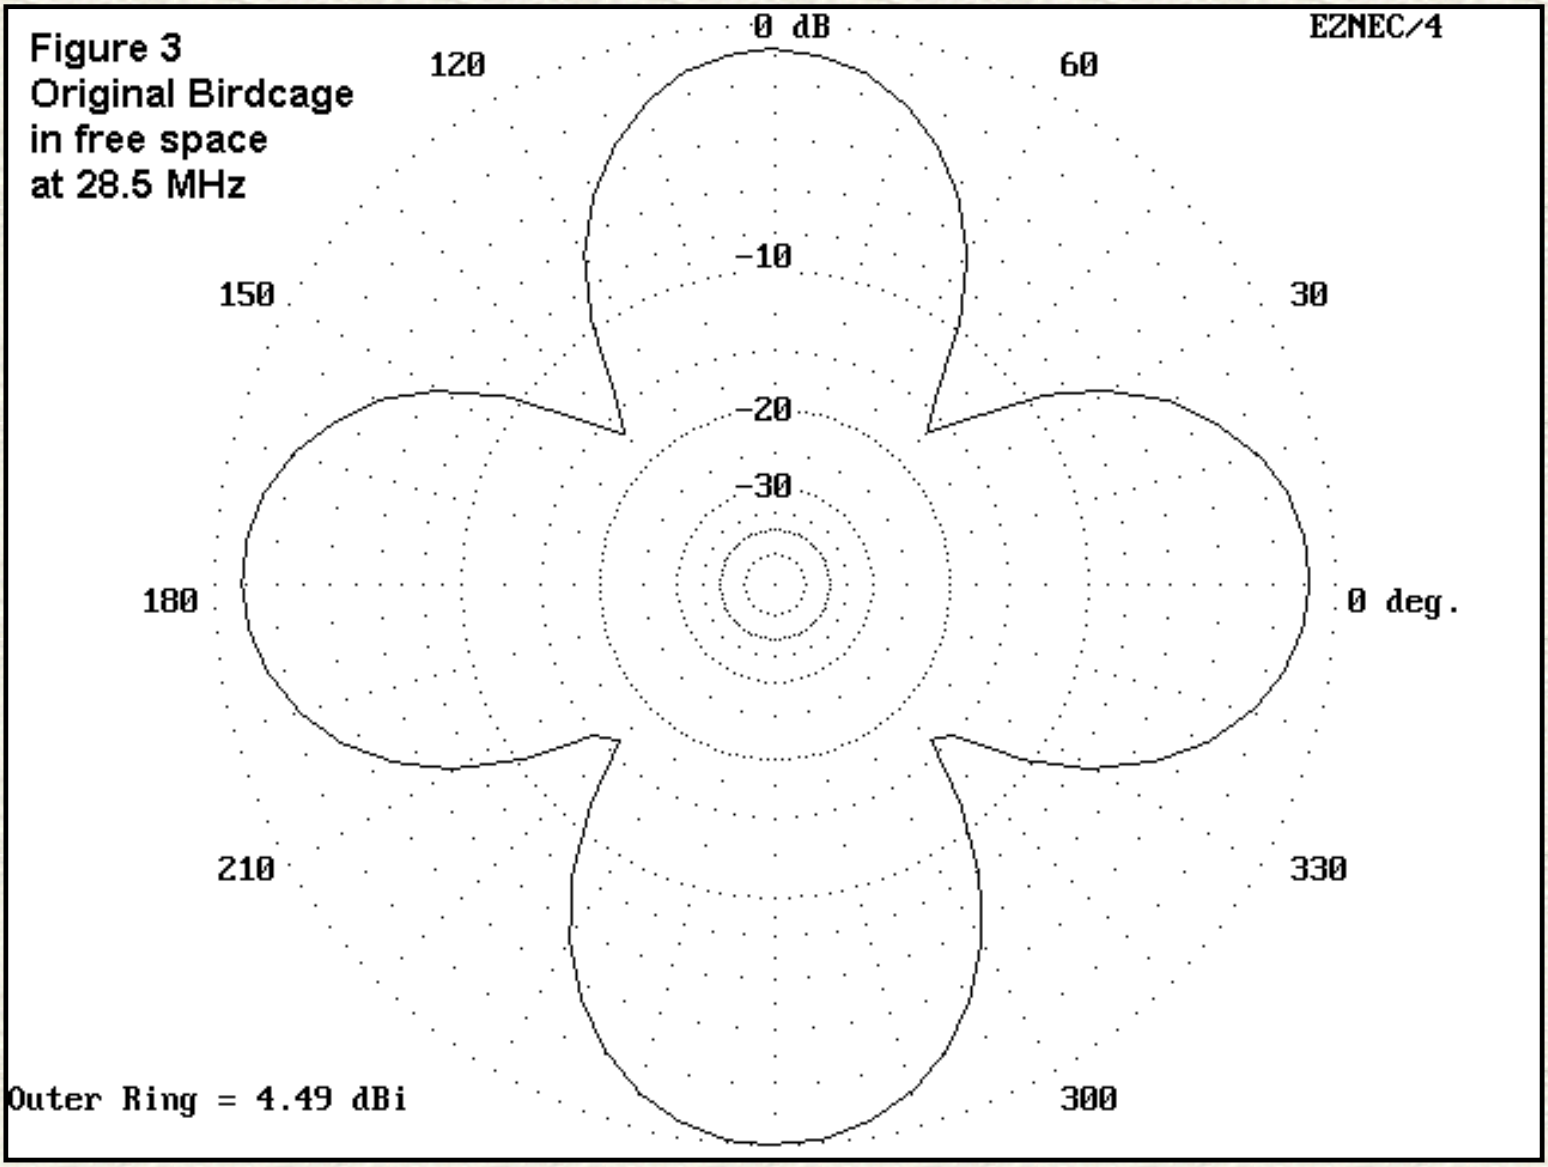
Birdcages come in two forms: with a reflector and with a director. Table 1 shows 10-meter models of each beginning with a self-resonant Birdcage with equal-size elements derived from data given in 1960's literature.(3)

Table 1. Modeled Dimensions of the Birdcage Antenna

Dimensions	DE Arm (A) L (ft)	Parasitic (C) L (ft)	Vertical (B and D) L (ft)
Basic Birdcage	5.05	5.05	8.666
DE and Refl Resonated	4.95	5.26	8.666
DE and Dir Resonated	5.16	4.91	8.666

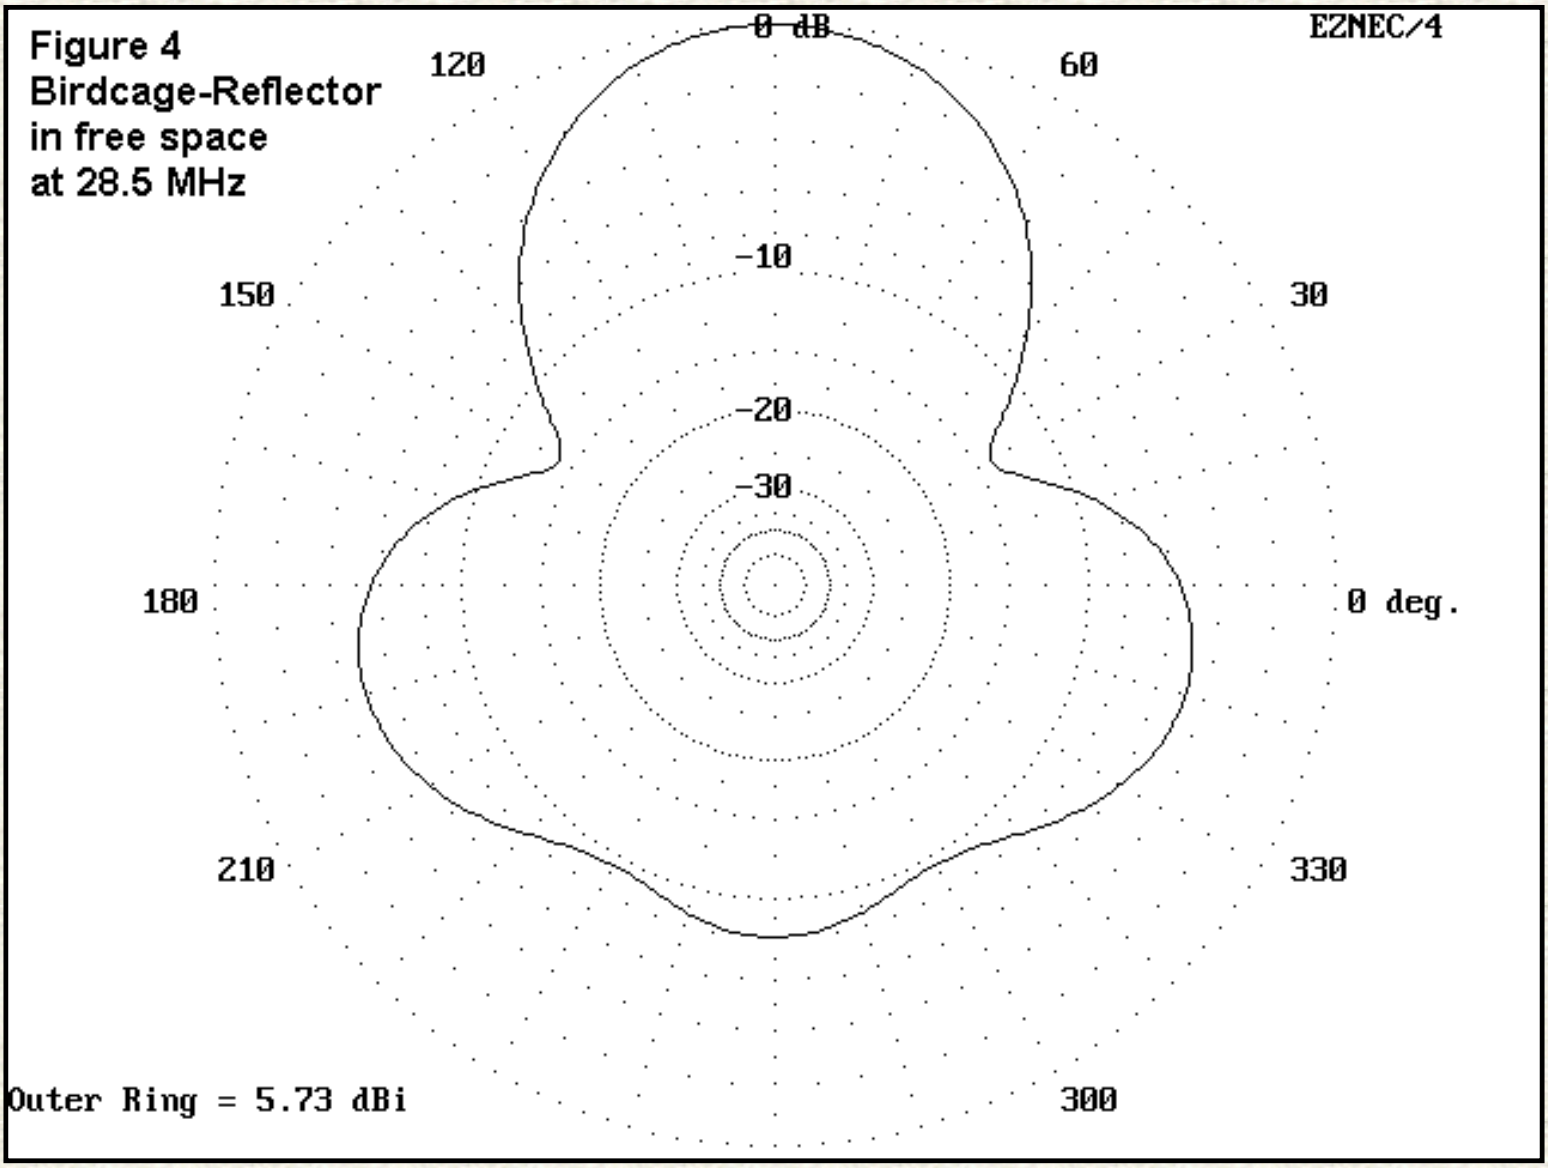
Note: all models used #14 copper wire in free space at 28.5 MHz on NEC-4.

Figure 3 shows the performance in free space of the basic Birdcage--a nice 4-leaf clover.

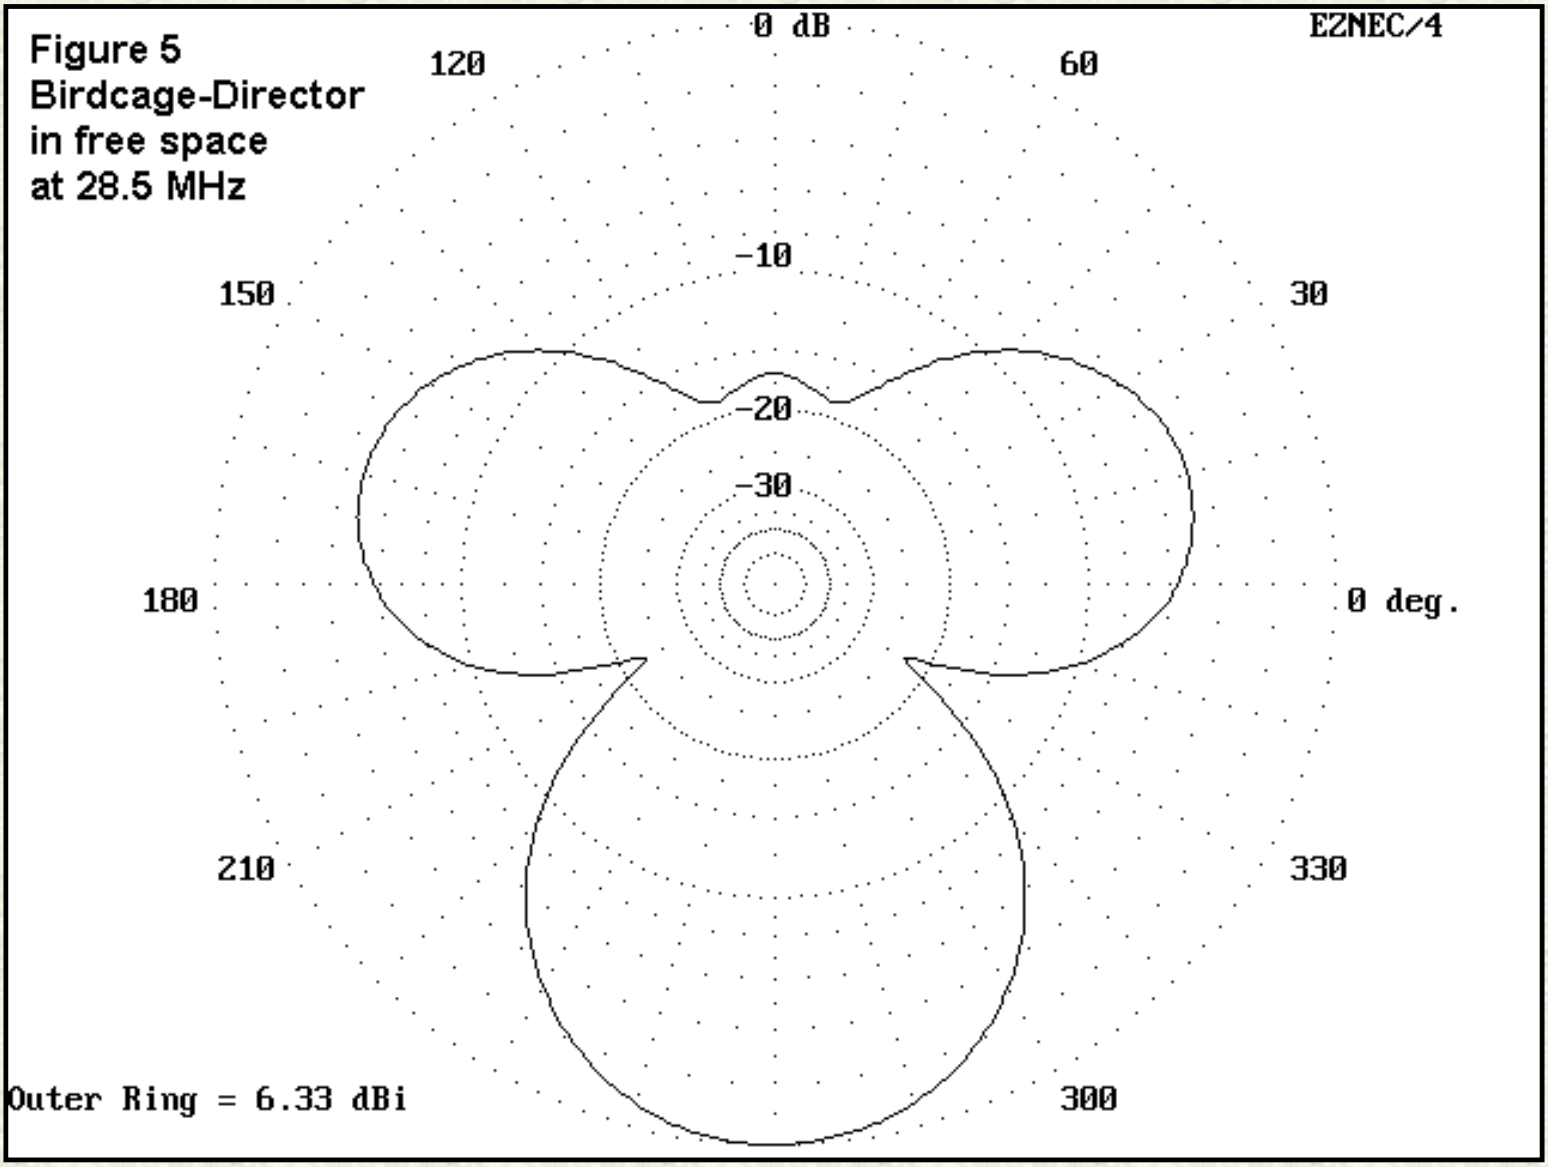


G4ZU favored the reflector version, which is perhaps the worse performer of the two possible versions. With a

forward gain in free space of under 6 dBi and a front-to-back ratio of about 8 dB, the beam is not the equal of a 2-element Yagi or even of the X-beam. Figure 4 shows its performance in free space.



The director version that parallels the development of the X-beam provides more gain and front-to-back ratio: 6.3 dBi and 17 dB, respectively. Figure 5 shows its performance in free space. The direction is reversed, since I simply re-dimensioned the reflector to form a director.



As shown in Table 2, the figures for the directed Birdcage surpass both the X-beam and the 2-element Yagi by a small bit, while the reflected Birdcage leaves much to be desired.

Table 2. A Comparison of Antenna Performance

Antenna Type	TO Angle (degrees)	Gain (dBi)	Front-to-Back (dB)	Feedpoint R ñ jX (Ohms)
A. Free Space				
Birdcage: DE + Ref	--	5.8	8.0	34 - 0
Birdcage: DR + Dir	--	6.3	16.9	40 + 4
Folded X-Beam	--	5.3	39.1	37 - 3
B. Height = 5/8 wl				
Birdcage: DE + Ref	22	10.5	8.0	31 - 3
Birdcage: DR + Dir	22	11.0	17.1	40 + 3
Folded X-Beam	23	10.5	21.8	35 + 0
2-El Yagi	23	11.3	10.9	34 - 5
2-El Quad	22	11.7	18.3	97 - 3
C. Height = 1 wl				
Birdcage: DE + Ref	13	11.3	8.6	32 - 2

Birdcage: DR + Dir	**14**	**11.8**	**17.0**	**39 + 2**
Folded X-Beam	**14**	**10.8**	**31.7**	**33 - 1**
2-El Yagi	**14**	**11.7**	**13.5**	**35 + 0**
2-El Quad	**13**	**12.4**	**17.9**	**92 + 8**

Note: TO angle=the angle of maximum radiation at which azimuth readings of calculated gain and front-to-back ratio were obtained. All calculations via NEC-4.

The pattern of the Birdcage in either version does not meet today's standards of front-to-side ratio or front-to-rear ratio. The quartering rear lobes of the X-beam become virtual side lobes of the Birdcage and are only down from the main lobe by some 4 to 5 dB in the either version. There is little QRM-rejection potential, especially in the reflector version. Over real ground, the pattern devolves into a mound of whip cream. However, over real ground, the director version tends to push its side lobes to the rear, and the pattern begins to resemble that of the folded X-beam.

Like the folded X-beam, the Birdcage retains its most optimal pattern only over a small portion of the band of design. The reflector version rapidly grows a tail below design frequency, while the director version grows its tail above design frequency. The SWR bandwidth is also narrow, less than 0.5 MHz at 10 meters for a 2:1 SWR. However, the complex structure of the Birdcage is less amenable to a tunable parasitic element than is the simpler X-beam.

All in all, the additional complexities of the Birdcage are not warranted by a significant increase in performance over the X-beam. Gain aside, the side and rear performance of the antenna falls far short of other compact designs. Consequently, while that antenna has a great name and an appealing look, performance models do not recommend the investment of time and resources in this antenna. In some ways, it is a shame to discover this: G4ZU contributed extensively to amateur practice in the field of antennas. Although the Birdcage antenna has had its day, Dick's other work--and his example--will long endure.

Notes

SPACING. - The lower relative efficiency of collinear arrays of many elements, compared with other multi-element arrays, relates directly to spacing and mutual impedance effects. Mutual impedance is an important factor to be considered when any two elements are parallel and are spaced so that considerable coupling is between them. There is very little mutual impedance between collinear sections. Where impedance does exist, it is caused by the coupling between the ends of adjacent elements. Placing the ends of elements close together is frequently necessary because of construction problems, especially where long lengths of wire are involved.

The effects of spacing and the advantages of proper spacing can be demonstrated by some practical examples. A collinear array consisting of two half-wave elements with 1/2-wavelength spacing between centers has a gain of 1.8 dB. If the ends of these same dipoles are separated so that the distance from center to center is 3/4 wavelengths and they are driven from the same source, the gain increases to approximately 2.9 dB.

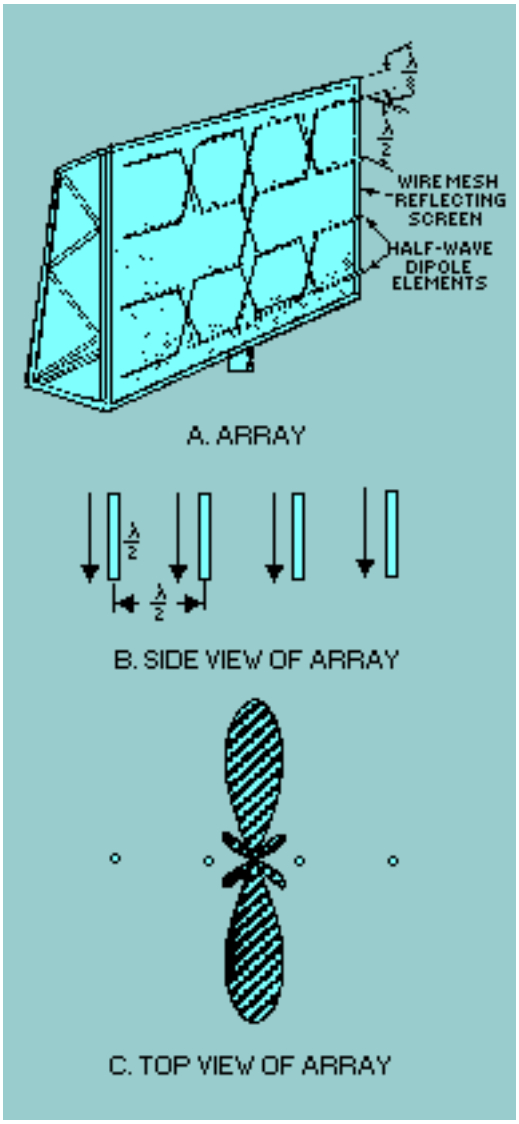
A three-dipole array with negligible spacing between elements gives a gain of 3.3 dB. In other words, when two elements are used with wider spacing, the gain obtained is approximately equal to the gain obtainable from three elements with close spacing. The spacing of this array permits simpler construction, since only two dipoles are used. It also allows the antenna to occupy less space. Construction problems usually dictate small-array spacing.

Broadside Arrays

Educational CD-ROM's
Printed Manuals
Downloadable Books

A broadside array is shown in figure 4-26, view A. Physically, it looks somewhat like a ladder. When the array and the elements in it are polarized horizontally, it looks like an upright ladder. When the array is polarized vertically, it looks like a ladder lying on one side (view B). View C is an illustration of the radiation pattern of a broadside array. Horizontally polarized arrays using more than two elements are not common. This is because the requirement that the bottom of the array be a significant distance above the earth presents construction problems. Compared with collinear arrays, broadside arrays tune sharply, but lose efficiency rapidly when not operated on the frequencies for which they are designed.

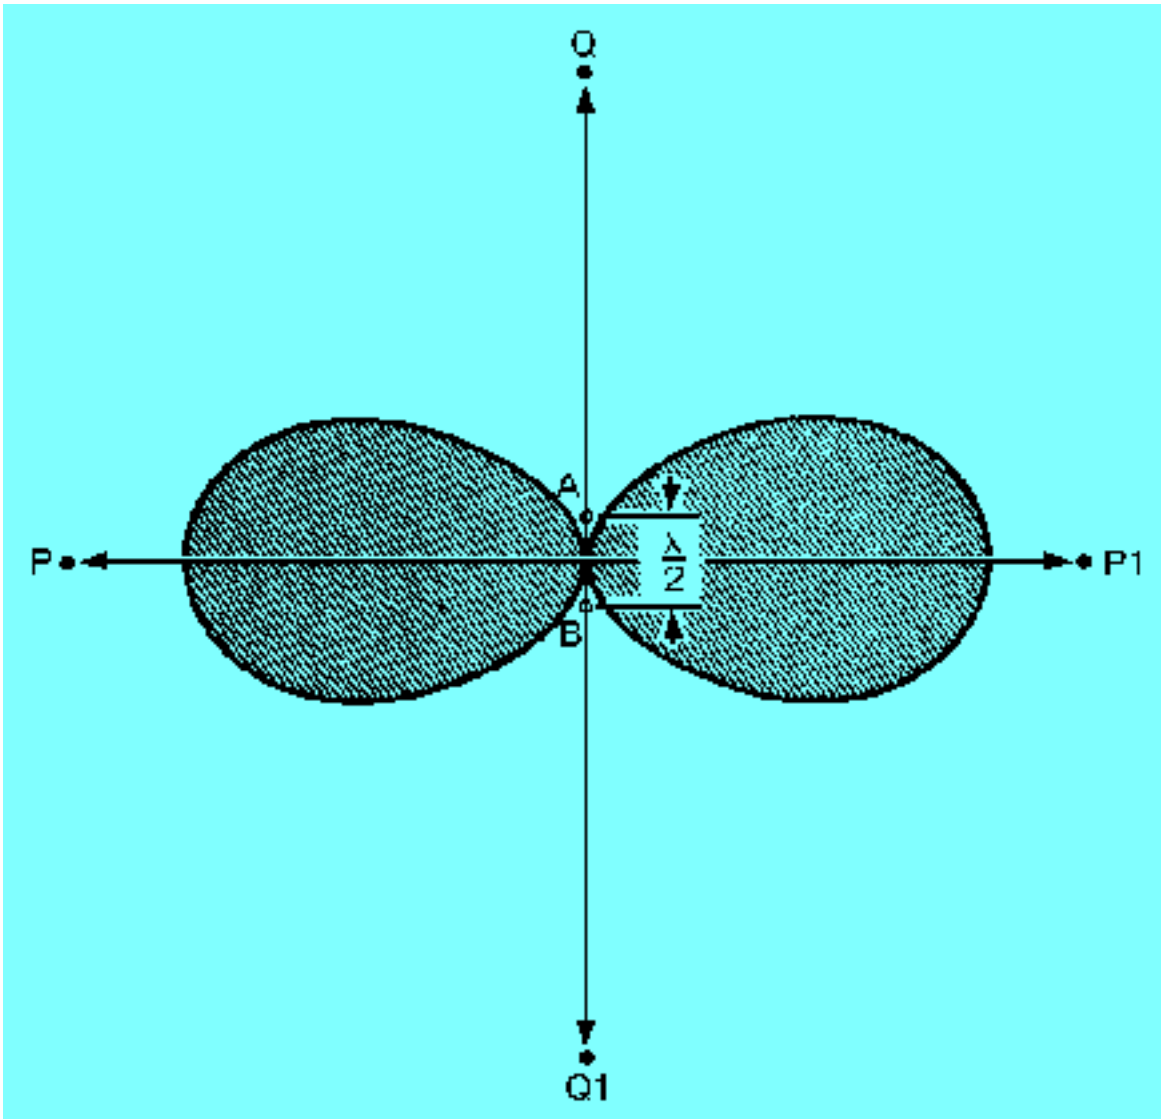
Figure 4-26. - Typical broadside array.



RADIATION PATTERN. - Figure 4-27 shows an end view of two parallel half-wave antennas (A and B) operating in the same phase and located 1/2 wavelength apart. At a point (P) far removed from the antennas, the antennas

appear as a single point. Energy radiating toward P from antenna A starts out in phase with the energy radiating from antenna B in the same direction. Propagation from each antenna travels over the same distance to point P, arriving there in phase. The antennas reinforce each other in this direction, making a strong signal available at P. Field strength measured at P is greater than it would be if the total power supplied to both antennas had been fed to a single dipole. Radiation toward point P1 is built up in the same manner.

Figure 4-27. - Parallel elements in phase.



Next consider a wavefront traveling toward point Q from antenna B. By the time it reaches antenna A, 1/2 wavelength away, 1/2 cycle has elapsed. Therefore energy from antenna B meets the energy from antenna A 180 degrees out of phase. As a result, the energy moving toward point Q from the two sources cancels. In a like manner, radiation from antenna A traveling toward point Q1 meets and cancels the radiation in the same direction from antenna B. As a result, little propagation takes place in either direction along

the QQ1 axis. Most of the energy is concentrated in both directions along the PP1 axis. When both antenna elements are fed from the same source, the result is the basic broadside array.

When more than two elements are used in a broadside arrangement, they are all parallel and in the same plane, as shown in figure 4-26, view B. Current phase, indicated by the arrows, must be the same for all elements. The radiation pattern shown in figure 4-26, view C, is always bidirectional. This pattern is sharper than the one shown in figure 4-27 because of the additional two elements. Directivity and gain depend on the number of elements and the spacing between them.

GAIN AND DIRECTIVITY. - The physical disposition of dipoles operated broadside to each other allows for much greater coupling between them than can occur between collinear elements. Moving the parallel antenna elements closer together or farther apart affects the actual impedance of the entire array and the overall radiation resistance as well. As the spacing between broadside elements increases, the effect on the radiation pattern is a sharpening of the major lobes. When the array consists of only two dipoles spaced exactly 1/2 wavelength apart, no minor lobes are generated at all. Increasing the distance between the elements beyond that point, however, tends to throw off the phase relationship between the original current in one element and the current induced in it by the other element. The result is that, although the major lobes are sharpened, minor lobes are introduced, even with two elements. These, however, are not large enough to be of concern.

If you add the same number of elements to both a broadside array and a collinear array, the gain of the broadside array will be greater. Reduced radiation resistance resulting from the efficient coupling between dipoles accounts for most of this gain. However, certain practical factors limit the number of elements that may be used. The construction problem increases with the number of elements, especially when they are polarized horizontally.

Q.32 What is the primary cause of broadside arrays losing efficiency when not operating at their designed frequency? Answer
Q.33 When more than two elements are used in a broadside array, how are the elements arranged? Answer
Q.34 As the spacing between elements in a broadside array increases, what is the effect on the major lobes? Answer

RADIO HABANA CUBA

The Broomstick Special: Part 1

A compact, easy-to-build shortwave antenna

BY ARNIE CORO
Host of "Dxers Unlimited"

SEND YOUR COMMENTS, QUESTIONS AND IDEAS DIRECTLY TO ME AT:
arnie@radiohc.org

Yes, this is a "helically wound" wire antenna. It can be built in a few hours... it will take longer if you really want to make it look pretty... UGLY versions can be assembled in minutes. It MAY be used without an antenna tuner, BUT... it works best when you do USE a TUNER.

Here are the easy-to-follow, step-by-step building instructions for Arnie Coro's "Broomstick Special:"

1. Obtain a nice broomstick.... you can use a "classic" wooden dowel broomstick, or substitute heavy walled PVC plumbers plastic tubing

2. Diameter of broomstick is not critical; anything from about 1.5 centimeters or better will work (this means that PVC tubing of about 19mm or 3/4 inch is ideal)

3. Prepare a base to hold the broomstick or PVC pipe vertical... Use a wide base, with enough counterweight attached to keep the broomstick vertical (I use mine next to the bedside radio, have convinced the wife that it is "modern art"

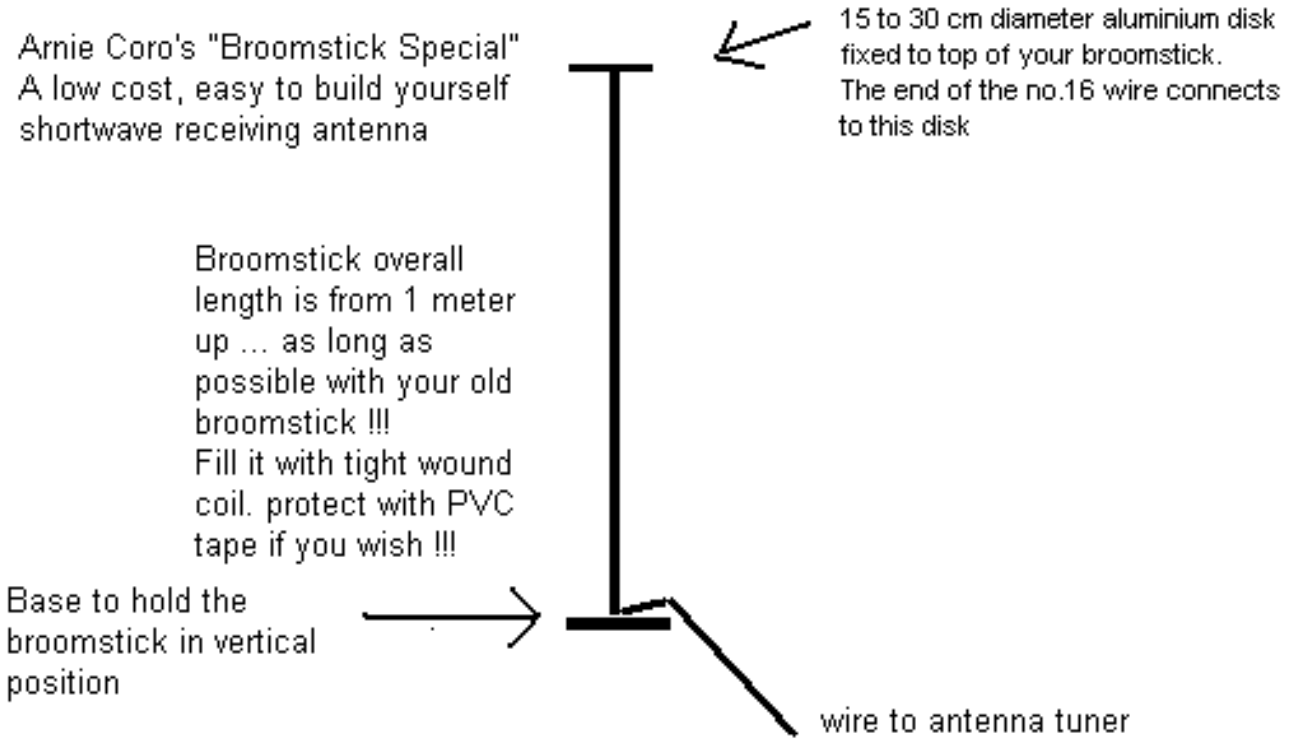
4. Obtain an aluminium disk of no less than 15 cm (6 inches) diameter. I prefer using a disk of around 30 centimeters (12 inches) but this is not critical. DO USE THE DISK... as it provides a capacity hat termination and helps reduce NOISE PICK UP

5. Obtain enough No.16 PVC plastic covered household wire; this is the ideal choice, but if you can't find it, then you may use No.16 or No.18 enamel covered copper wire (the one used for winding motors and transformers). If you can't find No.16 PVC covered wire, then your second best choice is No.18 "speaker wire"

6. Connect one end of the wire to the aluminium disk, and start winding a uniform coil using the "broostick" as the coil form. YOU WANT A NEAT JOB! Turns should fit tightly one next to the other... the "broomstick" will be filled with the wire forming the coil... When you arrive at the bottom end, make a termination> I use a long bolt with

nuts and washers to which I tie the end of the wire, and another wire that goes to the antenna tuner. This wire that goes to the tuner can be from 1 meter to 3 meters long (from 3 to 10 feet) but DO KEEP IT AS SHORT AS POSSIBLE.

7. After the antenna is built, you may want to protect it with tightly wound PVC plastic tape over the wire. For EXTRA protection, you can paint the whole antenna with several coats of SPRAY ENAMEL...



8. The antenna works best near a WINDOW!!! Or better yet, you can install it in your balcony or garden... BUT DO KEEP THE CONNECTIONS TO THE TUNER SHORT

9. The antenna is RESONATED with your antenna tuner.... YOU MAY USE IT WITHOUT A TUNER but results are not going to be as good as when the antenna is connected to the receiver via a well-designed antenna tuner

10. YES... YOU MAY USE IT FOR TRANSMITTING.... BUT... according to recent medical research information, keep it as far away as possible from your body!!!

11. The helically wound "broomstick" is a lot of fun to experiment with... It works best when you provide a ground connection to the antenna tuner - receiver combination. One way of providing an "artificial ground" is to connect a length of wire of no less than 5 meters as a "counterpoise," that meaning that you can let the wire hang around the room's floor or garden. Using the "broomstick" with resonant radials turns it into an excellent amateur radio antenna for a specific band... For example with 4 radials cut for

the 15 meter amateur band and a 4 feet high broomstick, (about 1.5 meters)

I can work a lot of stations on 21 mHz, something I do often to demonstrate to visitors what can be achieved with simple homebrew antennas, even when you don't have a lot of space.

12. QUESTIONS.... to: **arnie@radiohc.org**

13. FOR THE TECHNICALLY MINDED... ***Click here for Part 2 of The Broomstick Antenna!***

Home of the homebrew "Buddipole" - A Portable Dipole Antenna Design

Sorry, your browser does not support Java

This site is for those hams who are seeking a high performance homebrew antenna for hf portable use. As you will see, I am particularly interested in pedestrian mobile operating. I started out in early 2000 with a Gap backpack, a TS-50, and a 7.5 amp-hour, six pound battery. Because I wanted to take my radio with me and communicate on HF, I designed a portable dipole antenna out of easily-found and low-cost materials. The Buddipole is the result of those efforts. This is a lightweight, modular, and rotatable dipole (a great benefit, by the way) and is very efficient on the higher bands. See the links below for information on how to build this popular antenna.

The original antenna design is still great. But there were problems with the PVC plastic pipe. It sags. The connectors become loose. The Radio Shack whips are flimsy, and they bend easily. So, the homebrew Buddipole project took on another level of sophistication. The result is a commercial antenna with the same name. You can find it here: www.buddipole.com.

New materials, like epoxy composite and polypropylene, and 6061 aircraft aluminum, and Delrin. One set of higher-Q coils to work all the bands of the original version, plus 30m and 40m. Parts are custom-machined and we had new custom stainless steel whips manufactured to our specifications. We use stretch Velcro as a strain relief for the new coax rf bead assembly, and the assembly is encased in an adhesive shrinkwrap. Even the brass studs are drilled out to lighten them without sacrificing durability. We have a Delrin adaptor that takes painter's pole threads (Acme) to pipe threads that fit right into the new poly T's on the commercial product.

And now, we have the B.U.G. -- A Buddipole User's Group. You can sign up for this Yahoo Group on this page. A truly great resource to share many of the ideas, experiences, and suggestions for both the homebrew and commercial Buddipole.

Build the homebrew version on this site. Modify it. Tell us what you have worked with it on the air. We are always thrilled to hear from folks who build the antenna and who are active on the air with it! And consider upgrading to the new version, with the Rotatable Arms, that gives you a choice of six different configurations to play with.

Have fun and 73,

W3FF - Budd

Join the Buddipole User's Group!

HomeTech Solutions

RG6Q

RG-6/U Quad Shield Coaxial Cable

- Use RG-6/U Quad Shield for high quality or complex installations and where local over-the-air signals may cause interference.
- Available by the foot and in 1000' spool or box.
- Swept to 2200 Mhz.
- 18 AWG Copper coated steel center conductor.
- Running "FT" count printed on cable makes measuring easy.
- Type CL2. (In-wall rated.) UL Listed.
- **Note:** shipping charges for bulk wire and cable are actual cost.

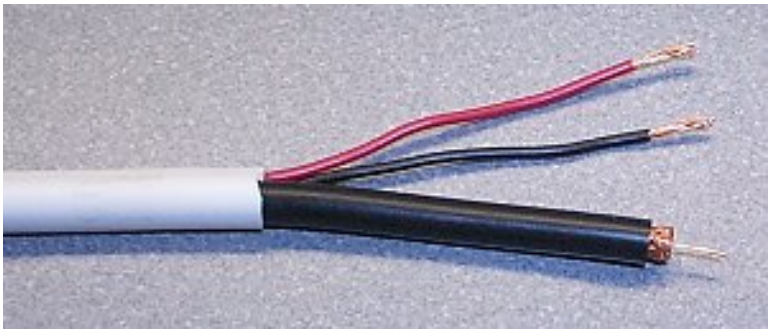
RG-59/U Coaxial Cable

98132

CCTV Camera Cable
1 RG/59U + 2 18AWG Power Wires

- One RG-59 single-shield 75ohm coaxial cable.
- Two 18 gauge stranded wires.
- In a PVC Class 2 rated jacket.
- Perfect for wiring video cameras: Use the RG59 for the video feed and the red and black wires for power to the camera.
- Available by the foot and in 500' spool.
- **Note:** shipping charges for bulk wire and cable are actual cost.



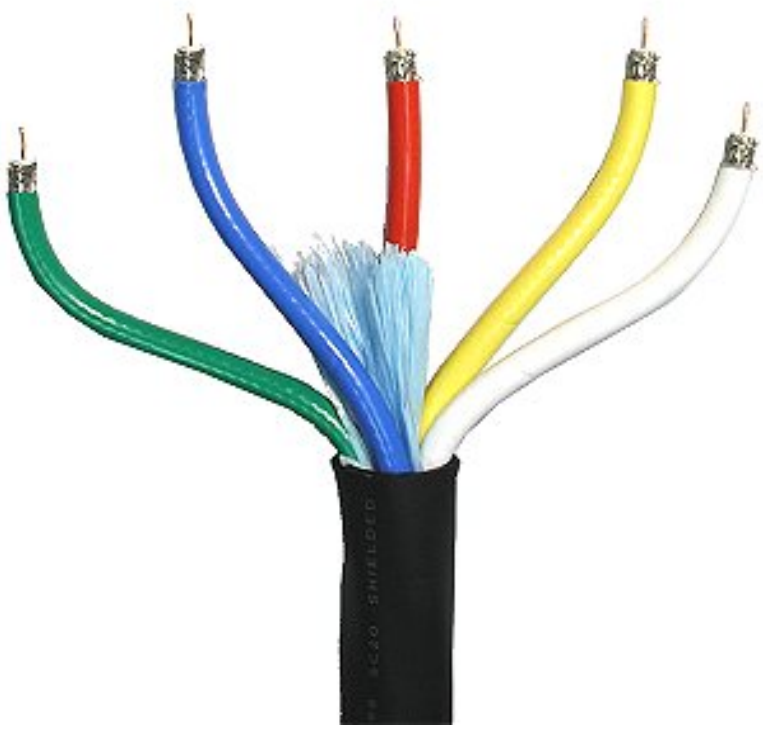
Earn TechCash	**AW-98132** RG59 and 18/2 CCTV Cable	List 0.72 foot	**$0.69 foot**		Enter Qty foot	IN STOCK
Earn TechCash	**AW-98132** RG59 and 18/2 CCTV Cable		37 lbs/spool/500ft **$189.95 spool/500ft**		Enter Qty spool/500ft	IN STOCK

Belden

Authorized Belden Reseller

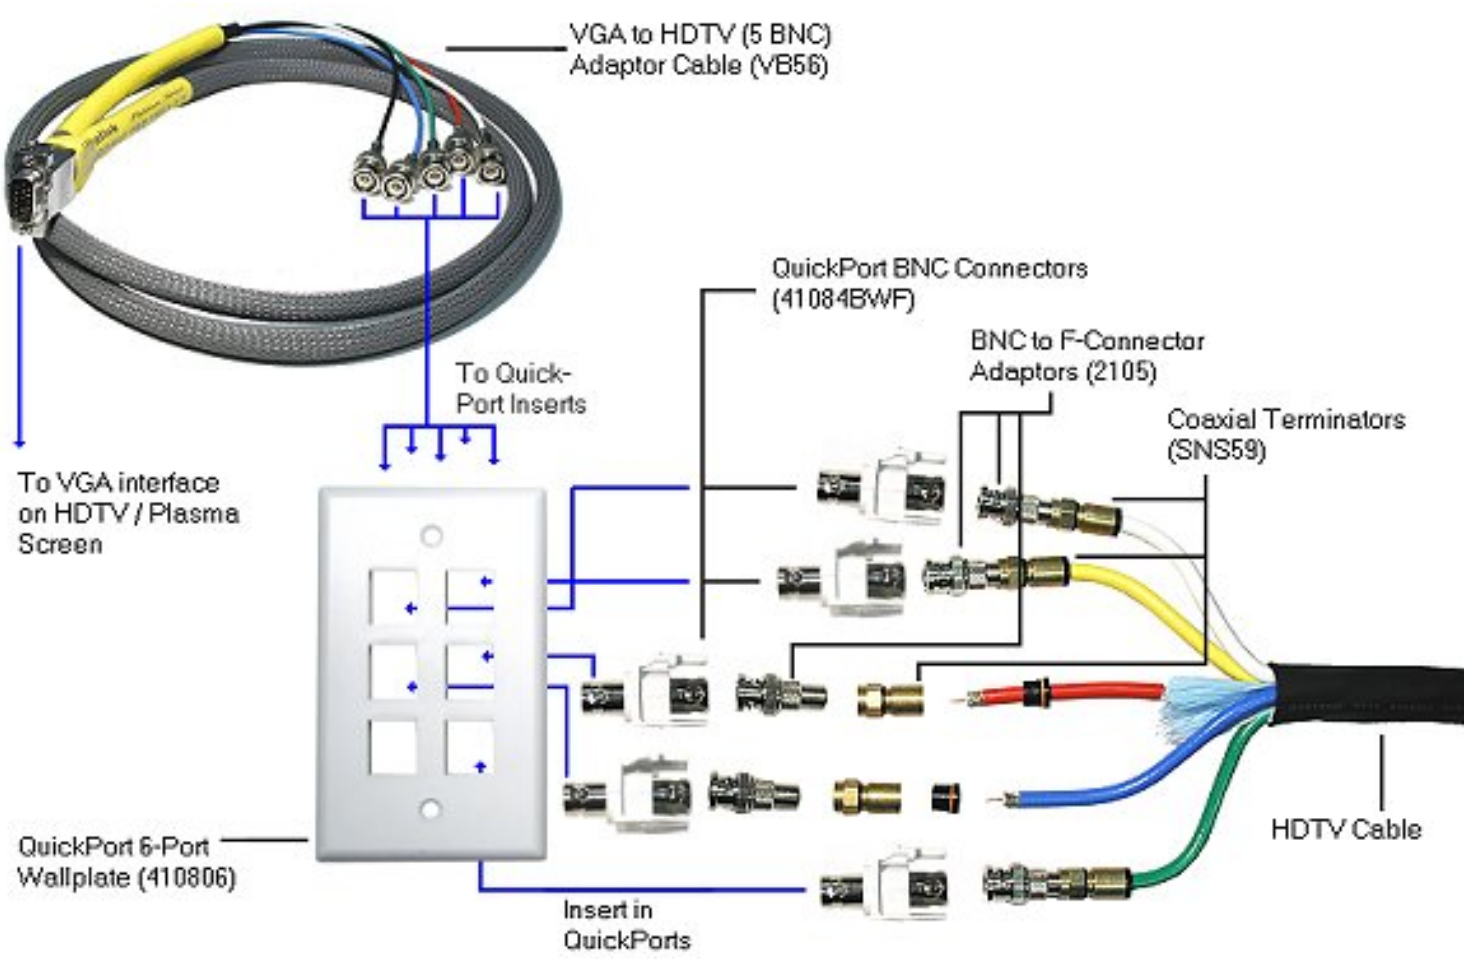
7796A

Five RG-59/U Cable Bundle (HDTV Bulk Cable)



- Belden Quality
- 5 RG59 Cables
- Color coded for easy Identification
- Low-Friction Jacket and filler for consistant shape.
- Easy runs.

This cable can be terminated to BNC male connectors in a two step process. First, strip the coax ends using an IT1000 Stipping/Compression Tool (or similar). Use the SNS59 connectors (along with the IT1000 tool) to terminate the ends. After the ends have been properly terminated, attach the BNC to F-Connector Adapters to each end. See Online Tutorial on terminating coaxial cables using the Snap N' Seal connectors.



You can use the Leviton QuickPort wallplate and the Barrel BNC QuickPort Inserts to professionally the in-wall cable and adaptors.

If your screen has only a 15-pin VGA interface, you need to purchase a UXGA to HDTV (5 BNC) Cable Interconnect. Otherwise, you can connect using BNC Patch Cables.

Earn TechCash	**BE-7796A** Bundled RG59 x 5 HDTV Cable	List 4.00 foot	0.3 lbs/foot **$3.35 foot**		Enter Qty foot	IN STOCK

Miniature Coaxial Cable

Belden

Authorized Belden Reseller

1855A

Brilliance Miniature Dual-Shield Coaxial Cable

Only .16" (< 3/16") in diameter!

- 75 ohm coaxial cable
- 23 AWG solid bare copper center conductor
- Dual shield
- Black suitable for indoor and outdoor aerial applications. All other colors suitable for indoor use only.
- Full Specifications (GIF)
- Connectors available: "F", RCA, & BNC
- Use our 200004 stripper and 300007 crimper.

An excellent coaxial cable for running baseband video (one cable required), s-video (two cables required), component video (three cables required), or UXGA video (five cables required). Also works great for line-level audio and subwoofer audio. The small size of this cable makes it easy to route and hide. The low loss makes long runs >300ft possible. **Not suitable for raw satellite, UHF/VHF, or CATV signals.**

Earn TechCash	**BE-1855AE** Miniature Coax Cable, Black Brilliance VideoFLEX	List 0.42 foot	**$0.35 foot**		Enter Qty foot	IN STOCK

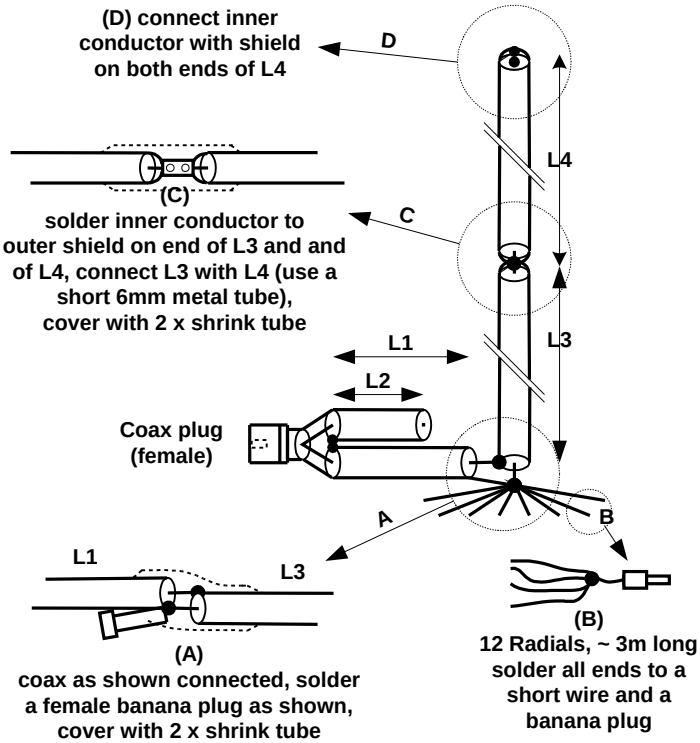
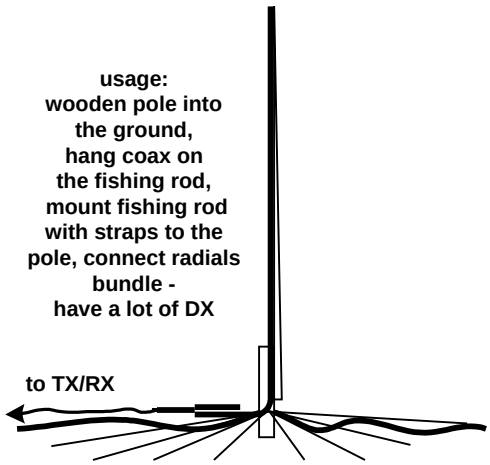
Coax Monopole Antenna
by OE1MWW
Feb. 2002





Feedpoint impedance of antenna is ~ 36 Ohms
YES, it's right, the inner conductor of L1 (feeding coax) is connected to the shield of L3 ! The radiating part of this antenna is the outside shield of L3 and L4.

L1,L2,L3,L3 is made of Coax RG/58 or RG/213

L1 & L2: use the software "coaxstub.exe" to calculate.
`http://www.qsl.net/oe1mww/coaxstub.exe`
you need VB6 runtime!

This document can be found at http://www.qsl.net/oe1mww/coax_monopole.pdf

L3 = f/4 * Vk
L4= (f/4 * 0,95) - L3,
tune L4 for best SWR,
important: inner conductor is connected to shield of L4 on both ends! instead of coax, you can use also a thick wire for L4.

f in meters of wavelength
Vk of coax is ~ 0,66 (RG58U)

DIRECTIONAL ARRAYS

You have already learned about radiation patterns and directivity of radiation. These topics are important to you because using an antenna with an improper radiation pattern or with the wrong directivity will decrease the overall performance of the system. In the following paragraphs, we discuss in more detail the various types of directional antenna arrays mentioned briefly in the "definition of terms" paragraph above.

Collinear Array

The pattern radiated by the collinear array is similar to that produced by a single dipole. The addition of the second radiator, however, tends to intensify the pattern. Compare the radiation pattern of the dipole (view A of figure 4-25) and the two-element antenna in view B. You will see that each pattern consists of two major lobes in opposite directions along the same axis, QQ1. There is little or no radiation along the PP1 axis. QQ1 represents the line of maximum propagation. You can see that radiation is stronger with an added element. The pattern in view B is sharper, or more directive, than that in view A. This means that the gain along the line of maximum energy propagation is increased and the beam width is decreased. As more elements are added, the effect is heightened, as shown in view C. Unimportant minor lobes are generated as more elements are added.

Figure 4-25. - Single half-wave antenna versus two half-wave antennas in

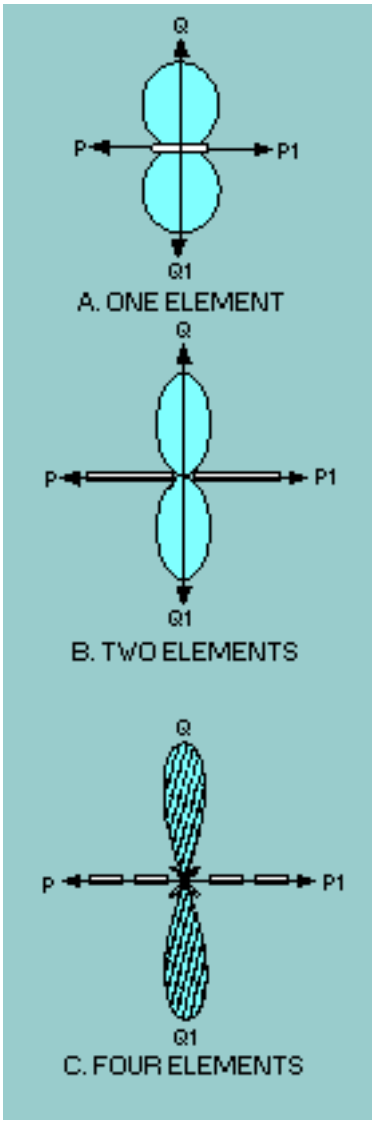
Printed Manuals
Downloadable Books

phase.



More than four elements are seldom used because accumulated losses cause the elements farther from the point of feeding to have less current than the nearer ones. This introduces an unbalanced condition in the system and impairs its efficiency. Space limitations often are another reason for restricting the number of elements. Since this type of array is in a single line, rather than in a vertically stacked arrangement, the use of too many elements results in an antenna several wavelengths long.

RADIATION PATTERN. - The characteristic radiation pattern of a given array is obtained at the frequency or band of frequencies at which the system is resonant. The gain and directivity characteristics are lost when the antenna is not used at or near this frequency and the array tunes too sharply. A collinear antenna is more effective than an end-fire array when used off its tuned frequency. This feature is considered when transmission or reception is to be over a wide frequency band. When more

than two elements are used, this advantage largely disappears.

LENGTH AND PHASING. - Although the 1/2 wavelength is the basis for the collinear element, you will find that greater lengths are often used. Effective arrays of this type have been constructed in which the elements are 0.7 and even 0.8 wavelength long. This type of array provides efficient operation at more than one frequency or over a wider frequency range. Whatever length is decided upon, all of the elements in a particular array should closely adhere to that length. If elements of different lengths are combined, current phasing and distribution are changed, throwing the system out of balance and seriously affecting the radiation pattern.

Q.28 What is the maximum number of elements ordinarily used in a collinear array? Answer

Q.29 Why is the number of elements used in a collinear array limited? Answer

Q.30 How can the frequency range of a colinear array be increased? Answer

Q.31 How is directivity of a collinear array affected when the number of elements is increased? Answer

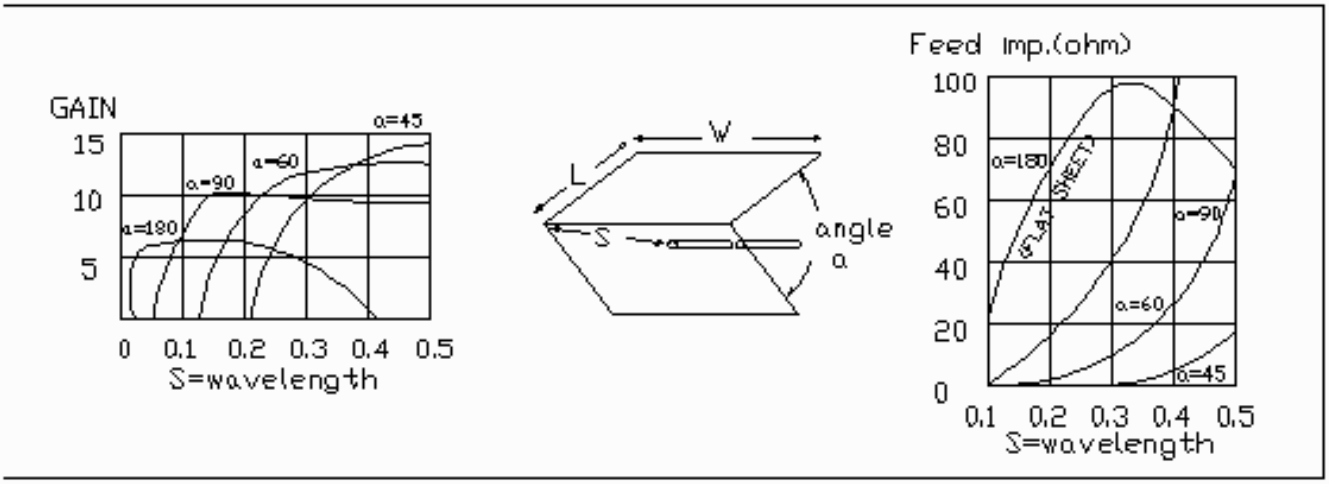
Corner reflector antenna

Do you need a high gain antenna? Have you suffered on picking up interference from unwanted direction? You need a directional antenna but a 12 element Yagi will be too attractive! Well, following might be the answer - a corner antenna. It can provide a forward gain of about 12dbi with a front to back ratio of well over 20dbi.

This design is a periodic plane spaced behind a radiating dipole. The critical factors are the corner angle and the spacing between dipole/vertex (fold point of reflector). The curves in fig.A show that as angle is reduced, the gain becomes progressively greater.

FIG-A RELATIONSHIP BETWEEN ANGLE/SPACING/GAIN



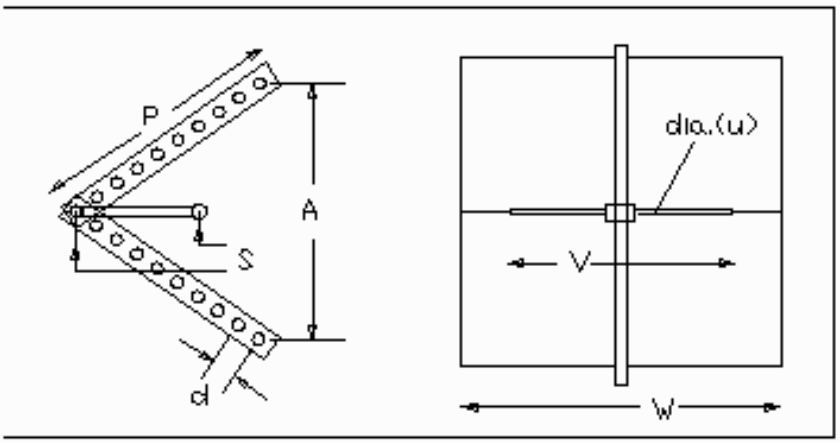


Fig.B
Dimensions for
a 60 degree
reflector antenna

At the same time the feed impedance of the antenna falls towards a lower value and starts creating difficulty in matching. In practice this angle is usually at 90 degree or 60 degree while 90 degree is easier to be matched although gain is lower.

Following are some key points when designing such antenna :

- Length (L) of the sides of reflector should exceed 2x wave-length to secure the characteristics. Reflector width W should be greater then 1x wave-length for a half-wave radiator.
- The reflector can be made of wire netting, sheet metal or even fabricated metal spines arranged in a V-formation. Such spines must be parallel to the radiator with a spine spacing of less then 0.1 wave-length of the operating frequency.
- Spacing between radiator and vertex should be adjustable. This might be the final key to tune-up such an antenna after radiator length is settled for a specific operating frequency.

Impedance of these antennas will change upon operating frequency. Typical value will be around 50 ohm to 75 ohm. A slightly higher S.W.R (1.7:1) has to be expected on lower end of the band. Fig.A also shows relationship between resultant impedance and a change in wavelength (frequency). Following is a table that shows the general dimension of such antenna at UHF and VHF band (Fig.B). All value below are in inches (except **Band** in MHz). Final dimension might vary due to difference in materials employed. Try by error is the key for success.

Band	**p**	**s**	**d**	**v**	**w**	**A**	**u**
144	100	40.0	6	38	50	100	0.375
440	34	13.0	1.4	13	20	34	0.25
435	35	13.5	1.5	13	20	35	0.25

We can discuss it further on the air if you are interested.

THE CROSSED-FIELD-ANTENNA
PART I

by
Maurice C. Hately GM3HAT
& Ted Hart W5QJR

PREFACE: Please be aware this article introduces a completely new concept in antenna theory. In fact, this is considered the most important development relative to antennas in this century. It is so pervasive that a series of articles are required to cover the concept and its applications to the depth and extent it deserves. This is the first publication about the ***Crossed-Field Antenna*** (CFA) in the U.S.A. Even as you read this, there are continuing developments in the application of this concept. ***antenneX*** has more than twenty articles about the CFA, including four construction articles (complemented by several more building experiments by readers from around the globe), plus a look at the actual CFA 1992 and 1995 versions of Tanta Station operated in Egypt. This is followed up by a tour of 10 of Dr. Kabbary's 17 more recent CFA broadcast stations in operation in Egypt and Australia. Further, of interest is that the Isle of Man, UK has chosen to install a CFA longwave broadcast station rather than a 845-foot (260m) tower. More stations are going up in Germany, Italy and Brazil. The articles are in the Reading Rooms now. To read more, goto: **Subscribe**

Where will this concept lead ? Let me tell you about one example, lest you think this is all for naught: A CFA only 21 feet (6.5 Meters) tall, located at Tanta in the center of Egypt, provides AM broadcast service at 1.16 MHz (258 Meters) to millions of people from Cairo north to the coast. Certified measurements provide evidence that this small CFA produces a radiated signal almost 6 dB stronger than the previous 1/4 wavelength vertical broadcast tower which was 211 feet (65 Meters) tall. To express the performance a different way >> with the tall tower, a 100,000 watt transmitter was required for the desired coverage. With the miniature CFA the same coverage was attained with the transmitter power reduced to 30,000 watts.

BANDWIDTH GREATER THAN TALL TOWER!

Unlike conventional small antennas, the CFA has greater bandwidth than the tall tower, thus giving better fidelity to the broadcast signal. If that don't tug your heartstrings, you need to go back to making mud pies. For all the rest—you ain't seen nothing yet. In spite of this, the

antenna "experts" have not widely accepted this concept. I can only conclude that those who did not invent it don't want to admit that someone else did. That is a common malady and is often referred to as the not-invented-here (NIH) syndrome. I personally went through the same thing with the small loop antenna. It is the purpose of ***antenneX*** to expose you to new concepts—whether you accept them or not is your personal preference. Some people still don't think man has set foot on the moon!

INTRODUCTION

While thinking about how to present this article, I (W5QJR) was scanning the web and found the following definition of an antenna: ***"An antenna can be any conductive structure that can carry an electrical current.*** **If it carries a time varying electrical current, it will radiate an electromagnetic wave."** In particular note that this definition of an antenna includes a ***current carrying conductor*****.** This is a concept that came about after Marconi threw up a piece of wire and began radio communications. Ever since it has been the accepted traditional concept of an antenna. While it does satisfy fundamental theorem, it is not the only way to develop electromagnetic waves, and therefore is not the only way to build an antenna. In fact, this is a very inefficient way to develop electromagnetic waves.

A number of years ago (1984) I (Ted Hart) wrote the book on small loop antennas and declared in that book, and several related articles, that the only way to build a small high efficiency antenna was to build a small loop. That statement was true until about 1988.

I am simply telling you that one doesn't have to have a wire antenna—there is another way. The other way came about due to a College Professor by the name of ***Maurice Hately, GM3HAT***, in Scotland, and a student named ***Fathi Kabbary*** who came from Egypt to study under Professor Hately while working on his Ph.D. Together, they reviewed the fundamental theory of antennas and decided there was a better way. This occurred about 1988. Subsequently they published articles and patented their new antenna design. Patent 2,215,524 was issued in Great Britain, 626,210 in Australia and others issued in Europe and Japan. In 1992 the U.S. issued Patent Number 5,155,495. But, I am getting ahead of history, so let me take you back to an earlier time.

However, before giving you a history lesson, I do want to note that Mr. Hately and Mr. Kabbary jointly own all rights to this invention. All rights are reserved by them. If you have a commercial interest, contact the author. Mr. Hately reviewed, modified and approved this article, so you are getting this information from the horse's mouth. I, W5QJR, am merely a ghostwriter and take no credit for any of the development. I have derived great pleasure in working with Mr. Hately for several years and he is now in the process of bringing antennas based on this concept for sale thru ***antenneX***.

A HISTORY LESSON

A long time ago, in a far away place, a fellow named Ampere and another fellow named

Faraday (1791-1867) independently developed the concepts and equations to define electromagnetism. Then along came a fellow by the name of Maxwell (1831-1879) who combined the works of Ampere and Faraday and developed the four (4) basic laws called ***Maxwell's Equations***. These equations are so fundamental that every Engineer considers them to be ***the*** four chapters of the engineering bible. Then along came Mr. Heavyside who developed the Differential form of Maxwell's Equations. Somewhere in there, Mr. Poynting presented his equation defining electromagnetic radiation.

Although many authors have quoted Maxwell, and many a college student has struggled trying to understand Maxwell, nothing interesting happened until along came Professor Hately and Mr. Kabbary (now Dr. Kabbary due to this work). As is prudent to do when tying to understand a concept, you go to the most fundamental version of the concept that can be found. In this case, Maxwell's Equations were only an arm's reach away in any good engineering reference book (for example see page 45-4 of ***Reference Data for Radio Engineers***).

Now, our time clock moves forward to March 1989, when ***Electronics and Wireless World*** published an article entitled "Maxwell's Equations and the Crossed-Field Antenna", by F.M. Kabbary, M.C. Hately and B.G. Stewart. To ensure you get all of this picture in proper perspective, the following paraphrases that article. It may get a little technical for some, but that is the essence of this new antenna concept. We will endeavor to translate to simple terms wherever possible, so please continue to read even if you are not an engineer. The picture would not be complete if the theoretical portion of this puzzle was not included in this series of articles.

A LOT OF HEAVY THEORY

All electrical and communications engineers are in some way acquainted with Heavyside's differential form of the third and fourth Maxwell equations, viz.

$$1)\ \Delta \times E = -B'$$
$$2)\ \Delta \times H = J + D'$$

In these equations, **'** is the derivative with respect to time, **E** represents the electric field strength, **H** magnetic field strength, **J** current density, **B** magnetic flux density = μ **H**, and **D** electric displacement = εE. D' is called the displacement current. Equation 1) is Faraday's law, while equation 2) is credited to Maxwell for adding **D'** to Ampere's law, which is $\Delta \times H = J$ to maintain charge conservation or charge continuity and thus obtain **J + D'** as the true or total current.

Unfortunately, the understanding of these equations still poses many conceptual difficulties for many people which inevitably lead to shortcomings in the basic understanding of their

engineering applications (and you thought you were alone?). One reason for this lack of insight is perhaps the inability to appreciate the physical meaning of the vector operations curl, div and grad. Many texts and research papers often detail the mathematical intricacies of these vector operations but few describe in practical simple terms their physical interpretation.

In addition to the above, it is often not realized that contained in equations 1) and 2) is the following extremely valuable information: (a) a time-varying magnetic field creates an electric field (or back EMF) and, importantly, (b) a current ***or*** a time-varying electric field ***or*** both will create a magnetic field. **Please read again and note that you do not need to run current thru a wire to develop a magnetic field.**

The essence of Maxwell's equations, conveyed through points (a) and (b), is that fundamentally they are reactive or field-production equations. The physical , mathematical and engineering importance of the field-production nature may be more readily relayed and understood if the forms of equations 1) and 2) are reversed:

$$3)\ B' \Rightarrow -\Delta \times E$$
$$4)\ J + D' \Rightarrow \Delta \times H$$

The reversal leads not only to a greater understanding of Maxwell's equations (which is hidden in the non-reversed form) but to a greater appreciation of the nature of time-varying electromagnetics and their associated engineering applications.

One significant engineering application, only fully realized through the reversed form of Maxwell's 4th equation, has been the recent development of revolutionary antenna systems called crossed-field-antennas (CFA) which synthesize directly the Poynting vector **S = E X H** from separately stimulated **E** (electric) and **H** (magnetic) fields. **S** is electromagnetic radiation, thus this says there are two (2) components to the radiated field, **E** and **H**. The **X** is defined as the cross product, meaning that they must be properly related both in time, phase, and position. *In other words, if you can separately create the two fields and properly combine them, you don't have to have a piece of wire carrying a current*. Because of this, **A fundamental feature of these antennas is that the physical size of the structure is small and also independent of the radiated wavelength, a truly remarkable concept in relation to present day antenna theory and design techniques.** (Frame that and hang it on the wall).

The principle of Faraday's Law (equation 1) as detailed by most textbooks, is that an electric field can be related to the rate of change of a magnetic field. This electromagnetic feature can be expressed in a more elegant and informative way by reversing equation 1) to give $B' \Rightarrow -\Delta \times E$ which is interpreted as a time varying magnetic flux, **B'** creating an electric field **E** such that the negative of the curl of the induced **E** field distribution is equal to the source **B'**. The directive arrow is present in the relationship to indicate that the left-hand-side causes or

creates the right-hand-side. The negative sign is a manifestation of Lenz's law. In fact, the application of the reversed form of Faraday's law is fully deployed in transformer theory, where a time varying magnetic flux creates, i.e., induces, a back EMF. Note that the **E** field in the reversed form of Faraday's law is the induced **E** field from **B'** and is not in anyway related to the independent electric field created from free charge through Gausse's law.

Consider now equation 2). In magnetostatics, it has always been accepted that current produces a magnetic field though the phenomenon called Ampere's law. To get across the importance of this statement in a more meaningful physical and mathematical form, Ampere's law should be expressed as: $5)\ J \Rightarrow \Delta \times H$ i.e., **J** (current density) creates a magnetic field **H**, such that the curl of **H** is equal to the source **J.** It is also known (though often ignored) that a magnetic field may be related to either a current as above ***or*** a time varying electric field. The latter source of magnetic field is sometimes refereed to as the Maxwell Law, and may be expressed in the more informative form as: $6)\ D' \Rightarrow \Delta \times H$ i.e., displacement current **D'** (a time varying **D** field) creates a magnetic field **H** such that the curl of the H field distribution is equal to the source **D'**. We now see the importance of reversing equation 2) to give equation 4), i.e., **J + D' => D X H,** which should now be interpreted as **J + D'** or both can create a magnetic field **H** such that the curl of the **H** field distribution is equal to the source **J + D'**. The plus sign can, and should, be interpreted as analogous to the digital-logic **OR** symbol.

Unfortunately, many people fail to realize that an **H** field may, at any time, be the combination of two separately induced fields from independent types of sources, i.e., charge motion and displacement current.

The editor says we are out of space, so we will pick up here next month and apply what we have learned to create a magnetic field without running current thru a wire. This will be accomplished by a simple demonstration. That is essential to the process of building this type of Crossed-Field-Antenna. The heavy theory is behind us so it is down hill from here. Stay tuned. **-30-**

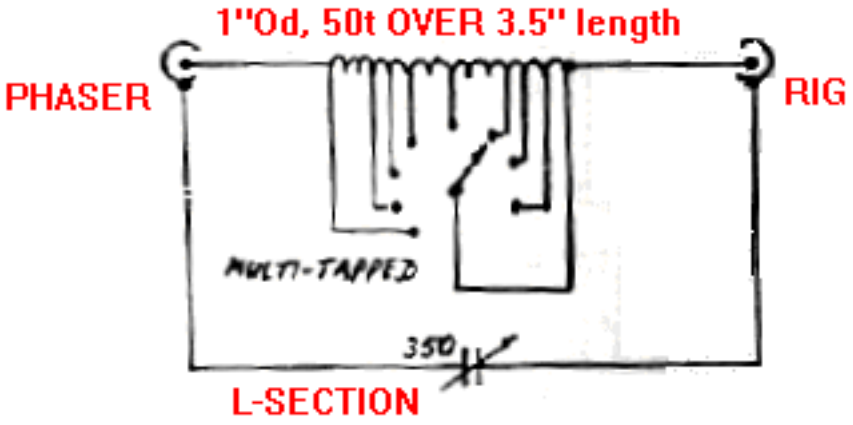
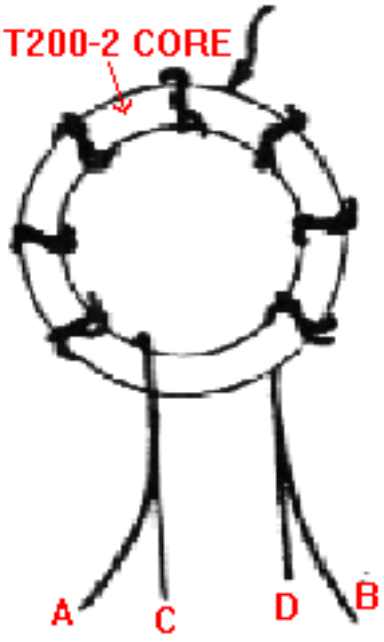
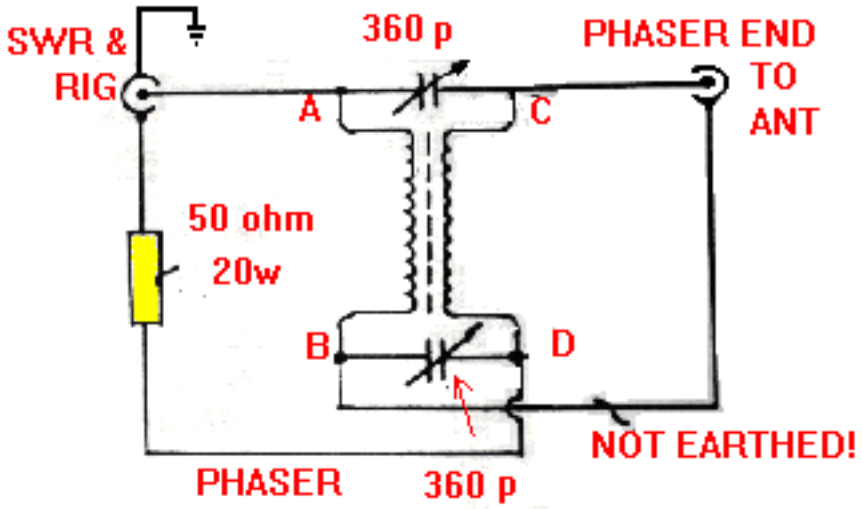
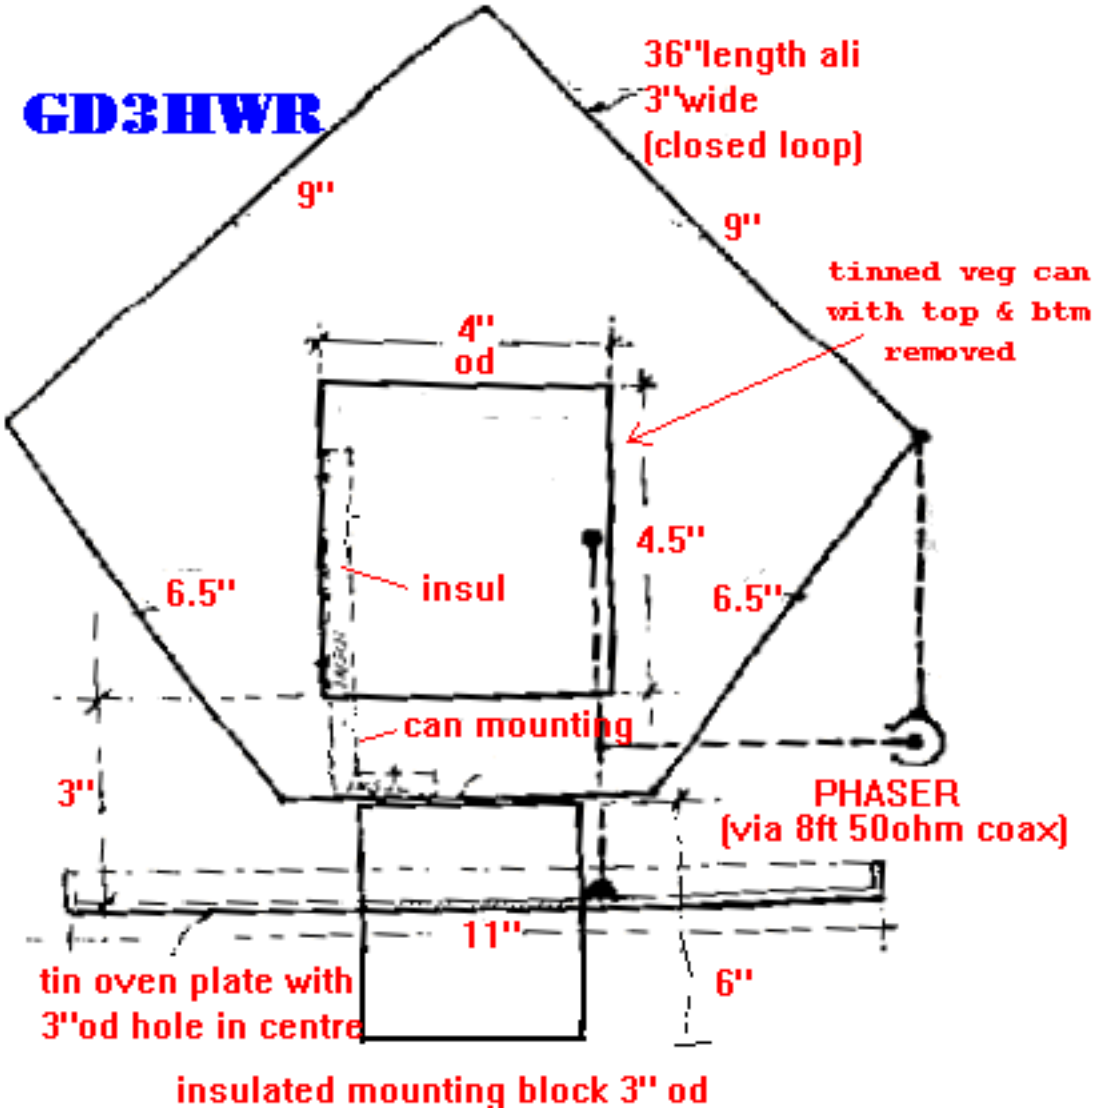
THE MARK II CROSSFIELD ANTENNA









The mark 2 Crossfield Antenna was described in Sprat 76 by **Alec, GD3HQR** . He notes that although it showed no directivity at HF, it was possible to null out time base noise from a TV in an adjacent room. If a valve PA rig with the usual pi section o/p is used, the L-section may not be required. However, it is essential when used with transistor rigs having fixed tuned o/p filters. When tuning the loop, first

approximately tune the L-match by adjusting for maximum RX noise. Then, with QRP, adjust C2 in small steps, at each step adjusting C1 and the L-netwprk for minimum SWR. When this is found, note the settings for future use. Repeat for other bands. Note C2 requires less capacitance at lower frequencies and more at higher frequencies. The author found that, with when properly adjusted, an SWR of at worst 1.5:1 was attained.

It was found that a 1m square sheet of metal - not earthed - placed under the wooden base improved high angle radiation for inter-G working on 3.5/7.0 Mhz.

Note that DC earth is connected to the coax used to connect the L-network to the phaser (it has a capacitive RF earth, which is all that is required).

The author found that his model, used indoors and only six feet above the floor, gave good results on 7 Mhz and above and was 'quite useful' on 3.5 Mhz. It even produced 'the odd QSO' on 1.8 Mhz.

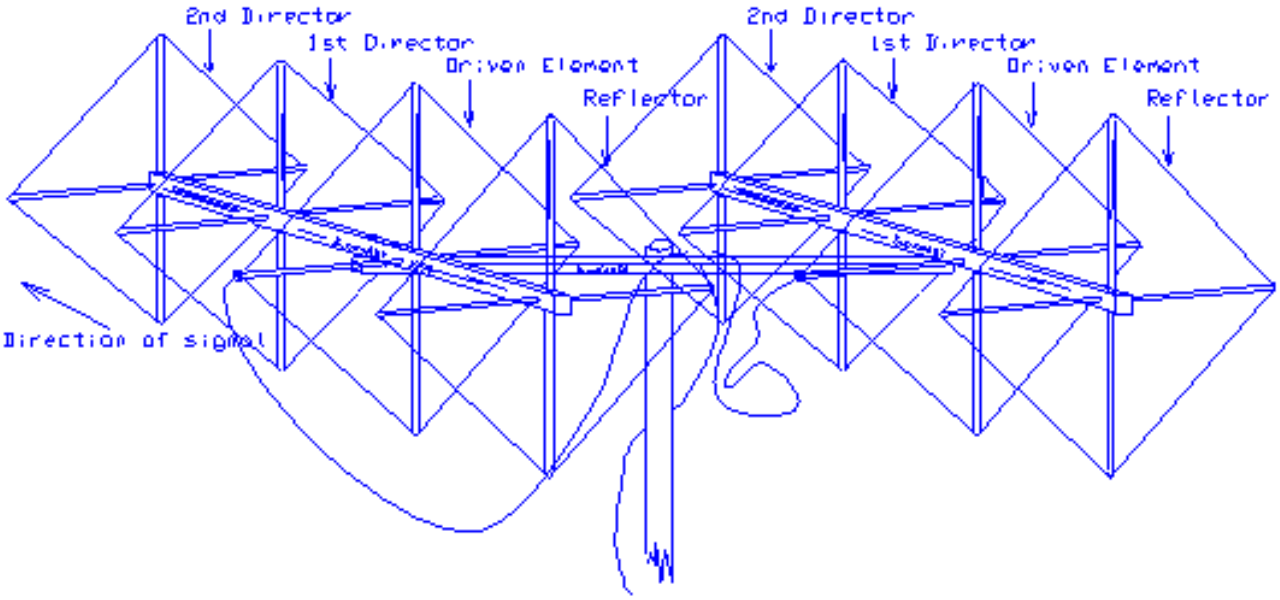
"A" = 1/2" ID hot/cold PVC. PVC should fit securely over 1/2" OD wooden dowel "B."

"B" = 1/2" OD wooden dowel 2 ft long through 1" ID boom. Dowel should extend approximately 9-1/2" out from each side of 1" ID boom. Fit 1/2" PVC ("A") over dowel. Make sure spreader is long enough to support each wire element length as determined by the calculations below. Once PVC is in place over the wooden dowels, drill with small bit and use short wire or picture hanger nail to secure on the dowel. Hot glue may be used as an additional keeper over the wire or nail head.

"C" = Boom may be made from square fiberglass or from round PVC 1" ID. Boom is drilled with 1/2" bit at points where wooden dowels are to be inserted.

NOTE: Make sure the vertical and horizontal dowel holes are drilled offset so the dowels will by-pass each other inside the boom. Drill dowels with 1/16" (or smaller) bit each side of boom and secure with small nail or wire to hold (centered) in place. BOOM is thick wall "Sked 40" 1" ID PVC.

"D" = 1" ID (sked 40/Thick wall) PVC 48" long. Use "fitted" wooden dowel inside to make it more rigid and provide "body" to area where "U" bolts may be attached (rotor head and to boom). See alternate boom mounting.



Horizontal "stacking" of quads will improve the signal strength by at least 3 DB.

Order *Practical Antenna Handbook with CD ROM*

By Joseph J. Carr. The world's favorite antenna book. The most popular book on antennas ever written, widely known as "the antenna builder's bible," Joseph J. Carr's Practical Antenna Handbook, Third Edition is a work for anyone, ham radio operators, short-wave radio listener's -- anyone with an interest in antennas, from the newest of

novices to the most experienced engineer. This empowering book gives you all kinds of projects, yes. And it gives you material that explains why what you did works. But most importantly, it prepares you to design and construct your own antennas "for the cases," Carr modestly suggests, "That the author thoughtlessly failed to cover." This third edition blends, in Joseph J. Carr's words, "the theoretical concepts that the engineers and others need to design practical antennas, and the hard-learned practical lessons derived from actually building and using antennas--real antennas made of real metal--not merely theoretical constructs on a blackboard." Add it to your working library, and pretty soon it'll assume a favorite spot inside your toolbox, beaten up, tattered, annotated with your personal notes...obviously used to the fullest extent. Introduction to Radio Broadcasting and Communications. Radio Wave Propagation. Transmission Lines. The Smith Chart. Fundamentals of Radio Antennas. High-Frequency Dipole and Other Doublet Antennas. C= Spreader arm Length

Reflector tuning stub

How to mount and feed.

Horizontal or vertical polarization of an cubical QUAD-Antenna is determined by placement of the feed point (feed gap on the driven element) - Parasitic elements need to be mounted in the same orientation as the driven element. If tuning gap is present on the parasitic elements, doesn't the placement of this gap effect the polarization. Feed line is made out of standard coaxial cable (RG8/RG58) 50ohm unbalanced, to attach this feed line to the balanced drive element (Quad loop) without proper matching is not advisable, instead use an 1:1 balun
see W2FMI High Power Baluns

Gain vs Spacing

The gain of an antenna with parasitic elements varies with the spacing and tuning of the elements, and thus for any given spacing there is a tuning condition that will give maximum gain this spacing. The maximum front to back ratio seldom, if ever occurs at the same condition that gives maximum forward gain. The impedance of the driven element also varies with the tuning and spacing, and thus the antenna system must be tuned to its final condition before the match between the coax and the antenna can be completed. However, the tuning and matching may interlock to some extent, and it is usually necessary to run through the adjustments several times to insure that the best possible tuning has been obtained.

Cubical Quad Antenna Design:

By: Dr. Carl O. Jelinek N6VNG

The frequency scaling formulas for Cubical Quad antennas are shown in Figure 1. Note that frequency is measured in Megahertz {MHz} and the total length of each element is measured in feet {ft}. The spacing of each element is the same and all directors are the same size. The gamma match uses a small air variable capacitor approximately the value given and an adjustable shorting bar at the end connected to the element. The antenna is tuned by adjusting the length of the shorting bar on the gamma match for minimum VSWR with the variable capacitor half engaged. Then adjust the capacitor for minimum VSWR at the mid band frequency. The enclosed EXCEL program can be used to determine the element lengths and the gamma match values for different frequencies. In general the design is robust and may be optimized for gain or front to back by adjusting the spacing of the elements. This antenna design has been built for both the ten and two meter versions and I have used them for T-Hunting and in two CVARC Field Day events with good results. Figures 2 and 3 show the calculated antenna patterns and performance. Table 1 shows an example output from the EXCEL Scaling program. Figure 4. Shows VSWR vs. Frequency for three different 2 meter antennas, a 4 element Quad, a 6 and a 12 element Yagi.

Cubic Quads

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 2/25/2000)

Cubic Quads

The cubic quad is a very popular way to get reasonably high gain and excellent front to back ratios as well as low angles of radiation for without going to extreme heights. Here I present several designs that that achieve the great performance that hams have associated with this antenna for years. Data are presented for 2 and 6 meter quads and a combined 2 and 6 meter quad that is optimized. The 2 meter 3 element design gets a great 9.5 dBi gain coupled with a F/B ratio of 23 dB.

Light weight portable cubic quads can be constructed rather easily from fiberglass tubes supported by central hubs. You should be familiar with the material presented in the Quad Loop and Pfeiffer Quad sections of the Antenna Magic page. Cubic quads for wavelengths shorter than 15 meters are easily constructed, however, you should be aware that the weight of these structures is larger by a factor of about 3 relative to most of the planar designs presented in the main menu. Because of this, a heavier mast must be used to support the structure in most cases. Also, be aware that the space needed to assemble and raise a full cubic quad is larger than for the planar designs, and this may be a significant limitation imposed in some locations. In my own case, the backyard associated with my town house is barely large enough to assemble a cubic quad with spreaders of 8' in length. Wires and guy cords get tangled in the fruit trees, and spreaders hang over into neighbor's yards. Anything larger 8' with extended spreaders is essentially impossible to assemble without working above the level of the fence and fruit trees. For that reason, I shall present only two designs which are more or less typical of what can be done easily. The two designs presented are for HF and VHF and should be useful to a wide audience. The HF design is a two element quad for 10, 12, and 15 meters while the VHF design is a two element design for 6 meters with three elements for two meters. A specific advantage of the standard quad design is that multi-band operation is easily accommodated.

2 and 6 Meter Quad

The spreader length necessary to support a 6 meter quad is less than 3.5 feet, so the standard 8' lengths of fiberglass tubing can be cut in half to make 4' sections. It is also possible to telescope shorter sections of 1/2" and 1/4" tubing to make a slightly lighter weight design. In that case, the 8' sections could be cut in quarters and the overlap of about a half a foot would be entirely adequate for the telescoping leaving spreaders of about 3.5 feet. The boom length for a full quarter wave spacing is less than 4.75 feet, so a single 8' piece of 1" fiberglass tubing is more than ample.

Looking quickly at the 2 meter requirements, the spreaders need be no longer than 1.25 feet and a three element wide spaced boom requires no more than 31.25", thus this can be easily tucked between the 6 meter 2 element quad. In fact, it is necessary to stretch it out a bit. So, a common design requires beginning with an optimized design for 6 meters and accommodating the 2 meter design to the locations of its two hubs. The third 2 meter hub occupies a space between the two 6 meter hubs.

Looking at an optimized 2-element 6-meter design, the following parameters give excellent performance:

Parameter	Length in "	Length of Loop in "
Reflector Loop	21.42 Side	85.70
Driven Loop	20.60 Side	82.38
Director Loop	20.18 Side	80.72
Reflector Location	-11.77 Boom	Relative to Driven Element
Director Location	19.44 Boom	Relative to Driven Element
Total Boom Length	31.21 Boom	

Table 1

Dimensions of a 3 Element Cubic Quad for 2 Meters

The 6 meter parameters are given in Table 2, which is a simple two element design:

Parameter	Length in "	Length of Loop in "
Reflector Loop	58.91 Side	235,64
Driven Loop	55.87 Side	223.48
Boom Length	47.41 Boom	

Table 2
Parameters for 6 Meter 2 Element Quad

The next step is force the 2 meter 3 element quad to have a total boom length identical to that of the 6 meter quad. Note that the 2 meter 3 element easily fits within the same space as the 6 meter 2 element, that the 2 meter quad will have a longer boom than is considered optimum.

(To Be Continued)

10, 12, and 15 Meter Quad

The construction of 2 element cubic quads for 10, 12, and 15 meters is not very difficult, but the structure requires some guy strings to keep the light weight elements from bending. The bending actually would not degrade the performance very much, but the nice square structure clearly looks better, and it will probably hold up better under high winds. In order to keep the spreaders from bending due to gravity loading and wire loading, you will need to have a place to guy them from two directions. The antenna wires can serve as structural elements to help reduce the bending in the plane of the loops. However, bending is also a problem perpendicular to the plane of the loops, and guy strings are necessary to stabilize that direction as well. The easiest way to provide a place to connect the guys is to use a boom extension. The extension does not need to be any longer than 3 feet for 8' spreaders. In the case of 15-meters, the boom can be about 8', and the two extension increase the boom to 14' or a turning radius of 7'. The actual turning radius of a quad depends upon whether it is set up as a diamond or square configuration, the square being the smaller of the two.

Theory - Practice - my Quad

MY QUAD (2 EL. FOR 10-12-15 MT)

I built two quad (one to me, the other to Mario, ik7zcq).

I used "+ " ("Diamond") configuration which gives just 0,1-0,2 db more in the gain than "Square" configuration: I built it in this way only for mechanical reasons. I used square-aluminum boom 30*30*1 mm 180 cm length; into it I put a steel pipe just to make it stronger; the mast to boom attachment comes from a CB antenna ($6)(see picture 1).

The spreader to boom attachment (one for each element) is home-made using a square-steel bar (35 cm length); on the tips there are 4 perpendicular

pipe (25 mm diameter) where you'll insert poles (see picture 2).

Poles are 5 mt length (21 mhz); I use four bamboo poles for each element ($1 each); each pole is 240 cm length so I made it longer using in the lower part a short aluminum pipe (25 mm diameter, 100 cm length).

I gave the poles a protective coat of boat-paint and then I covered it with PVC ribbon (thanks to Jan, G0KRL for info).
Loops are on copper-insulated multi-wire (1mm for my quad, 3mm for Mario's one).
Here are formulas for loop length:

L(Driven)=7658/F
L(Reflector)=7849/F
L(Director)=7430/F
L=Length for one side.

I never spent time tuning it (it's "no problem, no tune", and works fine!) but I know working some hours I can optimize Gain or F/B Ratio ecc.

I fed driven elements with 3 (one for each band) 1/4 lambda stub using TV 75 Ohm cable; on the Mario's quad i used RG 11 useful for high power; over the outside of the feed line, near the feed point, there are some ferrite beads taped up and sealed against moisture: that's my balun (see picture 3); on the boom there's also the rele' box for antenna switch (see picture 4); then a common 50 ohm RG 213 goes down on the shack.
I suggest you do not solder the stub directly on the loop, but using a SO239: here it's still working fine but will be better how i suggest.

The weigh of my quad is about 15 Kg.

HOW DOES IT WORK?

Oh guys! It works very fine! My quad is only 8 mt up, but it never performed worse than a 3 element yagi (sometime I hear what yagi doesn't; I don't know why european stations give me better reports than mine (If I give them 5/7 they give me 5/9, 5/9+); with Dx station reports are the same. The same occur with F/B Ratio: it's about 15 db with european stations, more with Dx.
Using the quad I forgot my antenna-matcher: SWR is less than 1:1,6 at the end of the band;

I think home-brew this antenna is easy: everybody can do it! I spent less than 100$ and I have a very fine beam; may be this summer I'll add 18 e 14 loops but this is an other story…

73 de iz7ath, Talino

Quad Loops

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 2/25/2000)

Quad Loops

Quad loops can be a practical way to get some gain without constructing a full Cubic Quad. The free-space gain of a square loop is about 3.13 dB which is a little improvement over a dipole. If you raise the center of the loop up just one half wave length, a peak gain of 7.75 dBi is reached near 24 degrees elevation. This is not too bad for a simple antenna, and even for 20 meters, the center height will only be about 32 feet. You have the choice of either horizontal or vertical polarization and the decision as to whether to set the spreaders up as a cross or and X. Most people choose horizontal polarization which places the feed at the bottom of the loop. The cross or X selection may depend upon the structure and how close the antenna is to the ground. Normally, the X construction can be more stable in that the weight of the wires is supported by two spreaders while a single spreader must support the entire wire mass as well as part of the weight of the horizontal spreaders in the cross configuration. The cross configuration has definite advantages in height over the X and puts more of the wire at a greater height above the ground. This configuration puts a high current region at the upper apex and gives a better elevation pattern for a given height of center above ground. And if you live in lands of snow and ice, the water runs down the wires and off the corners rather then freezing to the horizontal wires. A definite advantage!

I have constructed quad loops for several bands, but most of my effort went toward a 17 meter loop using 1/2" diameter spreaders extended by 1/4" telescoping sections approximately 2 feet long. There are few secrets to success here, however, the information in the ARRL handbook for driven elements seems to give antennas that are a little small, but that could be due to my environment. The ARRL Antenna book gives the formula 1005/fMhz for computing the length of wire needed for the full loop. It may be better to begin with 1030/fMhz and cut back if the frequency comes out too low. The #14 flex-weave wire is a good choice as it stretches out easily, however, it is definitely over-kill and much lighter wire can be used.

The driving impedance of these loops is a little inconvenient, mine measured about 130 Ohms which agrees well with theory, so a 2:1 balun is recommended or a quarter wave of 75 Ohm

line as a matching section. I have found it a bit of a trick to make a good balun that raises the impedance by a factor of two, but there are excellent directions in Jerry Sevick's, W2FMI, book "Building and Using Baluns and Ununs." It is important to make the characteristic impedance of the transmission line winding 100 Ohms as directed, otherwise the high frequency properties will be compromised. An alternative way to feed these loops is to use 300 Ohm twin line or ladder line. I've used a half wave length of 300 Ohm foam filled line with good results by connecting to the balanced line terminals on the antenna tuner. This presents roughly 130 Ohms to the tuner that is expecting 200 Ohms for a perfect match. This small SWR is easily tuned out. And, if weight is an issue, then this is definitely the way to go!

Let's consider the spreader length. Using the formula for the wire length (1005/fMHz), we see that the spreader must be at least (1005/fMHz)/(4*sqrt(2)). For 15 meters, this comes out to about 8.4 feet. Thus, short extensions to the 8' spreaders are required. The extra 0.4' is really no problem for 1/4" rods or tubes, but 17 and 20 meters require special attention. The spreaders for 17 meters must be about 9.82 feet, or an extra 1' 10". In the case of 20 meters, the extensions need to be 4.5'. This latter case is really pressing the limits of what can be done with the light weight materials. All versions of the quad loops require guy lines for wavelengths longer than 15 meters. This means that you must have a boom section that extends about three or four feet either side of the hub. The guy lines can be Nylon fish line, however, Kevlar line works better in this application,because it does not stretch like the Nylon and the lengths can be accurately calculated. Even with guy lines, the 20 meter loop will require lighter wire, i.e., you will not be able to stretch out #14 flex-weave on this structure. Although the 15 meter structure can be managed without guy lines, the spreaders can be bent out to tension the wire. Using #20 stranded copper wire will cost less than 0.25 dB of gain. So you could use stranded hook-up wire. This wire normally comes with insulation, so, you could strip it off exposing the wire to weather, or leave it on and shorten the length by a few percent to compensate for the dielectric loading. I suggest that you leave the insulation on, and buy black Teflon insulation to make the wire less visible. Radio Shack offers a black #18 hook-up wire that also works well.

The construction of loops for 2, 6, 10, 12, and 15 meters is rather straight forward, so the parts list is short. The construction of loops for 17 and 20 meters requires more extensive guy lines, so the parts list grows to cover extra guy ties and spreader extension. We suggest using a short boom with guys for all bands longer in wavelength than 12 meters. As a short boom is required to put the hub in vertical position, adding extra length to the boom and the extra guy lines is really no inconvenience and provides a much more stable structure. Loops for 2 and 6 meters require no guys at all. You should order only enough 1/2" tubing to make the four spreaders for the VHF loops. The 1/2" Guy Ties are convenient for mounting the wire.

In all cases, you will need a mast-to-boom plate with appropriate U-bolts for mounting the 1" boom to the upper mast section. You also must decide if the hub or the boom plate is to be in the center, i.e., both can not be in the center of the boom. In general, it is simpler to put the hub in the center in that all the guy lines can be cut the same. This choice slightly unbalances the the weight at the top of the mast, but this can be compensated easily by adding weight (fishing

sinkers) to the shorter side of the boom relative to the boom plate. The construction of boom plates is given in detail in the ARRL Radio Amateur's Handbook. The material of choice is usually aluminum, however, I have been using 1/4" PVC plates with success, and it is even easier to cut and drill than the aluminum and seems to have adequate strength. I have been using four U-Bolts on both the mast and the boom, i.e., two on each side of the mast and boom.

You should order the following parts for 10 and 12 meters:

Item	Quantity	Description
1	1	HUB 4-050-100, Central Quad Hub (RFJ)
2	4	8' 1/2" OD fiberglass tubing, spreaders (MGS)
3	1	8' 1" OD fiberglass tubing, boom (MGS)
4	4	GT 4-050 1/2" Guy Ties, for tips of spreaders (RFJ)
5	2	GT 4-100 1" Guy Ties, for tips of boom (RFJ)

Additions for 15 meters:

Item	Quantity	Description
6	1	1/4" OD fiberglass tubing, spreader extensions, quarter it! (MGS)
7	4	1/2" stainless steel hose clamps, compression clamps for extensions
8	4	GT 4-025 1/4" Guy Ties, for tips of extensions or wire attachment (RFJ)

Additions for 17 meters:

Item	Quantity	Description
9	1	8' 1/4" OD fiberglass tubing, spreader extension, halve it! (MGS)

Additions for 20 meters:

Item	Quantity	Description
10	2	8' 1/4" OD fiberglass tubes, spreader extenders (MGS)
11	8	GT 4-050 1/2" Guy Ties for cross truss ties, (RFJ)

Note, the spreader extenders can be full 8' lengths of 1/4" tubing, i.e., you don't need to cut them, but you can reduce the weight slightly if you do. They can be cut to 5' lengths leaving 3'

pieces for use with smaller quads. The 20 meter structure requires cross truss guy lines (for details see our Construction Page). These require more guy tie points near the centers of the 1/2" spreaders. It is easier to align the tensions if the Guy Ties are separate for the interior and exterior guys, but common tie points can be used if the guy lengths are cut accurately. The total number of guy lines is as follows:

Item #	Quantity	Approx. Length ft.	Description
1	8	9.0	interior spreader to boom posts (4' post assumed)
2	8	13.2	exterior spreader extension to boom posts
3	4	11.3	interior perimeter guys (could be wire loop)
4	4	17.7	exterior perimeter guys (could be wire loop)
5	8	9.0	interior cross lateral trusses
6	8	13.2	exterior cross lateral trusses

Table of Guy Line Lengths and Definitions

for a grand total of 40 lines requiring 80 attachment clips and a total length of material of 1084.4 ft. You should plan a full day for the first construction of the 20 meter loop. Once assembled, the antenna can be disassembled in about the time required to roll up the guy material. Re-assembly takes about an hour.

Reden

Veel heb ik geleerd van artikelen die door andere zendamateurs geschreven zijn in Electron en andere electronica bladen. Als tegenprestatie probeer ik hetzelfde te doen voor anderen.

Doelgroep

Volgens vele zendamateurs wordt tegenwoordig in tijdschriften van verenigingen een onderwerp veel te theoretisch gepresenteerd. Daarom zal hier zoveel mogelijk de praktische kant toegelicht worden. Beginnende of nog onervaren zendamateurs worden dan mogelijk ertoe aangezet om ook eens te experimenteren of zelf iets te maken. U hoeft zich niet te schamen, begin eenvoudig en bedenk dat velen over zelfbouw praten, maar het verder daarbij laten. De meeste kennis wordt opgedaan door het zelf te doen. Tijdens het bouwen en experimenteren wordt inzicht verkregen, vooral als het niet meteen lukt of er iets kapot gaat. Men gaat fout zoeken, meten, vragen, lezen en proberen. Als tenslotte het zelfbouwproject goed werkt of de koopdoos door u is gerepareerd, verbouwd of afgeregeld, dan is de voldoening niet te beschrijven. Er is geen drempelvrees meer en een verlangen naar een volgende uitdaging is een feit.

BACK BACK

Activiteiten PAØFRI

Mijn voornaamste bezigheden zijn experimenteren, bedenken, veranderen, proberen, "ontwerpen" en af en toe publiceren. Er zijn ongeveer 20 verschillende praktische onderwerpen van mijn hand verschenen in ELECTRON (14), CQ-PA, Radio Communication, CQ Friese Wouden, QRP NIEUWSBRIEF en andere tijdschriften die artikelen hebben overgenomen. Zelfbouw wordt ook veel gedaan, maar als alles naar wens werkt neemt de belangstelling af. Vaak wordt het bouwsel weer gedeeltelijk of volledig gedemonteerd om over onderdelen te beschikken voor een ander idee. Als het de bedoeling is om het apparaat te gebruiken, wordt het ook netjes afgebouwd, maar het afwerken van de frontplaat laat nog wel eens lan…g op zich wachten. Veel schakelingen en andere bedenksels die hier getoond worden zijn eigen ontwerpen. Praktische ervaring is vooral opgedaan met antennes, antenne tuners, baluns, HF versterkers, ontvangeringangen, mixers, AF& HF spraak processors en 2m transistor eindtrappen.

Voornamelijk wordt gewerkt op HF met een gemodificeerde Ten Tec Corsair II, R5 vertical en inverted zelfbouw W3DZZ gevoed met openlijn via een S-Match symmetrische antennetuner.

Er zijn zelfbouw lineaire versterkers FRI-400 (4 × PL519 400W), FRI-750 (TB3/750, 750W), een gemodificeerde Ten Tec Centaur (3 × 572B, 800W) en een opgeknapte Heathkit SB-200. In ontwikkeling is een FRI-1500 (1500W) met een Russische tetrode GU-43B in een passief rooster schakeling. Lineairs worden zelden daadwerkelijk ingezet op HF banden. Het bouwen is leuker en zij worden het meest gebruikt om tuners, dymmy-loads, low-pas filters, coaxkabels en openlijn te testen.

Inmiddels zijn ook vele anderen geholpen bij het oplossen van problemen met hun HF versterker.

BACK BACK

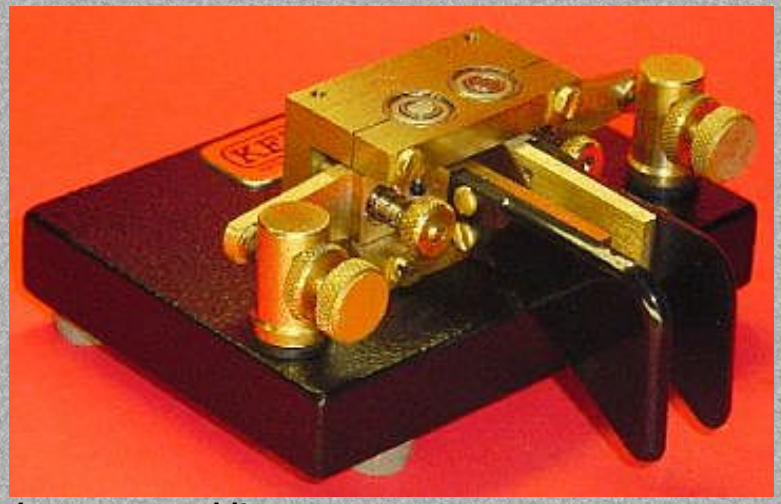
Biografie PAØFRI

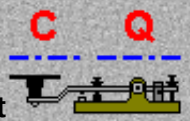
Toen ik 10 jaar was zijn de eerste schreden op het electronicapad gezet met het bouwen van een kristalontvanger. Wie deed dat destijds niet? Niet veel later doneerde een radioknutselaar uit de buurt mij een paar oude "lampen" en andere onderdelen. Daarmee zijn onder zijn supervisie rechtuitonvangers gebouwd.

De volgende stap was de zelfstandige bouw van een supertje met 1.4V batterijbuizen. Destijds een sensatie als je als enige met een draagbare ontvanger (formaat kleine koelbox) op het strand van Castricum en Scheveningen verscheen. De 90 V batterij was veel te snel leeg en een nieuw exemplaar was een behoorlijke aanslag op het zakgeld. Verder zijn veel projecten nagebouwd uit Radio Bulletin, Radio Electronica en Jongensradio delen 1, 2 en 3.

Daadwerkelijke kennismaking met het zendamateurisme vond plaats in 1961. In dat jaar werd ik CW operator van PI1KMA. Één van de verantwoordelijke zendamateurs was wijlen Henk, PAØDB. CW lessen konden op vrijwillige basis gevolgd worden en samen met instructeur van Lieshout heeft hij mij de edele kunst van  morse seinen en opnemen geleerd. Hun geduld werd op de proef gesteld omdat de leerling niet paste bij de gangbare lesmethode, hi! Gelukkig werd de drill losgelaten en met bijlessen in de schaarse vrije tijd is een ontbrekende morsevaardigheid nog betrekkelijk snel opgedaan.



Een paar jaar later is met goed gevolg examen gedaan voor een A-machtiging en de overheid gaf een "bevoegdheid" af. Een zender moest toen een half jaar na het examen ter keuring aangeboden worden als meteen de call werd aangevraagd. Zag men ervan af dan werd een "bevoegdheid tot het bedienen van…" verstrekt. Daarmee is regelmatig als gastoperator bij clubstations of andere zendamateurs gewerkt. De eigen call PAØFRI is pas in maart van 1969 telefonisch aangevraagd en toegewezen. Toen kon dat nog en was het binnen een paar minuten geregeld!



Gestart werd met en EL500 in een eigenbouw 30W CW zender. Ook de ontvanger was een zelfgebouwde Semcoset Semiconda.

Het bouwpakket kwam van Schaart die zijn commerciële activiteiten in zijn woonhuis begon.

De eerste antenne, een 5 m legerspriet, was schuin gemonteerd tegen het 60 m lange metalen balcon. De flat lag op de zesde en hoogste verdieping en daarom was ik tijdens een pile-up er meestal als eerste bij. In 1982/1983 is gewerkt met PAØFRI/OD tijdens een UNIFIL missie in Libanon. Begin 1993 is mij in het voormalige Yugoslavië als UNPROFOR waarnemer in Croatië een machtiging verleend met de call 3A/PAØFRI. Daarmee is in de omgeving van Dubrovnic gewerkt. Vermoedelijk ben ik een van de eersten met een officiële geldige schriftelijke Croatische machtiging, want locale amateurs hadden nog documenten met een YU prefix. Tijdends die periode is ook nog gewerkt op het clubstation van Goràzde in Bosnië.

Verder ben ik ongeveer acht jaar VERON/VRZA QSL mananger geweest voor amateurs in Etten-Leur en twee jaar voorzitter van de VERON afdeling Breda.

De advertentie site www.zendamateur.2dehands.nl is door mij opgestart als service voor collega radiozend-en luisteramateurs. Het is een min of meer zelfstandige dochter van 2dehands.nl. Voor het beheren en bewaken krijg ik geen vergoeding. Helaas word ik regelmatig lastig gevallen met onbeschofte email van lieden die zich niet voor kunnen stellen dat alles pro deo gedaan wordt in mijn toch al schaarse vrije tijd.

Door het experimenteren en af en toe publiceren krijg ik onderdelen van andere amateurs en daarvoor wil ik hen hierbij nog eens bedanken. Hun spullen zijn respectievelijk kapot gegaan, werken nog, zijn ingebouwd of liggen klaar voor een volgend project. Ter geruststelling, ik heb ze nooit verkocht, maar een enkele keer weggegeven aan een andere experimenterende of zelfbouwende zendamateur.

I used to be KM7W. How does a 7-land call end up in the 4th Call District? Simple -- it's a vanity call, and one of the only ones left that contained my initials. I've held four call signs in my time, N4UYT (bad on CW and Sideband), KN4BH (bad on CW!) and KM7W ("you're not from around here, are you boy?" -- HA HA!). Had my old call been better on Morse Code, I would have kept it and not bothered with the vanity stuff.

But, since getting interested in Low Power (QRP) operation, I needed a shorter, more "CW-friendly" call sign.

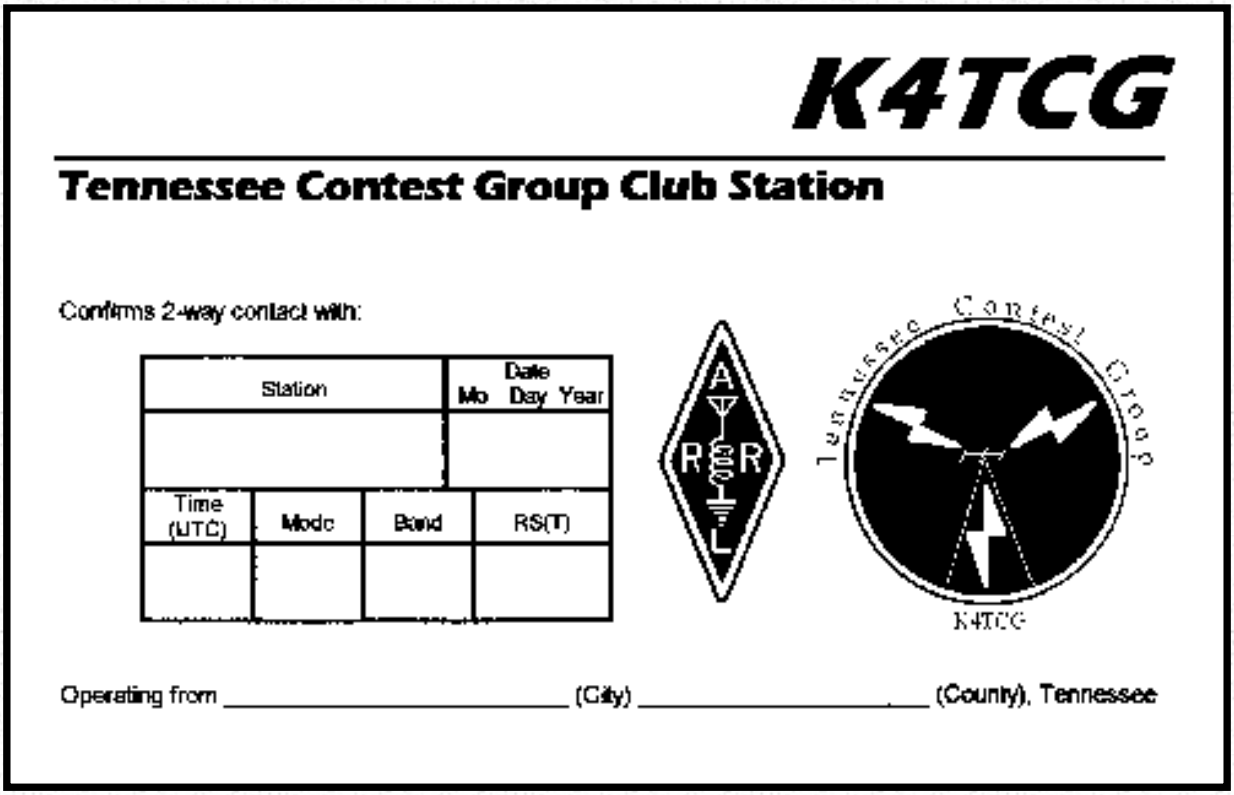
The current station consists of an Icom IC-706MkIIG for VHF and UHF, and a Kenwood TS-570D(G) for HF. Antenna is an off-center fed doublet, vertical dual band (2m/440), a 2m Squalo, and a 6m Horizontal loop. I'm hopeful to get a beam up in a year or so. I have a CMOS III SuperKeyer, Kent paddles, Vibroplex Brass Racer paddles and the Envirotronic 501G paddle through the computer). I've also got a CMOS II SuperKeyer for backup.

Past stations have consisted of homebuilt tuners and power supplies, a Sierra multi-band QRP rig, and a complete Kenwood TS-430s with MARS modifications. Former rigs include a Kenwood TS-570D(G), a couple of Kenwood TS-940sat, and an Icom 706MkIIG. I was the Net Manager (callsign NNNØGBU-3) for Tennessee Navy/Marine Corps MARS. My personal Navy MARS call (officially a NAVMARCORMARS STA) was NNNØRBB. I also have owned a TenTec Argonaut 556 (nicknamed the "Cubbie", because it is a low-power version of the Ten Tec Scout), a homebuilt 38 Special (one of the NorCal Projects), and various VHF rigs, with an MFJ-1278 multi-mode

controller.

The Antenna Farm used to consist of one parallel dipole for the 40 and 30 meter bands. It is made of 450 ohm twinlead, and only requires 100 feet of the stuff for four band construction! E-mail me for details, or check the ARRL Handbook, available from the American Radio Relay League, a national Ham Radio organization. Now, I just have some wire around! You can find more detail on the antenna page. This page also has information on my favorite compact antenna, the Distributed Capacitance Twisted Loop, or DCTL.

I'm a member of the Tennessee Contest Group. I'm currently classified as a pop gun, although I hope to make it up to little pistol some day. My idea for a club QSL card:



The font is Eros Bold ITC @ 34 point for the callsign and 14 point for the text below the line. Other text is in Arial 8 point, except in the confirmation block where 7 point Arial is used.

I'm a member of the QRP Amateur Radio Club International (#7514), the Internet QRP Club (#953), the Alaska QRP Club (#098), and the Northern California QRP Club (#2031). Click on the Club Names to go to their pages -- links for ham radio are abundant elsewhere, and I don't want to bore anyone with another page full of cross-links.

Tennessee Special License Plate application for Amateur Radio. Click on this link. Takes a while to load ... be patient.

Antenna tech page

New antennas, simulations, antennas related projects and information.

The DDRR antenna
designed by Dr. Boyer for Northrop

The DDRR (Direct driven ring radiator) was invented by Dr. Boyer from Northrop, for military applications in the 50s. It stayed classified until Dr Boyer published an article titled "Hula hoops antennas" in Electronics (Jan 11, 1963). "73 Magazine" published also a two part article from Dr. Boyer titled "Surprising Miniature low band antenna". The article is quite technical and contains a very precise mathematical formulation of the DDRR based on transmission line theory.

In layman's terms a DDRR is just a short vertical monopole (vertical post) attached to a transmission line tuned by a reactance (ring plus vacuum capacitor). The reactance of the capacitor is transformed by the transmission line and will under specific conditions (length, value of the capacitor, etc.) make the vertical post resonant. Slight variations of the capacitor will lengthen or make the transmission line "shorter" and allow tuning of the antenna on a certain range.

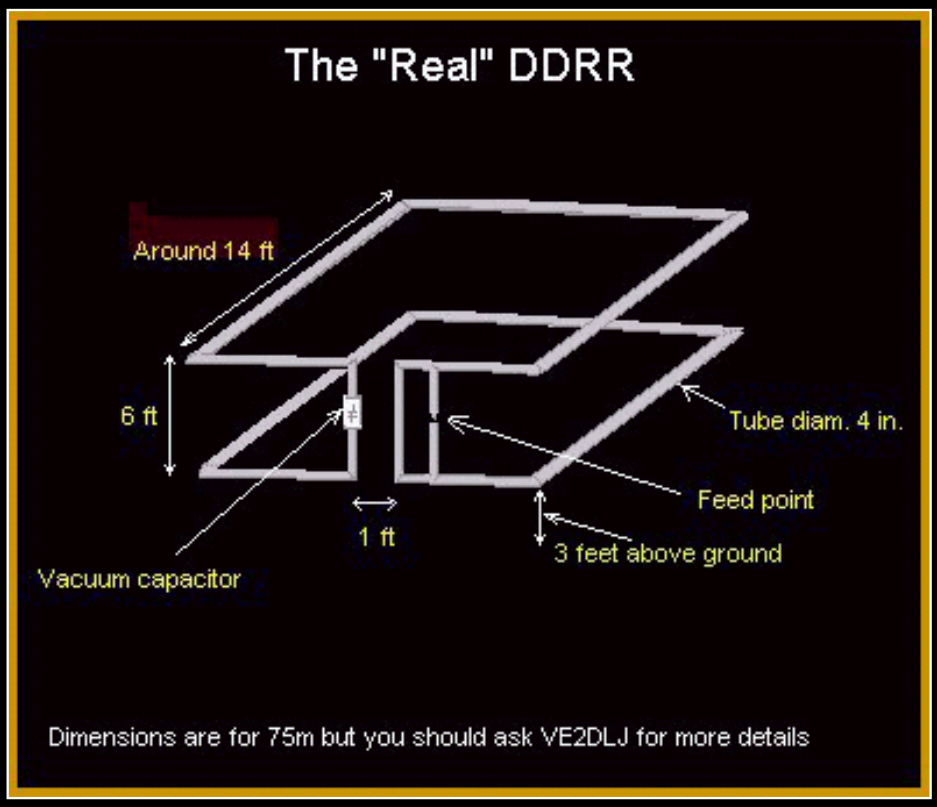
First lets make a difference between the DDRRs patented by Dr Boyer and the ones that we can find here and there in amateur publications. Boyer designed two basic models: the one ring DDRR and the two rings DDRR.

The first one is made of an opened ring made of aluminum tubing (4 in.) over the perfect ground of a metallic structure like a warship, and with two aluminium posts connected at the extremities of the ring. A set of fiberglass post supports the ring. One of the vertical post is attacked at the base by the coax, the other one contains a variable vacuum capacitor to tune the antenna. This faded picture from the 50s from Northrop show a set of concentric DDRR for 2 to 30Mhz. The engineer is standing below the 75m loop (6 feet height) and is looking at a 50Kv vacuum capacitor. This type of DDRR was installed on some special communication and ELINT warships, and was apparently used in the early stages of the Apollo project.

Contrary to most ham publications, Dr Boyer in all the articles he wrote, and in his discussions with VE2DLJ and VE2AMT stressed the importance of using big fat aluminium or copper tubes and to avoid at all cost chicken wire as ground plane. **In a one ring DDRR he insisted on the fact that you needed a solid metallic ground plane**.

The advantages of DDRR compared to a vertical are obvious, especially on a ship. Small size and height, remotely tunable, low noise due to loop structure, extremely low impedance and therefore no or little influence on connected electronic equipment from voltage transients and lightning. Low angle for long range communication and possibility of a secondary high angle for NVIS, indispensable in fleet communications, can be achieved by using a configuration using a central post and two posts with vacuum

capacitors.



The second type is a double ring system isolated from the ground with the same two vertical posts connecting the opened extremities of the rings. One is solid aluminium, the other one contains a Vacuum. A third aluminium post cut in the middle is used to feed the antenna and can be moved to adjust the SWR. The coax enter in the middle of the right post, then up then down to the "feed point" where the shield is connected to the top part and the center of the coax to the bottom part of the post. This configuration creates a coaxial balun for a symmetrical attack. Matching is achieved by moving the "feed point post".

The antenna is standing and supported by very high quality isolating posts made of PVC or fiber glass, and Dr Boyer even recommended beehive isolators at the extremities of the posts to limit losses. The whole structure is placed some 3 feet above the ground.

Contrary to the one ring model, there is no need here for a perfect ground and Dr Boyer was confident that this antenna could perform well even on very poor ground. He referred in his articles to the fact that DDRR are essentially "magnetic" antennas in the near-field and that losses in the ground my magnetic field are negligible. This is not entirely true and computer simulations and experiments by VE2DLJ showed that even if losses in the ground are negligible there is an improvement when radials are inserted.

Tests made by Boyer and his team for Northrop and the US Navy showed that the antenna was very low noise and very low angle. This was done in side to side comparisons made with a collapsible vertical on 160m in the Arizona desert, using a half square mile ground plane made of solid copper sheets soldered together (visible in the picture).

VE2DLJ and VE2AMT found some ten years ago an old copy of the 73 Magazine article and decided to build a prototype. They contacted Dr. Boyer and have numerous discussions with him. He warned them and told them "not to cut corners". His recommendations were:

- Use big tubing: 4 inches or more for 75m.
- Do not use automotive exhaust pipe. It will rust and contacts losses will transform the antenna into a dummy load.
- All contacts and connections must be A1. Solder corners if you make it square, use Penetrox everywhere.
- Use very high voltage vacuum capacitors, and high quality isolators to support the rings.
- No chicken wire. Dr Boyer was horrified by some description of DDRRs using chicken wire. He explained that measurements made by Northrop engineers showed that the near field is in concentric rings on a one

ring DDRR and that chicken wire could add losses.

Our two explorers decided to build the antenna following scrupulously all recommendations. Some years ago, Alex, VE2AMT, made a square DDRR for 75m, with special machined metal brackets in the corners so that it could be disassembled if necessary. He adjusted it and worked two VK and a ZL the first day he used it on the air using 100W. He explained that listening on this antenna was a real experience. He could hear no noise at all and the DX was Q5 all the time, even when other stations couldn't copy the DX. The antenna was at that time sitting on the side of his house on wooden blocks 2 feet above the ground.

VE2DLJ followed suit a few years later and his DDRRs are visible in the Picture page. He is very often in the 75m DX window working VK, ZLs and other pacific stations.

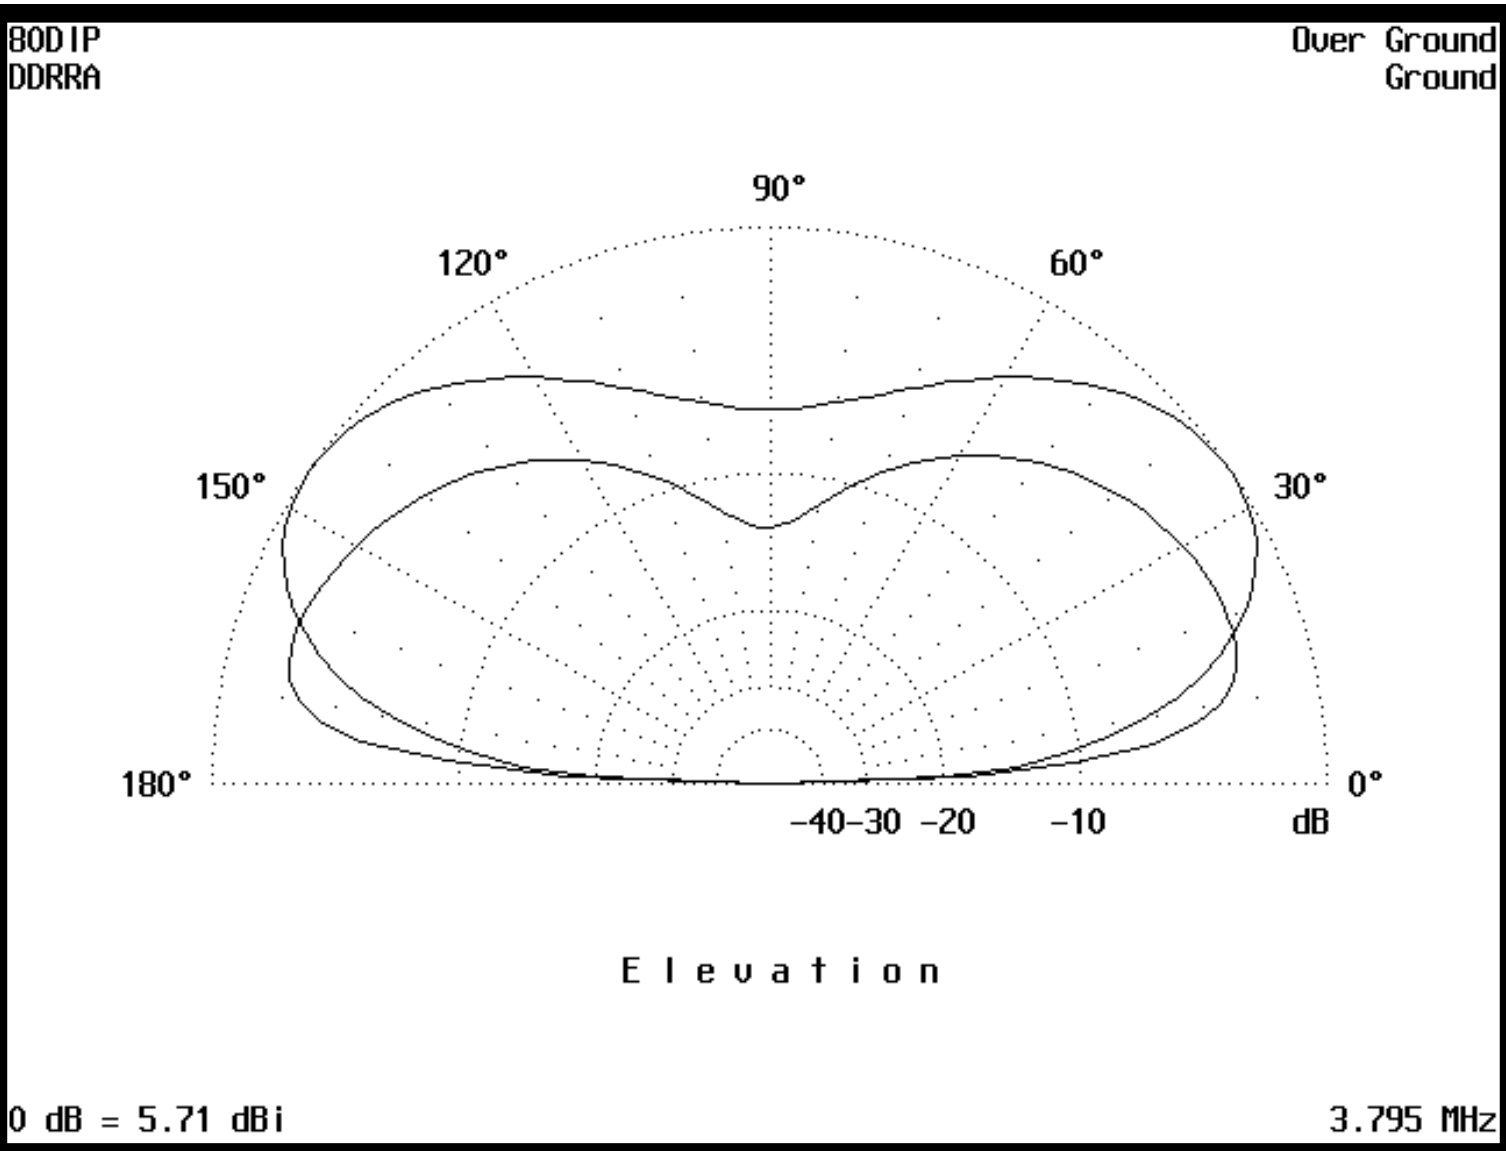
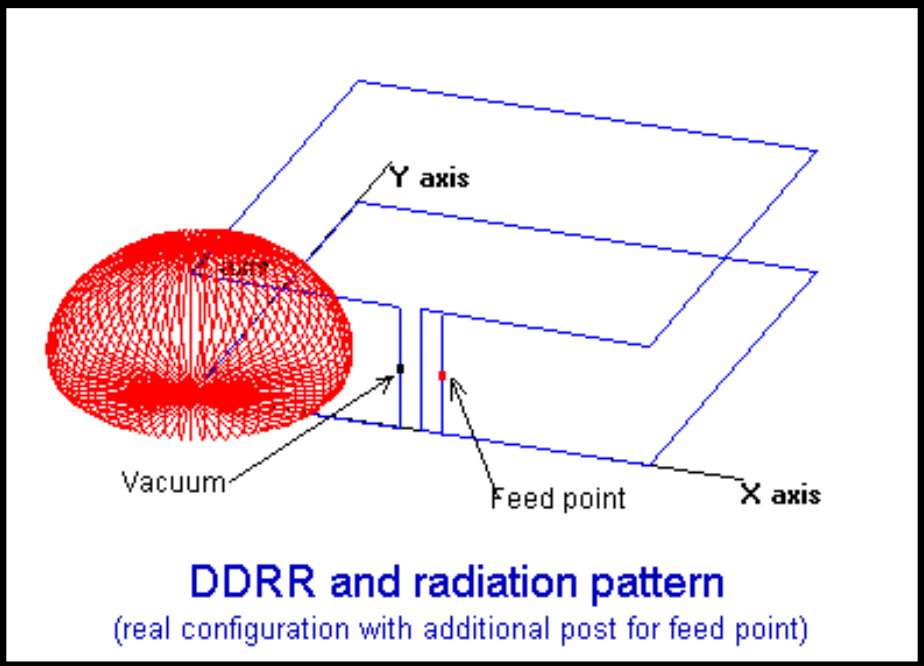
Maximum Gain 3.81 dBi at 132ø Azimuth
Radiation Peak 164ø Elevation (3.77 dBi gain)

DDRR with radials vs a Dipole at 130 feet DDRR is better at low angle (<18 deg)





DDRR and radiation pattern
(real configuration with additional post for feed point)

Comments and remarks

The DDRR impedance is very very low. At 0.5 ohms, any wire or connection losses will transform the antenna into a dummy load. This is why one needs big fat tubes. Losses in the tuning capacitor must be minimized too and a vacuum of very high voltage is indispensable.

Contrary to Dr Boyer's predictions, **the addition of radials increased gain and lowered radiation angle**. This was confirmed by VE2DLJ experiment's. We see from the zenith patterns that the TOA is below 20 degrees and that the antenna is a low angle radiator. **This could be OK for long range DX like VK and ZLs but it is not very good for medium range DX**. This was confirmed by long term testing over a year and a half period. Tony, VE2DLJ, has a horizontal loop "reference antenna" and the loop will always beat the DDRR toward Europe in transmission even in Winter. The horizontal loop will also give better reports (in average) than DDRR on long range DX *outside of Winter DX period* but starting around beginning of October the DDRR will start beating on average, the horizontal loop by one to two S units in transmission on VK, ZLs and JAs.

In reception, the DDRR (according to Tony, and most hams who listened on them) will always beat the loop for QRN and man made QRM. Signals will be sometimes one to two S units lower but always perfectly Q5. The bandwidth is some 20 to 30Khz and the Q is in the 300 to 400 range, so the antenna is very selective which is a big advantage.

We can see from the comparison of a **dipole at 130 feet vs the 3 feet high** DDRR that the DDRR is better on low angle signals. The difference is even more important for a lower dipole.

What are the advantages of the DDRR? Low noise antenna, low angle. "Small size" requiring little real estate. Could be easily installed in a backyard at ground level or on a flat roof. No tower needed, no climbing. Immune to noise, static electricity and ligthning. Tunable, very high Q. Boy that seems great!

Does that mean that I will "recommend" a DDRR? Hell No! To build a good system you need some 100 feet of 4 in. tubing, then solder the corners (or use special machined brackets) to reduce losses. If you want to transmit full legal power you need 50 KV vacuums, and they are not cheap. Add the cost of good isolators to support the rings etc and you end up with a two to three thousand dollars antenna. Even if ground does not influence much the DDRR in the near field, ground is important for the first reflection and you need good ground around the antenna. If you have neighbours the low angle may create TVI. Another major point is directivity. The DDRR doughnut is omnidirectional and to work DX you need directional antennas. That's the only way to eliminate QRM and concentrate the energy in one direction. This means that one DDRR is not enough and you will need at least two.

To build low band DDRRs, there are cheaper alternatives using salvaged Heliax. Three or four VE2 designed DDRRs using plumbing copper tube, wire and Heliax with variable success. The only area where price/performance is interesting, is in VHF/UHF. At these frequencies, DDRRs are easy to build and very small. Otherwise, stay away from them unless you know what you are doing.

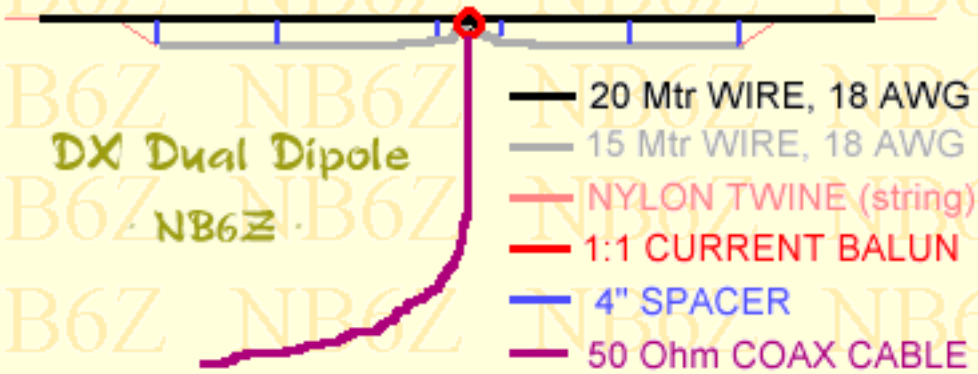
First the Dipole...

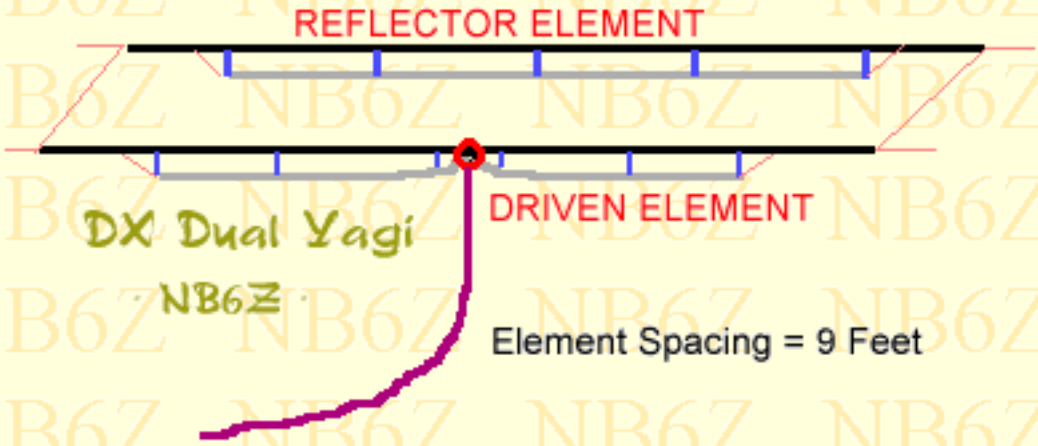


The antenna diagram you see before you is nothing more than two dipoles fed from the same coaxial line. I call it a " DX Dual Dipole" because it is cut for two very useful DXing ham bands. There is no harmonic relationship between 20 and 15 meters, and so they "play" well together when sharing the same transmission line. The wire length cutting chart for HF ham band dipoles is found in any antenna handbook. (The half wave dipole cutting formula is: Length in feet = 468 divided by the Frequency in Mhz.) Both dipoles are cut per the chart (or formula) to the low end of each band, leaving a little extra wire length for SWR tuning. Construct the dual dipole using the techniques described for the NB6Zep Antenna and make the wire spacers from plastic coat hangers as described there. Follow the instructions in the handbooks to make a 1:1 current type balun device using a small toroid core. (The smaller T130 red HF material cores work fine for several hundred watts.) The use of a balun is not strictly necessary for the dual dipole, but it is strongly advised if you are going to add a parasitic element (reflector) as described later. If your feed point is not supported, as was the case for me, you will want to use a strong stranded wire (#20 thru #12 AWG) and light weight coax.

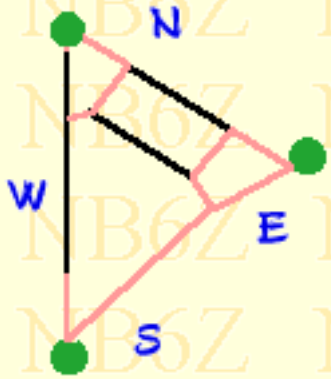
Here is a **HOT TIP** for light weight and portable operation. Use short runs of RG-174 coax for low power operation at HF frequencies. I tested 30 feet of this very small coax at 50 watts before beginning construction and found no objectionable loss or leakage at 14 Mhz. (Do not use this coax at power levels greater than 100 watts or with antennas that require a tuner!) Another advantage with RG-174 is you can make a current balun (coax choke) simply by wrapping 10 turns of the coax around a T150 toroid core at the end of the cable where you attach it to the wires. I have been using this cable successfully for several years...

To tune the antenna, each dipole must be trimmed separately by cutting small equal length pieces from each end until a low SWR (below 1.5 to 1) is achieved for the low end of the band. (You may tune them to the desired frequency if you do not intend to add a parasitic element later.) This can be done with the antenna at six feet off the ground, but expect the SWR to change slightly when you bring the antenna to full elevation. (Always listen for a clear frequency before testing SWR. SWR tuning is not needed for receive only operation.) There will be interaction between the two dipoles, so alternate between dipoles until you find the right match. (Note: Yes you can add additional half wave elements for other HF bands to this configuration. Adjusting multiple elements for a low SWR becomes problematic and will take some patience. I recommend a multi band wire with tuner such as the NB6Zep.)

...then the Yagi.



The two element yagi style antenna I am most comfortable with is one that employs a reflector instead of a director element. The yagi I chose to build has a parasitic reflector nine feet behind each dipole. (Nine feet was a compromise for dual band operation.) My computer modeling looked good with standard reflector lengths, so I cut the reflector wire lengths to what I found in the antenna handbooks for 2 element yagis. You should have reasonable results if you cut the wires to 5% greater than the dipole length (dipole x 1.05) for each band. When the reflector is in place behind the driven element as shown, you should notice a slight change in the SWR. This is due to mutual inductance as the reflector is inducing power from the driven element. The effect is to lower the impedance of the driven element. If you trimmed the dipole SWR for the low end of the band as previously instructed, you may find the resonance is now in the middle of the band. However, you may need to do some final trimming on both driven elements to compensate and make a better match at the transmitter side of the coax. When you are satisfied with the SWR on both bands, raise your yagi as high as possible and free from large objects and other tuned antennas.



I have my dual yagi at 30 feet above the back yard and pointed at 33 degrees towards Western Europe from Beaverton, Oregon. A major challenge was to figure a way to support the yagi in the direction I wanted it to operate. I used two trees supporting an existing 15 meter EDZep wire and used a third tree to triangulate enough nylon twine to create the configuration shown. My Dual Band Yagi has been in place, with zero maintenance needed, for over two years... A ***closer view*** shows more detail of the wire spacers, (note the NB6Zep at 40 feet).

Basic Performance: The antenna modeling was done with all the wires in the yard included in the model to get the whole story of how well this antenna should do for me. First on 20 meters... ***CLICK for DETAIL***. Slightly better results is predicted for 15 meters... ***CLICK for DETAIL***. Needless to say, after seeing these predictions, I was excited about building and testing this antenna! Comparison testing has shown that the gain from the yagi is close to what the model predicted. Granted, it is impossible to measure a 3.6 dB gain while operating under skip conditions, but the yagi out performed all wires I tested it against. The Front to Back ratio is a bit hard to confirm from

Oregon; but I note that my 15 meter EDZep used on 20 meters always works better to the South Pacific than does the yagi. The differences between the yagi and the NB6Zep (SE and NW) on 20 meters is typically greater than 20 dB for skip conditions. The beam width is noticeably broader on the yagi than on the NB6Zep and I can use it for contacts to the NE sections of the USA.

With the yagi antenna I am able to work any European station I hear on 20/15 meter CW, MFSK16 or Hellschreiber mode with 50 watts. I can hear good PSK31 sigs from over the pole, but still have a hard time decoding them here in the North West.

Would you rather use a tuner instead of manually trimming each dipole? The Super Zep antenna is a more "elegant" solution for a multi-band wire beam.

Rotatable, Self Supporting Dipoles

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 2/25/2000)

Rotatable Dipoles:

There are quite a few ways to make full-sized dipoles that can be rotated. How you attack this mostly depends upon what band is to be covered (basically how big) and whether the wire is to be horizontal or is permitted to slope downward from a central post. In the horizontal case, the wire is threaded through the spreaders and may extend out the ends. The ¼" tubes have an adequate ID that #16 wire is easily passed through the tube, so extenders can be added to the usual fiberglass ½" tubes that fit the hub. In doing this, you should be aware that the velocity factor will be less than unity, so the physical size of the dipole will be slightly smaller than that of free space. In order to make connections to the feed line at the hub, two ¼" diameter holes have to be drilled at an outward slant into two opposite spreader sockets. These should be drilled at about a 45 degree slant beginning about ½" out from the center. A ten meter dipole requires no extenders. Longer wavelengths require extenders, and the 20 meter dipole may require wire extending slightly beyond the extended spreaders. In general, feed the wire through the extender first, then into the ½" tubing, then slide the extender into the half inch tubing and push the wire beyond the end of the spreader about 4". Feed the wire into the hub and up through the access holes that you drilled. Then push the spreader into the hub. Now, from the tip of the spreader pull the wire until there remains just enough wire at the hub to make the connections to the feeder. Adjust the length of the spreader extenders, and tighten the hose clamps. Leave about a foot of extra wire beyond the extender. You will then need to trim this to get proper resonance once the structure is in the air. In the case of ten meters, you are done, simply mount the hub on the mast and put it up. No guy lines are needed if you don't mind a bit of droop. In the case of 20 meters, there is much more to do. Here, the length of the spreader will be about 15' if you have a 1' overlap with the extender. So you will need a central guy post 6' long, i.e., use a full 8' section of 1" tubing with 2' below the hub. You will need guys to both the inner spreader at 8' and the outer extender at 15' up to the central hub for both spreaders. You also may need rotational stability if you want this to settle down after rotation or gusts of wind. The two unused socket holes are there for a reason, so, fit two 6' or 8' (if you have room) ½" spreaders in these sockets and guy them in the same manner as before at the 8' and 15' locations. Always set the guys from the inside first, then add the outer ones. This is still a fairly

loose structure since only gravity holds it in the downward direction. If this structure is still not stiff enough, you can guy downward to the mast as well. The limiting tension is set by the point where the extenders begin to buckle. That turns out not to be a whole lot of tension, because a 7' section of the ¼" tubing sets the limit.

The second procedure is to make an inverted V dipole, where the antenna is the upper guy lines from the center pole out to the spreader tips. For the ten meter case, this is nearly identical to the ground/counterpoise discussed in the Quick Vertical section. In that case, there are no extenders, so the construction is very simple. In the 20 meter case, all the same problems are encountered as above except that the wire load is acting as the upper guy lines rather than being in the spreaders. We also suggest using light wire for the 20 meter version. In fact, # 18 or # 20 hook-up wire works well, and the insulation should be left on. We prefer the un-tinned type that is commonly available at Radio Shack. Using, the 6' center pole, the length to the tip should be just about correct, however, the insulation slightly reduces the velocity factor, so you can shorten the extender or use a small length of Nylon fish line to extend the wire.

Note, the 17 and 20 meter versions of these dipoles are fairly large structures and can not be built up in small spaces. They are also rather flimsy, and go through lots of distortion when being tipped up. These are better erected from a push-up mast with the rotator near the top of the mast. This Dipole antenna gives the same gain as all other dipoles, however, the Half Square is a much better DX antenna for a given elevation and may be worth the extra effort. All parts used for the construction of the dipole can be used to construct the Half Square, so there is no loss in investment if you decide to switch. Note that 6 and 10 meters require no extenders, but we do recommend that you use guys from the tips to the center post. The post should extend about 3' above the hub.

Parts required for all 6 and 10 meters versions:

Item	Quantity	Description
1	1	HUB 4-050-100, Central Quad Hub (RFJ)
2	2	8' 1/2" OD fiberglass tubing, spreaders (MGS)
3	1	8' 1" OD fiberglass tubing, boom (MGS)
4	2	GT 4-050 1/2" Guy Ties, for tips of spreaders (RFJ)
5	2	GT 4-100 1" Guy Ties, for tips of boom (RFJ)

Extenders are required for 12 , 15, and 20 meters. To determine how much 1/4" fiberglass to buy, you need to calculate the approximate length required for the dipole. If the wire is to be inside the fiberglass, the velocity factor is slightly less than 90%. The size of a typical dipole is given approximately by 468/fMHz. This formula has a small correction factor for finite wire diameter and end effects. When the wire is inside the fiberglass tubing, the appropriate factor is about 435/fMHz, so the lengths of the spreaders require for 12, 15, 17, and 20 meters is roughly as 8.72', 10.25', 12.02', and 15.33'. Assuming 6" overlap and 8' lengths of 1/2" OD spreaders, the extenders will have to be 1.22', 2.75', 4.52', and 7.83'. Obviously, there is no compelling reason to cut the 8' of 1/4" OD tubing for the 20 meter spreaders. You can get both a 15 and 17 meter extender our of a single 8' length of tubing. 15, 17 and 20 meters require lateral guys to increase the stability. This requires two 4' lengths of 1/2" OD tubing inserted in the two remaining sockets. Guys should be run to the tips of both the 8' dipole tips and the extended tips. This is also true from the central Guy post. The guys can be either 50 lb. test Nylon fishing line or Kevlar thread. The photos associated with the Half Square antenna show structures built with both fiberglass and PVC.

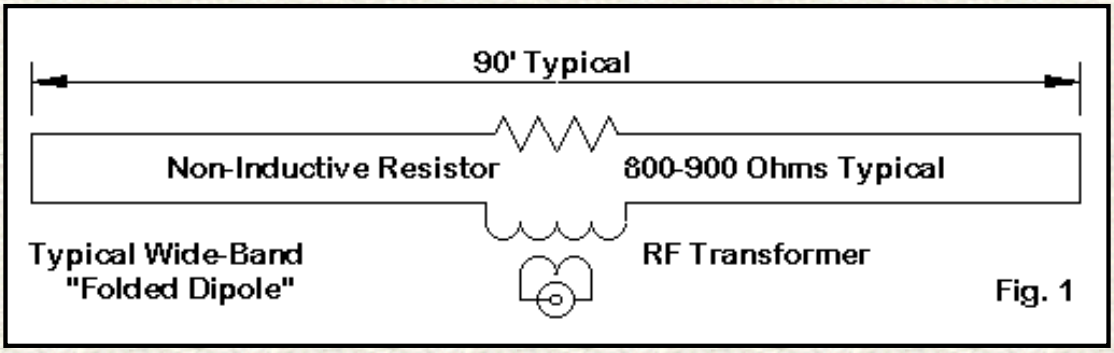
Notes on the Terminated Wide-Band "Folded Dipole"

L. B. Cebik, W4RNL

As space for antennas continues to shrink in the present era of smaller urban and suburban yard, hams have begun to turn to 1-antenna solutions to their operating needs. Among the choices for a horizontal antenna that operates on all of the HF amateur bands, the wide-band "folded dipole" (WBFD) has been gaining popularity. I thought that it might be useful to do some comparative studies using this antenna as a base-line.

The basic WBFD looks something like **Fig. 1**.



The antenna design appears to be a folded dipole. However, a folded dipole is a resonant antenna, while the WBFD is designed to operate with a low feedpoint impedance across a wide range of frequencies. Moreover, the WBFD contains a non-inductive terminating resistor usually located at the point in the loop directly opposite the feedpoint. Normally, the resistor is in the 800-900 Ohm range. This impedance is roughly replicated at the feedpoint. Therefore, builders install a 16:1 RF transformer (either of transmission-line transformer or normal transformer design) at the feedpoint. The result is a low SWR value for 50-Ohm coaxial cable across the entire frequency range.

For receiving use, such as in SWL service, the terminating resistor can be a low wattage carbon type. For transmitting service, the resistor must have a power value capable of dissipating a fair share of the applied power. The exact amount will vary with frequency, but commercial versions of the antenna are often rated for reduced power at the low end of the operating range, where power dissipation is highest.

Commonly, WBFD antennas are offered in a 90 to 100 foot length (27-28 meters) for service between 2 and 30 MHz. However, one can build WBFD antennas in almost any length. Only the effective operating range of frequencies will change.

Since we may also construct doublets of the same length and feed them with parallel transmission line to an antenna tuner, it seemed fair to compare the gain of such a doublet with that of a WBFD of the same length across the 2-30 MHz range. The model I chose for the WBFD is 27.2 m (89.25') long, with the wires separated 0.2 m (7.8"). The terminating resistor is 820 Ohms, a standard value used in some commercial models. The wire is #14 AWG. The doublet is a simple length of #14 copper wire exactly as long as the WBFD.

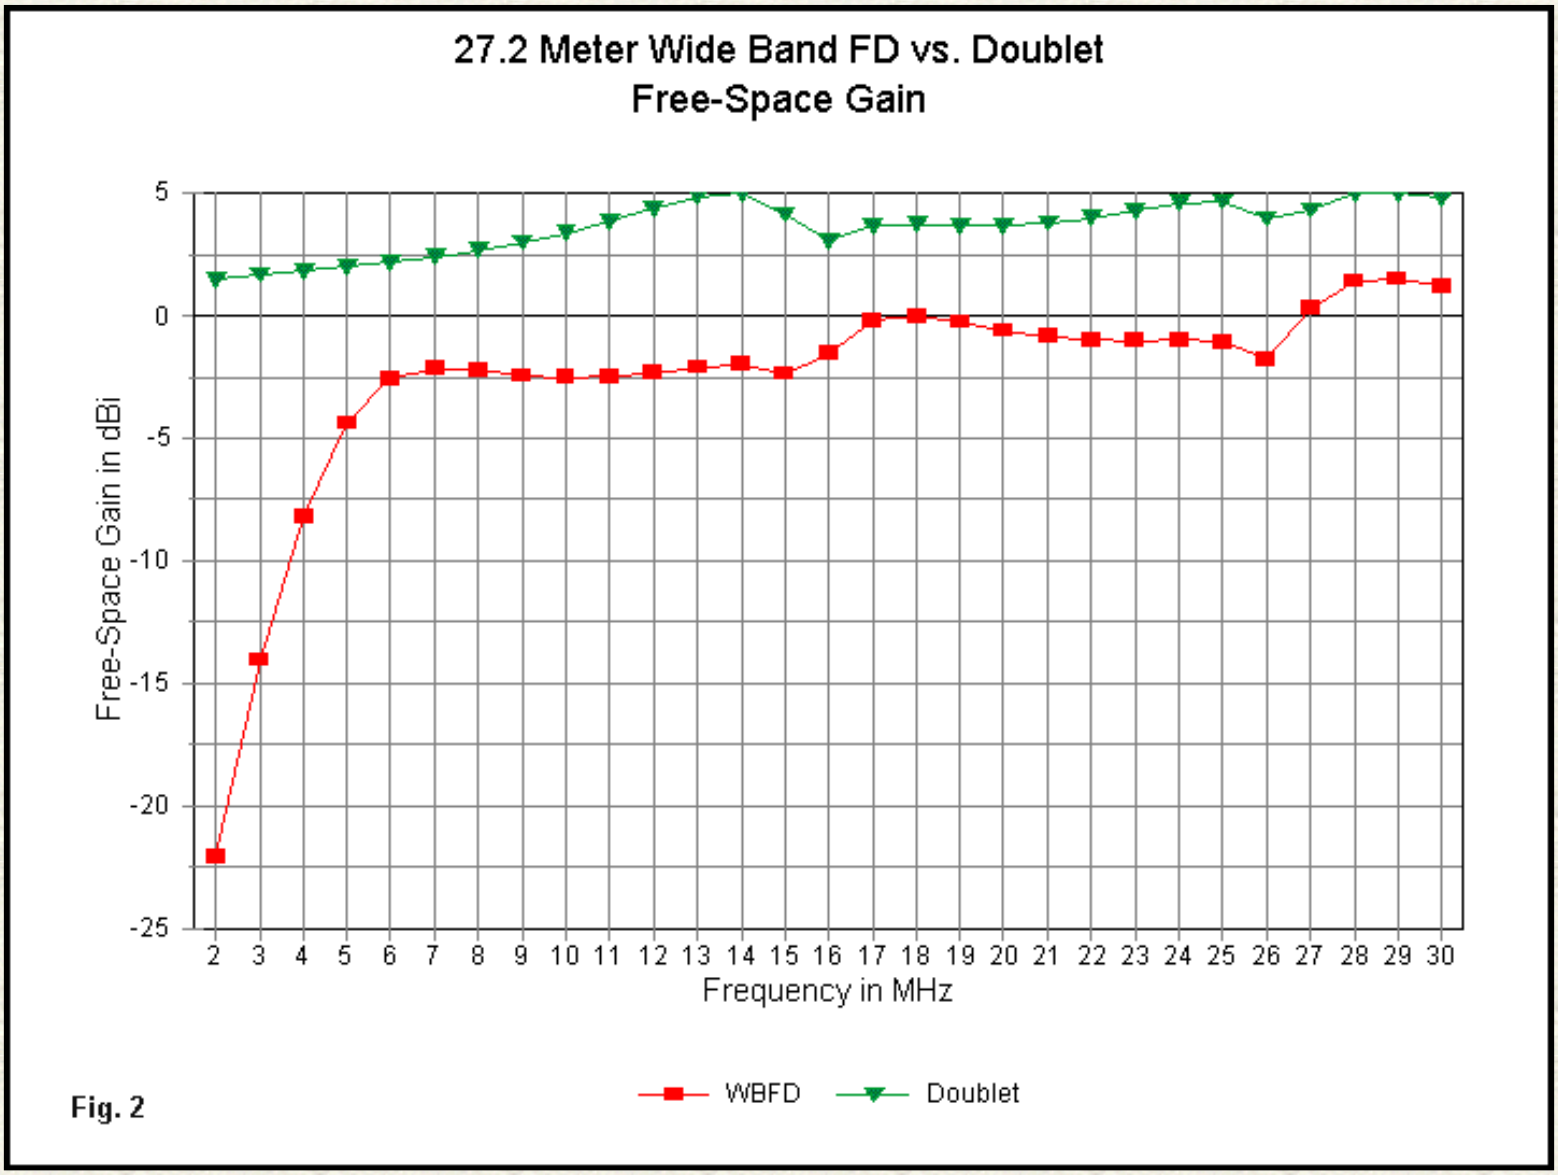


Fig. 2

Fig. 2 compares the free-space gain of the two antennas at 1 MHz intervals from 2 to 30 MHz. Since the elevation angle of maximum radiation will be the same for both antennas for any height above ground and for any ground conditions, any differences that show up in the free-space model will also show up in actual antennas at any height above ground.

Several instructive notes emerge from the comparison of gain in **Fig. 2**. First, the overall average difference in gain between the two antennas is nearly 6.3 dB, with the advantage going to the doublet. If we neglect frequencies below 7 MHz, the average difference diminishes to 5.0 dB. For most of the range of use of the WBFD, then, there is about a 1 S-unit deficit in gain relative to a standard doublet of the same length in the same position.

Second, the WBFD gain curve displays a significant knee--a frequency below which its gain deteriorates rapidly. In the case of the current model, that frequency is about 6 MHz. At or below the knee-frequency, the terminating resistor dissipates more and more of the power. The result is not only a large decrease in gain and higher temperature stresses on the resistor, but as well, very low SWR values at the feedpoint. The knee-effect as the WBFD becomes significantly short relative to the length of a resonant dipole easily accounts for the need to derate the antenna relative to transmitting power below a certain frequency.

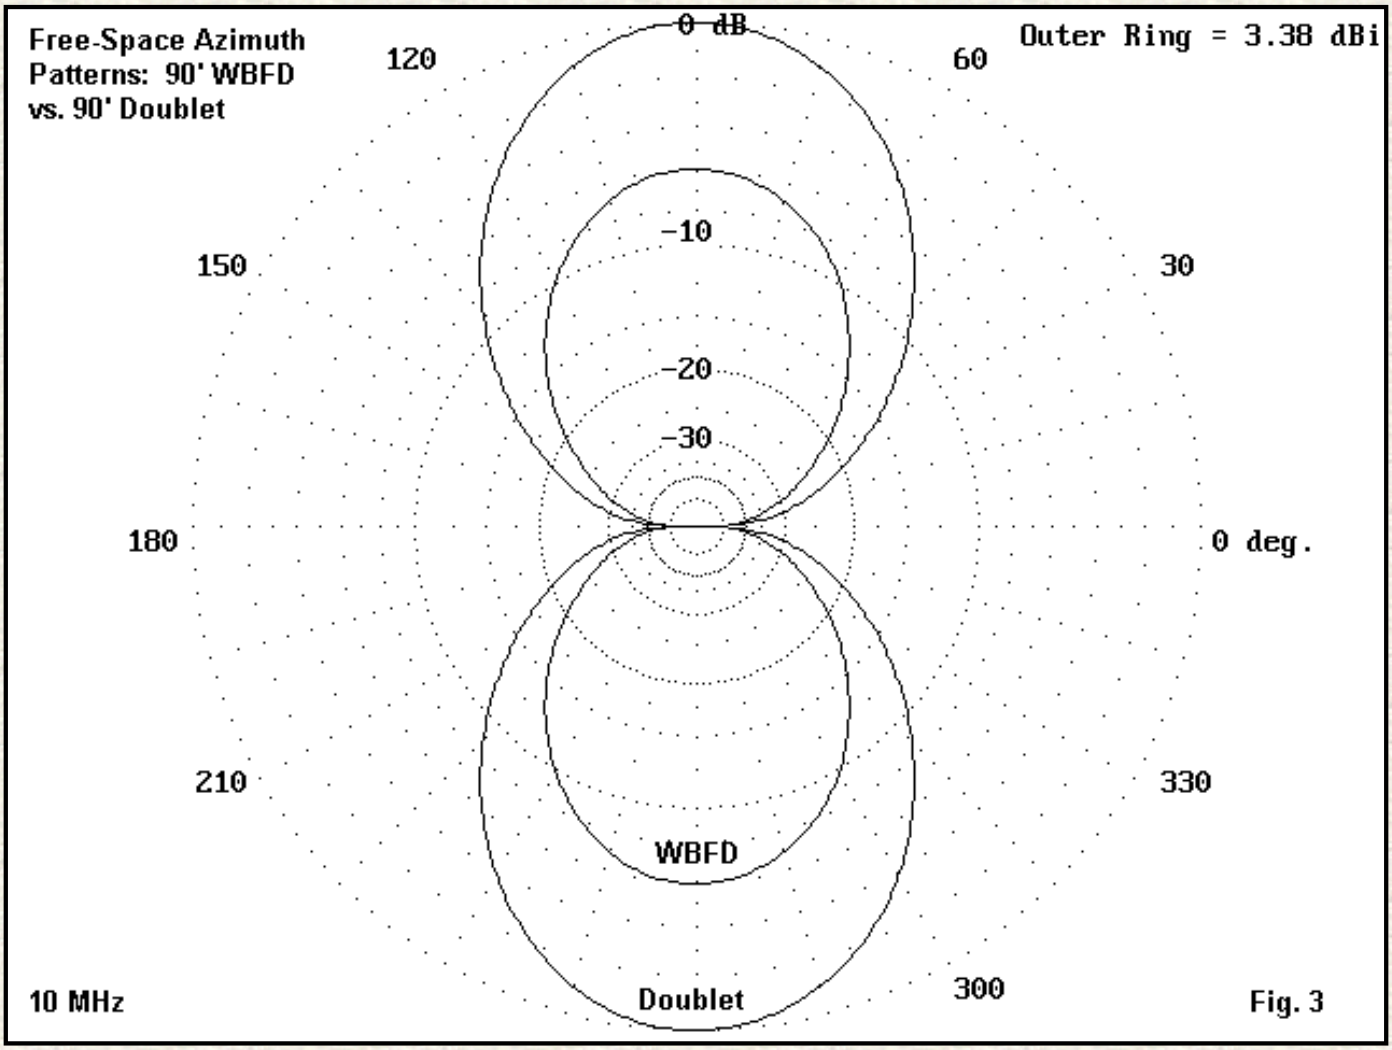
The deficit in gain is not necessarily a disadvantage for receiving purposes. Modern receivers tend to be equipped with receiving pre-amplifiers that the user can switch in as desired. The gain may range from 10 to 20 dB, depending upon design, and in some receivers may be stepped or variable. Therefore the gain deficit can be largely made up in the

lower HF range. Moreover, the basic receiver, apart from preamplification, already has excess gain that is rarely used in the lower HF region.

In addition, one of the major problems in reception in the lower HF range, especially with respect to SW broadcast stations, is front-end overload from excessive signal strength. The overload also tends to produce spurious products within the receiver. Hence, reduced gain of the antenna can be in some circumstances an advantage rather than a disadvantage. Combined with the RF attenuator built into many receivers--which may be a single reduction value or stepped--the WBFD offers a potential for excellent lower HF reception, free of some of the problems that occur with higher gain antennas.

Because the WBFD is also a closed loop with a terminating resistor, many users claim quieter reception relative to doublets for a given receiver input signal strength. The degree to which this is both true and separable from the freedom from front-end overload is difficult to determine. Nonetheless, SWLs have found the WBFD a very useful tool for their efforts.

In order to establish that the WBFD has the same pattern as a doublet of the same length for any given frequency and height above ground, let's look at a couple of sample free-space patterns. For example, see **Fig. 3**.



The 27.2 meter WBFD and its comparison doublet exhibit a bi-directional pattern at 10 MHz. The shape of the pattern is identical, with only the 6 dB gain differential separating the two antennas. The -3 dB beamwidth points are also virtually identical. Since the take-off angle (elevation angle of maximum radiation), the reflection from a given set of ground conditions, and other such factors are not dependent upon signal strength, the two antennas would also show elevation patterns for any equal antenna height that are likewise congruent.

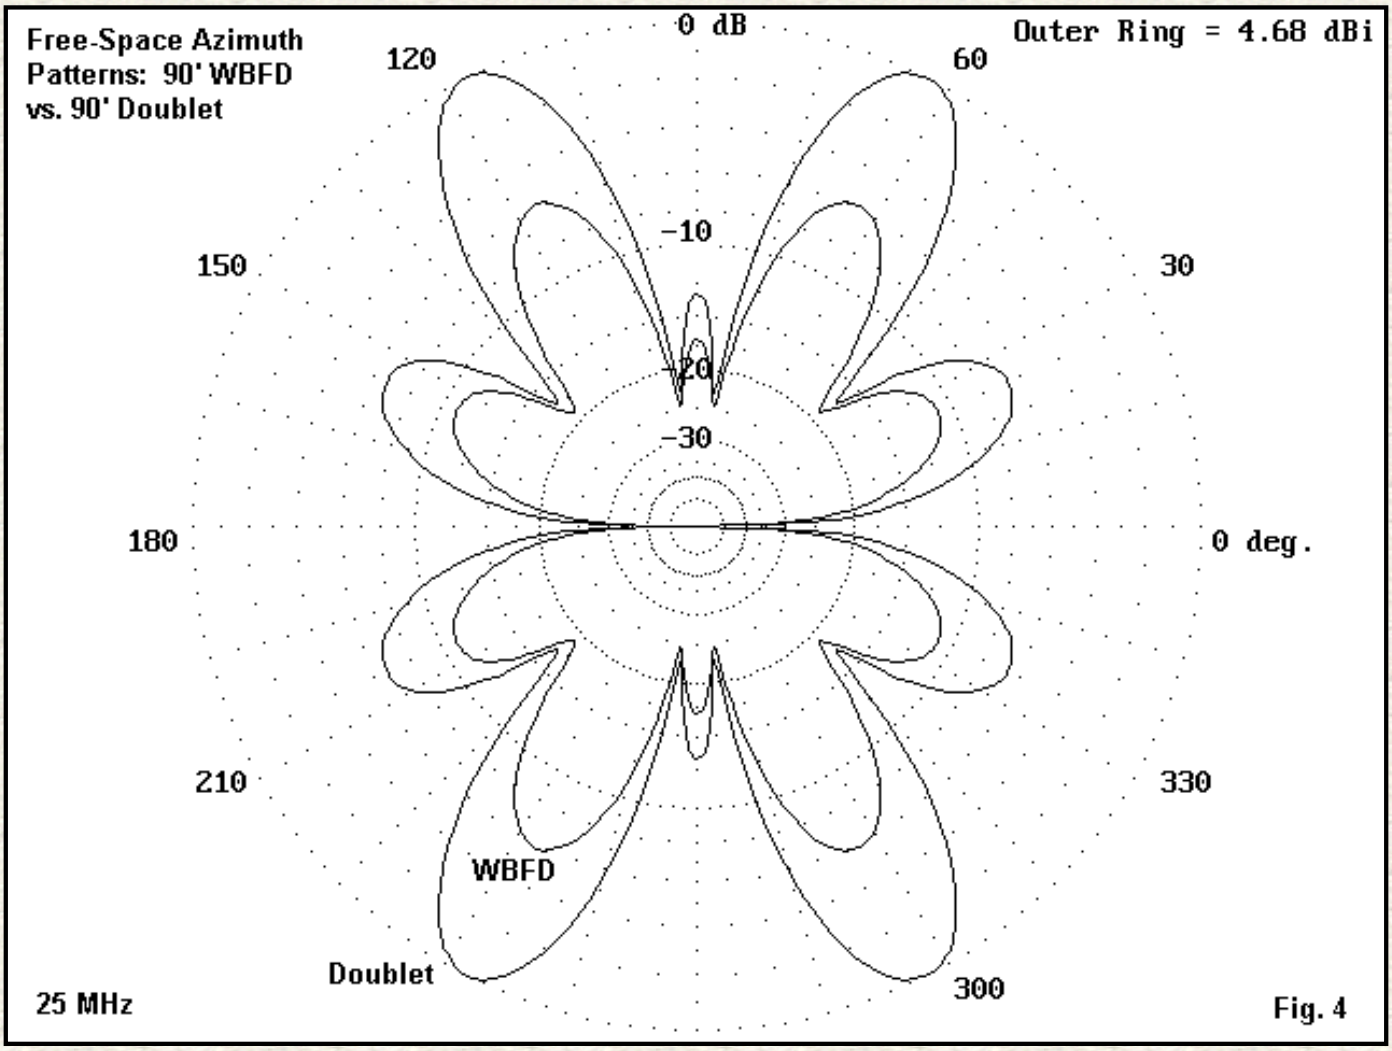


Fig. 4 shows comparative free-space azimuth patterns for the two antennas at 25 MHz. The WBFD pattern is simply a "mini" version of the doublet pattern, with about a 6 dB difference in strength.

There is an additional point in displaying these patterns. The exact pattern of lobes and nulls in the azimuth readings for a WBFD is identical to that of a doublet. As the length of the antenna exceeds 1.25 wl and approaches 1.5 wl, the bi-directional pattern at lower frequencies will break up into a collection of lobes and a collection of nulls. Therefore, the antenna is variably selective in its favored directions of good signal strength as one changes frequency. Those who contemplate installing either a doublet or a WBFD antenna need to consider well the patterns at key frequencies of interest in order to orient the antenna for maximum effectiveness.

The antenna type has also been used vertically to provide omnidirectional coverage. However, in this orientation, when the antenna exceeds 1.25 wl in over length, the pattern begins to show primarily high angle radiation--exactly the opposite of what one normally desires from the upper HF band. As a result, some installations may use a pair of vertical WBFDs for full low-angle HF coverage.

A Note on Knees and Length

The knee we observed in the gain of the 27.2 meter WBFD is interesting, since it suggests that we may vary the low frequency gain by changing the length of the antenna. Changing the length, of course, will also change the frequency at which the antenna changes from a bi-directional pattern into a multi-lobed pattern.

To examine this question, I recreated the 27.2-m antenna model to perform frequency sweeps on both longer and

shorter versions. As a sample, I ran a 50-m version and a 15-m version. All of the models used 820-Ohm terminating resistors, #14 AWG copper wire, and a spacing of 0.2 meters.

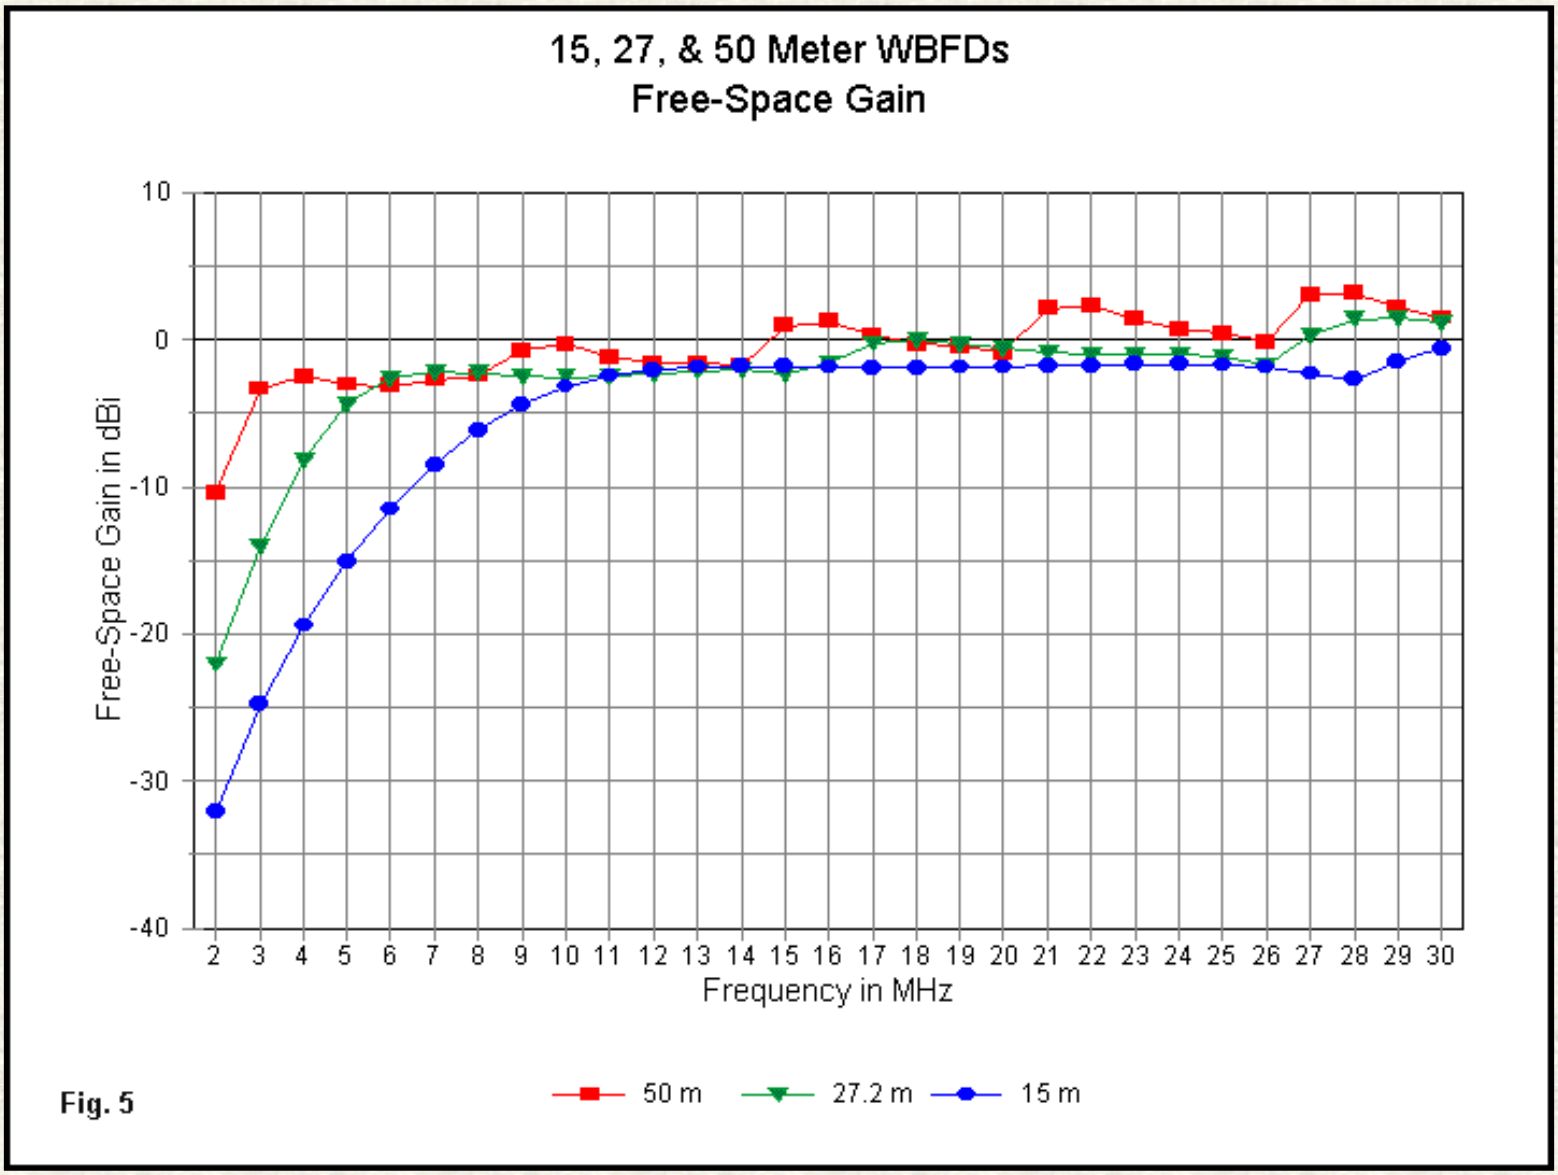

Fig. 5

Fig. 5 compares the gain of the three antennas from 2 through 30 MHz in 1 MHz steps. As suspected, the 50-m antenna reduces the knee frequency to about 3 MHz. In contrast, the 15-m version increases the knee frequency to about 10 MHz. In general, a home builder may interpolate values for the knee frequency for other lengths in the overall range.

The longest of the antenna models shows a mere -10 dBi gain at 2 MHz, a value easily made up by the receiver and only about 1.5 to 2 S-units below the average gain of the antenna. Hence, it is likely to be more satisfactory as a transmitting antenna in the lower HF region. In contrast, the 2 MHz performance of the 15-m version is more than 30 dB lower than the average antenna performance, making it more suitable for higher HF transmitting.

The variations in gain among the curves in the relatively flat region of performance are a function of lobe formation. Maximum gain tends to attach to the major lobes of patterns taken at just higher than integral multiple of a wavelength, relative to antenna length. Minimum gain levels tend to be associated with antenna lengths near the "x+.5" wl (where x is an integer) points. When an antenna is 1.5, 2.5, 3.5, etc. wavelengths long, its pattern consists of a combination of emerging and disappearing lobes, all of relatively equal strength. For example, a 1 wl wire has 2 strong lobes that are 180 degrees apart and a 2 wl wire has 4 strong lobes that are roughly 90 degrees apart. A 1.5 wl wire has 6 lobes, as

the 1 wl lobes diminish and the 2 wl lobes grow. Hence, coverage is wide, but at a reduction in maximum strength.

The number of peaks and valleys in the three gain curves is a function of length. The 50-m antenna passes through many more transitions from x wl to x.5 wl (where x is an integer) across the frequency span than do either of the shorter antennas. Hence, we should expect more highs and lows in the gain pattern.

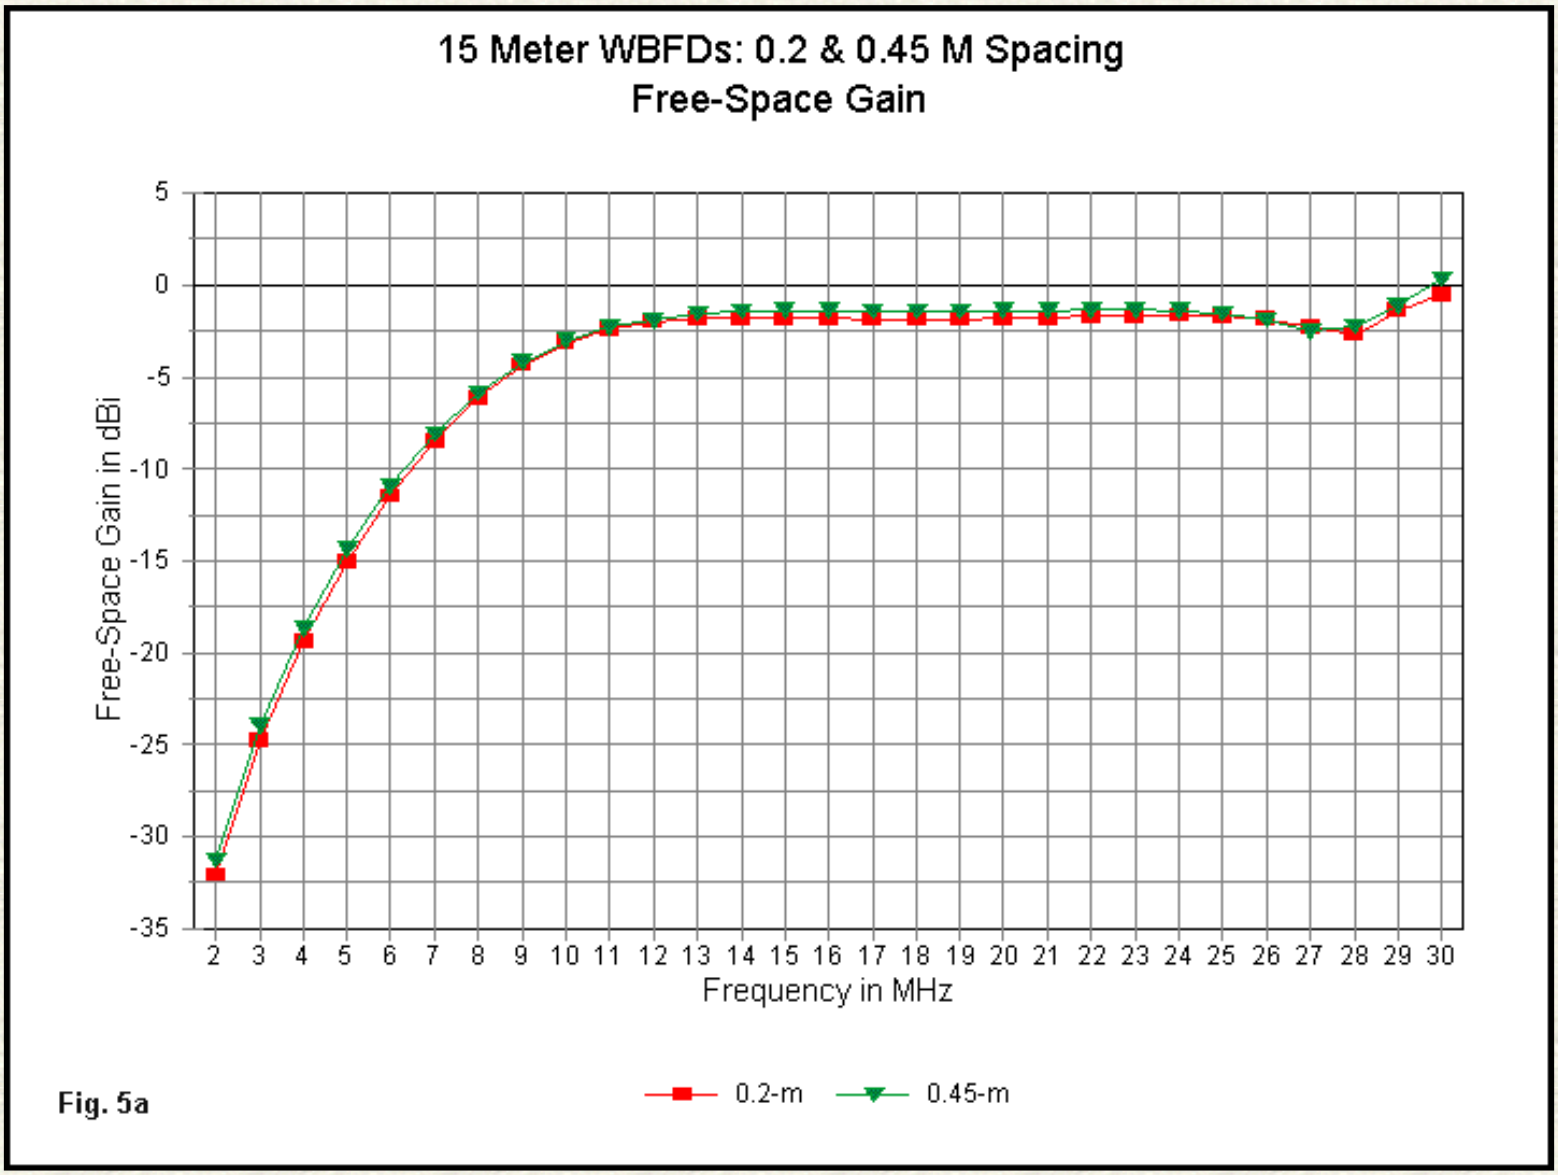

Fig. 5a

One question posed by various recommended wire spacings in past literature is whether wire spacing makes a difference to performance. **Fig. 5a** provides something of an answer as it compares the gain values for models of a 15-meter long version in 0.2-m and 0.45-m spacing. The gain values are insignificantly different, ranging from 0.2 to 0.4 dB.

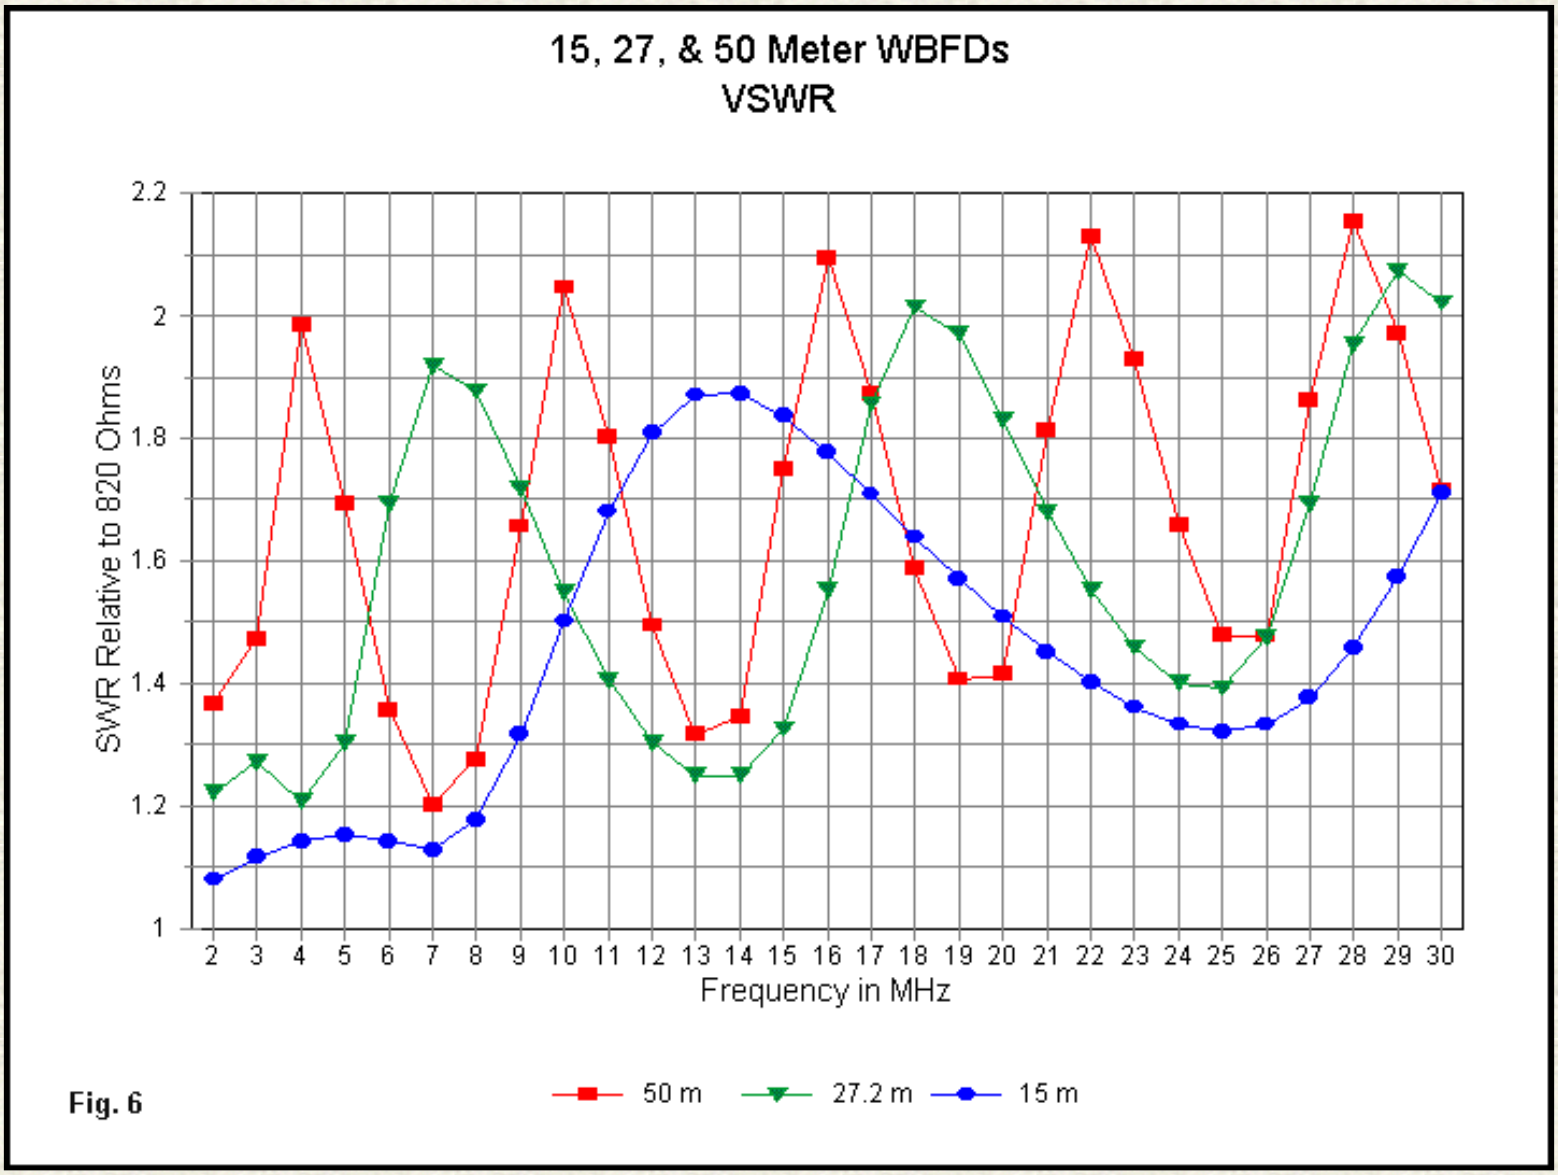

Fig. 6

We find that the curve of SWR relative to the value of the terminating resistor will also show similar transitions according to WBFD antenna length. **Fig. 6** shows the SWR pattern for the three antenna models. If we look at the most dramatic fluctuations--in the case of the 50-m antenna, we discover SWR peaks at x+2/3 wl points (where x is an integer). In contrast, we find SWR minimum values at the x+1/6 wl points (where x is an integer). The frequency span between points relative to the antenna length is 1/2 wl. The shorter antennas show the same pattern. However, the pattern is less evident because there are fewer maximum and minimum values to sample.

We may also note that the longer the WBFD, the higher the SWR excursions for a given value of terminating resistor. However, if we examine the lowest values of minimum SWR and exclude the region below the gain knee of the curve, the corresponding low points in the curve show the longest antenna also to exhibit the lowest minimum value of SWR. In other words, for a given wire size, spacing, and terminating resistor, longer WBFDs will exhibit a larger range within any given SWR cycle. As we approach the upper HF range, the values may exceed the desired 2:1 SWR limit.

The amount by which a long WBFD exceeds a 2:1 SWR is not great, but it is noticeable. For receiving applications, mild excursions beyond the 2:1 limit have virtually no affect on the received signal strength for any length of 50-Ohm coax. Some transmitters use automatic power reduction circuitry as the SWR approaches 2:1 (using an internal reverse voltage sensor), and some linear amplifiers begin reducing power at lower levels of SWR in order to protect expensive transmitting tubes.

There are two means of overcoming the potential problems of "high" SWR. Some manufacturers recommend the use

of very long coaxial cables. Since the losses in the line increase with frequency, the SWR observed at the station end of the line will be lower at higher HF frequencies than at lower HF frequencies for any given value of SWR at the antenna end of the cable. The result of using longer coaxial cable runs will then be an SWR curve at the transmitter output that never exceeds 2:1. Compared to the reduced gain already inherent in WBFD design, the added losses of a long cable run are not considered excessive when totalling the overall system gain.

Alternatively, modern amateur transceivers (and those in other services) are routinely (but not universally) equipped with automatic antenna tuner circuitry. Although limited in range compared to a wide-range external antenna tuner, these tuners are certainly adequate to handle the modest SWR values presented by even the longest WBFDs. Hence, the transmitter output circuitry prior to the tuner will show a very low SWR.

Construction

The decision to use a WBFD involves an evaluation of one's goals in operating or listening. Only with a set of specifications of this order can one decide whether the WBFD will meet the needs. The description of the antenna's advantages and limitations must be set against the operating specifications and along side other potential antennas that are candidates. Then selection becomes a matter of choosing the antenna that does most of the jobs well enough.

If you do decide to use a WBFD, you can purchase one of the commercially made types. B&W (USA), Giovannini (Italy), and others produce these antennas in a variety of lengths. Alternatively, you can build your own.

The antenna proper uses standard techniques of wide-spaced folded dipole construction. You will need twice the length of wire as you determine the antenna length to be. There is nothing critical about the exact length, although the general length will be a function of where you decide to place the frequency that forms the knee separating relative even performance at higher frequencies from diminishing gain at lower frequencies.

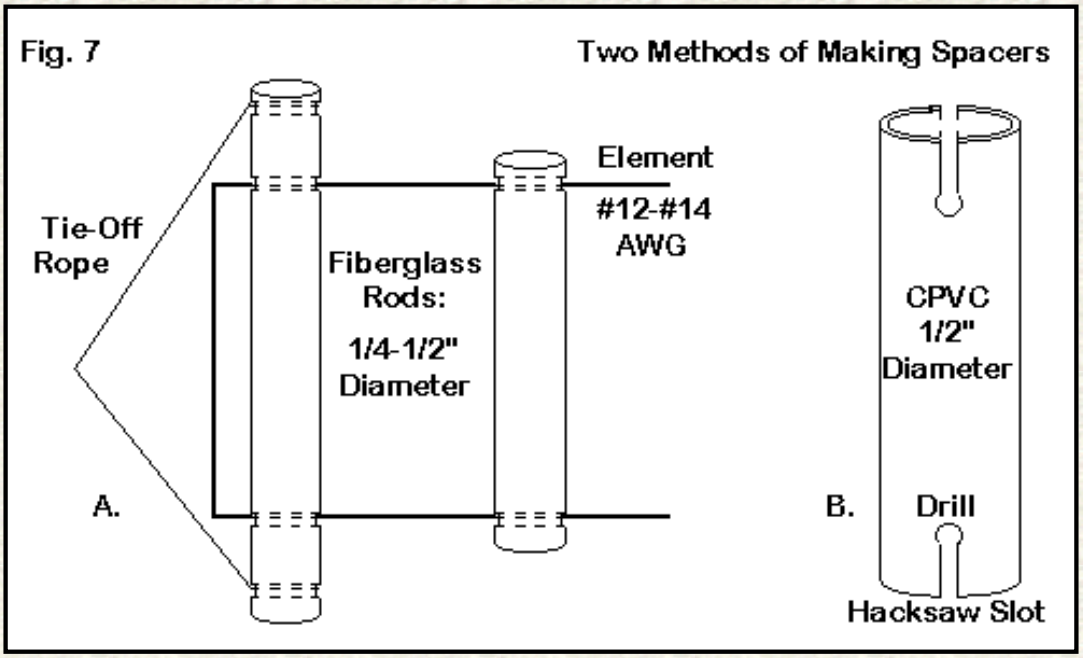

Fig. 7 shows just 2 of many ways to space the wires along their length. In the 1930s, we might have used wood dowels boiled in paraffin. Today, we have access to a variety of better materials. Part A of the sketches shows fiberglass rods, with holes drilled to pass the size wire we decide to use. #12 to #14 AWG copper wire (0.06-0.08" or 1.5-2.0 mm) is likely to be the most common choice. The end post can be longer to hold tie-off ropes for the assembly. Fiberglass rods can be purchased from mail order sources. However, local home improvement centers often carry adaptable materials. For example, I recently spotted some 1/2" diameter fiberglass rod under the guise of chimney flue brush extension handles.

Alternatively, I have also had good luck using 1/2" diameter CPVC, a thin-wall form of PVC tubing that replicates copper tubing sizes, shown in Part B of **Fig. 7**. A hacksaw cut in each end leads to a hole drilled to pass the chosen wire size. The wire press fits down the slot and into the hole. If the holes are not deburred, the wires stay put, although the spacers can be repositioned with fair ease.

These are simply two of many ways to make the required spacers. Narrow strips of polycarbonate, acrylic, or plexiglass would also work. Polycarbonate likely has the best UV resistance of this group. When adapting materials to a new use and environment, it is wise to check the structure every so often to ensure that it is wearing well under the influence of sunlight, precipitation, and temperature excursions. Of course, cut any spacers that you use to the desired length--about 8" (0.2 m) between wire holes for the models examined here. However, this spacing is not very critical.

Locating a non-inductive resistor of sufficient power dissipation is likely to be the chief problem for WBFD builders who intend to transmit with the antenna. Unless you can find a suitable resistor at one of the surplus outlets, purchasing an antenna may prove economical in the long run, if we add both cost and parts-searching time together. Any value in the 800-900 Ohm range--or even "thereabouts," if a bargain appears--will serve.

Manufacturers use different methods of packaging the resistor into the antenna assembly. Some prefer a total enclosure to weather-proof and bug-proof the resistor. However, one might have to derate the resistor's power handling capability under these circumstances. To maximize power dissipation, the resistor can be placed within a tube that is about twice the diameter and about 1.5 times the resistor's length. Air passing through the tube provides cooling, while the tube itself protects against immediate weather impacts. Since the antenna wire and resistor terminals will attach to strips of metal bonded to the tube, the resistor itself is relieved of strain. The down side of this technique is the need to clean out bugs and others debris on a regular basis. However, semi-annual inspection and antenna maintenance is always a good policy.

For receiving-only applications, the resistor problem is much simplified. A series-parallel combination of carbon resistors with a net value of about 820 Ohms is easy to arrange. 1 to 5 watt non-inductive resistors provide the sturdiest construction. The assembly should be mounted in a UV-resistant plastic housing with strong terminals for connecting the antenna wires.

The other challenging component is the 16:1 RF transformer. The builder has two general types of transformers to use: a transmission-line transformer or a standard wide-bandwidth transformer using a toroidal core. Transmission-line transformers are slightly more efficient for transmitting purposes, although they prefer purely resistive loads. Jerry Sevick, W2FMI, has written extensively on these units, with instructions on how to build them for many impedance transformation ratios. In a pinch, one might place two 4:1 baluns in series.

There are proponents of standard RF transformers using toroidal cores. Doug DeMaw, W1FB, has written on their use, including calculating the power-handling capability of various cores. For receiving-only applications, small cores can be used, and the basic requirements and calculations are described in recent editions of the *ARRL Handbook*, Chapter 6.

Whatever form of RF transformer you use, package it to withstand weather. A sealed UV-resistant plastic box with a correctly placed "weep" hole for moisture drainage is a good choice. Obviously, you will need connections for the antenna wires as well as a coax connector.

A 3-Wire Version of the WBFD

The WBFD has many variations, and from time to time--as I encouter and model them--I shall add a few notes on them. The first addition to the list is a 3-wire WHFD, outlined in **Fig. 8**, with the 2-wire version shown for contrast.

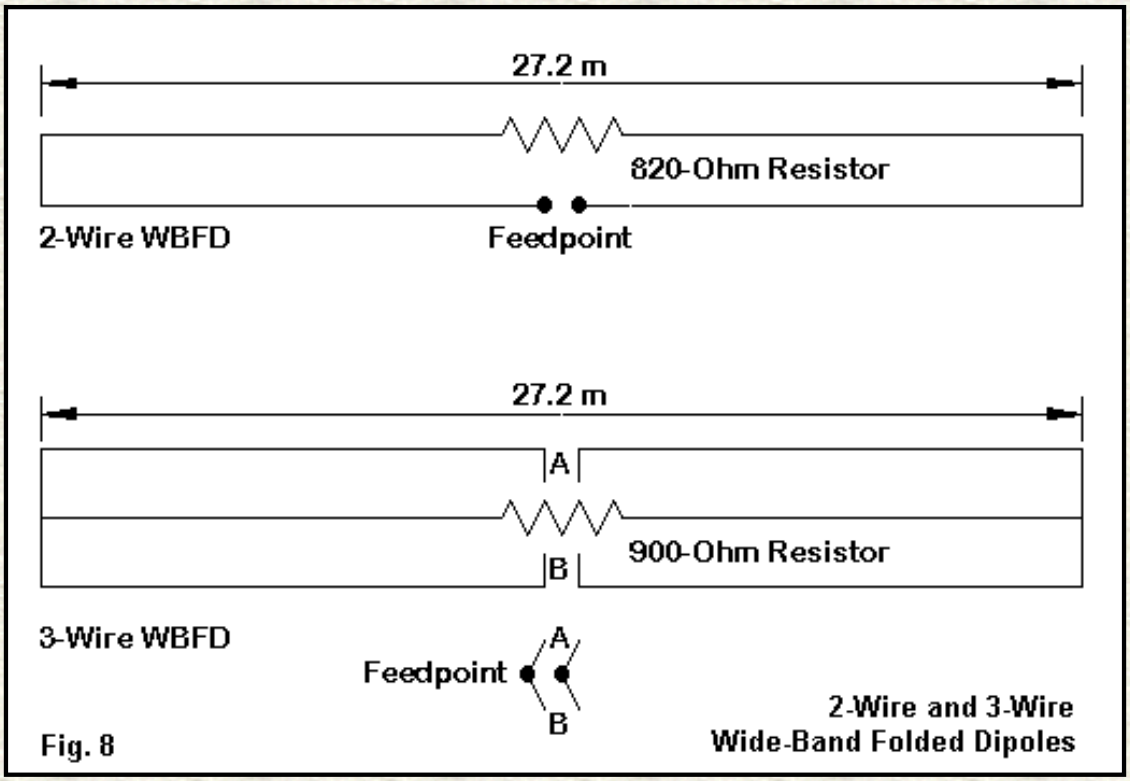

Fig. 8

For comparative purposes, I have made each antenna 27.2-m long, with a 0.2-m separation between wires. The 3-wire version places the terminating resistor in the "center" wire and parallel feeds the two "outer" wires. Although the arrangements is shown as a flat configuration, one can, as a variation, create a triangle of wires.

With two parallel-fed wires, the terminating resistor needs to be about 1.5 times the anticipated center feedpoint impedance. Hence, the model uses a 900-Ohm resistor, with 600-Ohms as the expected feedpoint impedance. Of course, the feedpoint impedance is a nominal value, since the actual resistive component of the impedance will fluctuate continuously above and below that value as we move across the operating span.

In general, the 3-wire version of the WBFD is capable of about 1-3 dB (depending upon frequency) gain advantage over the 2-wire version. The following brief table provides a glimpse at the fluctuations for the 27.2-m antennas. All gain values are for free-space.

Frequency MHz	2-Wire Gain dBi	3-Wire Gain dBi	3-Wire Advantage dB
5	-4.39	-1.62	2.77
10	-2.51	-1.11	1.40
15	-2.42	-0.39	2.02
20	-0.56	+0.74	1.30
25	-1.20	+0.53	1.73
30	+1.28	+2.58	1.30

Despite these fluctutations, the gain curves for the two versions of the WBFD are remarkable congruent, as shown in **Fig. 9**. The dual or parallel feed system of the 3-wire WBFD increases gain by feeding 2 wires, but it does not change the main characteristics of the antenna. Besides the congruence of gain curves, the patterns yielded by the 3-wire antenna differ from those of the 2-wire version only in peak gain, but not in strength. Since the gain increase is marginal, both antennas have patterns that replicate those of a simple doublet (with its widely varying impedance with changes in frequency), but remain smaller, that is, have much lower peak gain values.

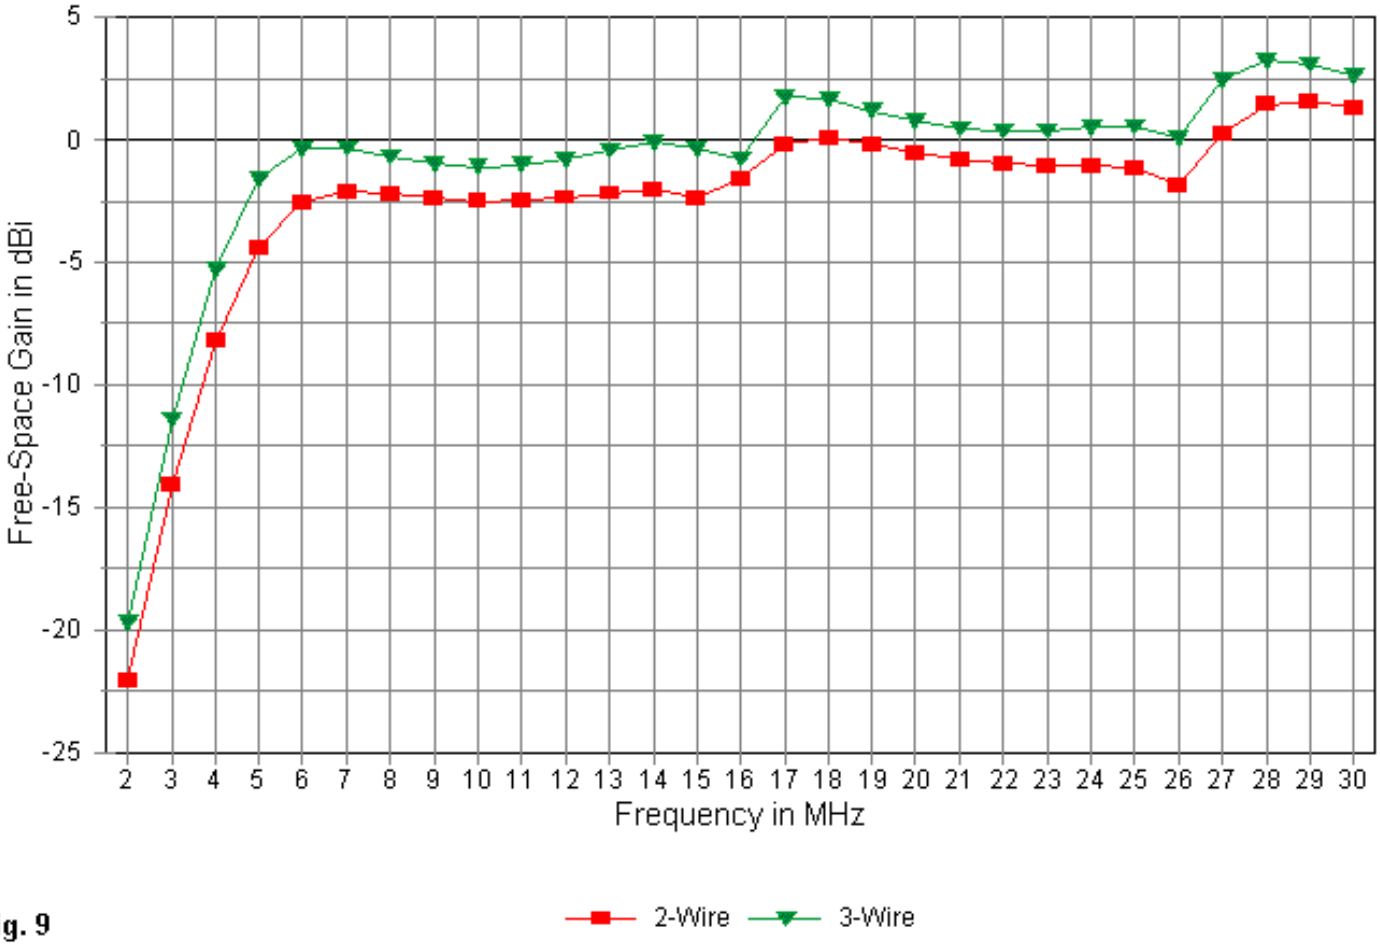

Fig. 9

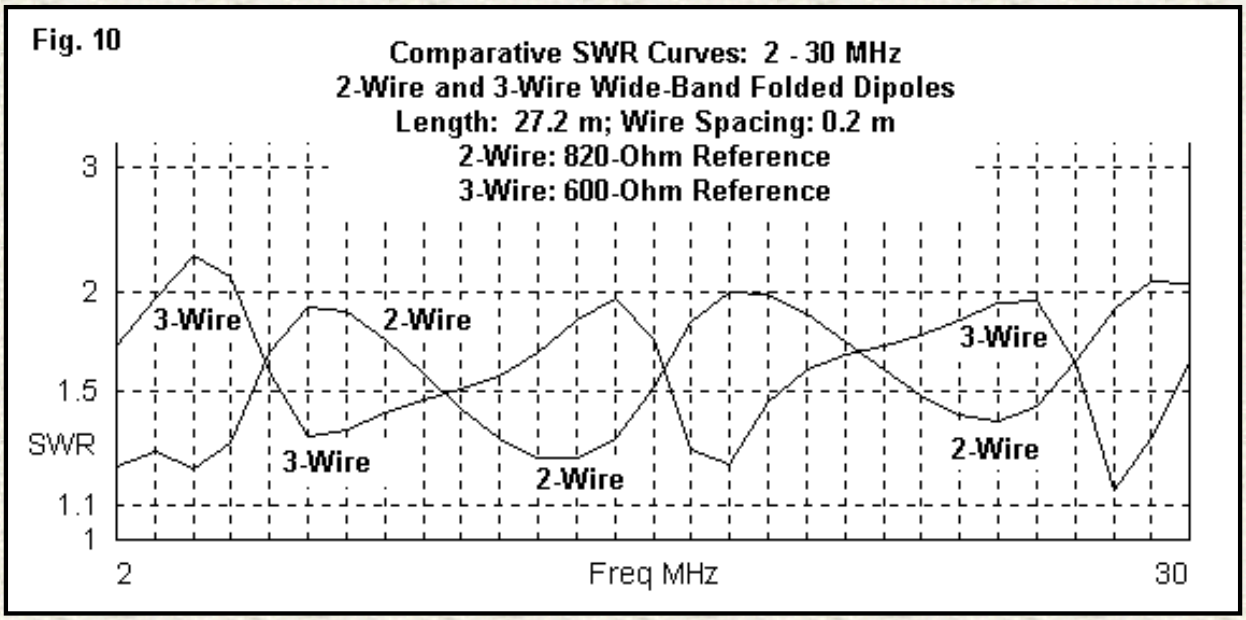
The cost for the small increase in gain is a wider fluctuation in the impedance about a central impedance value. The reactance tends to be somewhat higher than for the 2-wire WBFD. **Fig. 10** shows the comparative SWR curves for the two antennas, with each one using its own reference value: 820 Ohms for the 2-wire version and 600 Ohms for the 3-wire version.



In addition to having higher peak values in the 2-30-MHz span, the 3-wire version curve slopes differ from the corresponding 2-wire slopes. The shallower parts of the curves are on opposite sides of the peaks.

The construction of a 3-wire WBFD can generally follow the same set of techniques used for the 2-wire antenna, with the separators enlarged to handle the broader plane. The additional wire will increase the weight of the antenna proper by nearly 50%, and center support of the terminating resistor and the feedpoint area is advisable. Short sections of 600-Ohm (or thereabouts) open-wire feedline can create the feedpoint junction. Like the 2-wire WBFD, the 3-wire version requires a balun system or a wide-band transformer to match a 50-Ohm coax feedline.

WBFDs can be used in inverted-Vee configurations. However, expect a decrease in the broadside gain and some vertically polarized radiation off the ends of the array--just as you would find in a simple doublet. The steeper the angle of the two side of the antenna, the greater will be the radiation off its ends. As the antenna length exceeds 1 wavelength, the patterns may increasingly differ from those of the antenna used horizontally.

Conclusion

A WBFD antenna is not for everyone. However, gaining some understanding of its operation, its advantages, and its limitations may be useful in the process of choosing an antenna--or even simply learning more about what various antenna types can do. The WBFD has its niche among amateur, governmental/military, and SWL antennas, but that niche is certainly not universal.

Receiving versions of the antenna can be home built for not much more than the cost of the wire, since the materials necessary for low-power terminating resistors and wide-band RF transformers are low. However, building a transmitting version of the antenna at home may be much more problematical, since parts may be hard to find or hard to fabricate. The alternative, of course, is one of the commercial versions, in an exchange of bucks for bother.

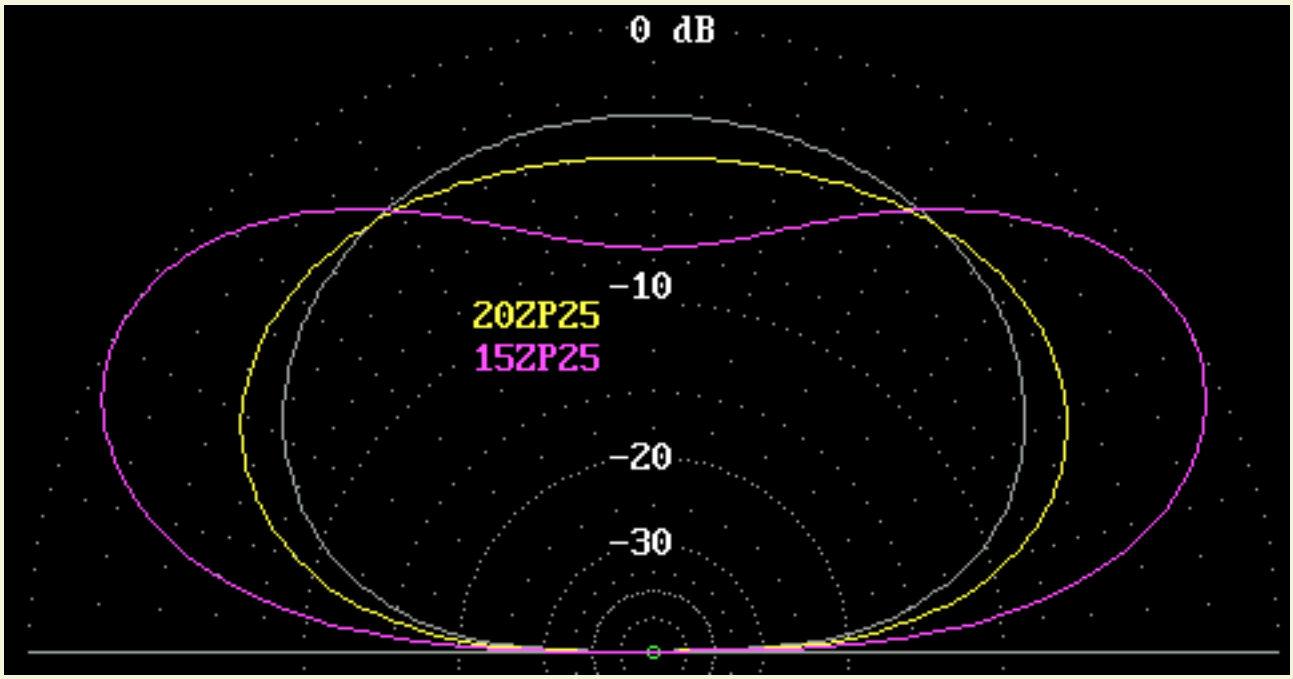
The Extended Double Zepp Dipole

Cut for 15 Meters

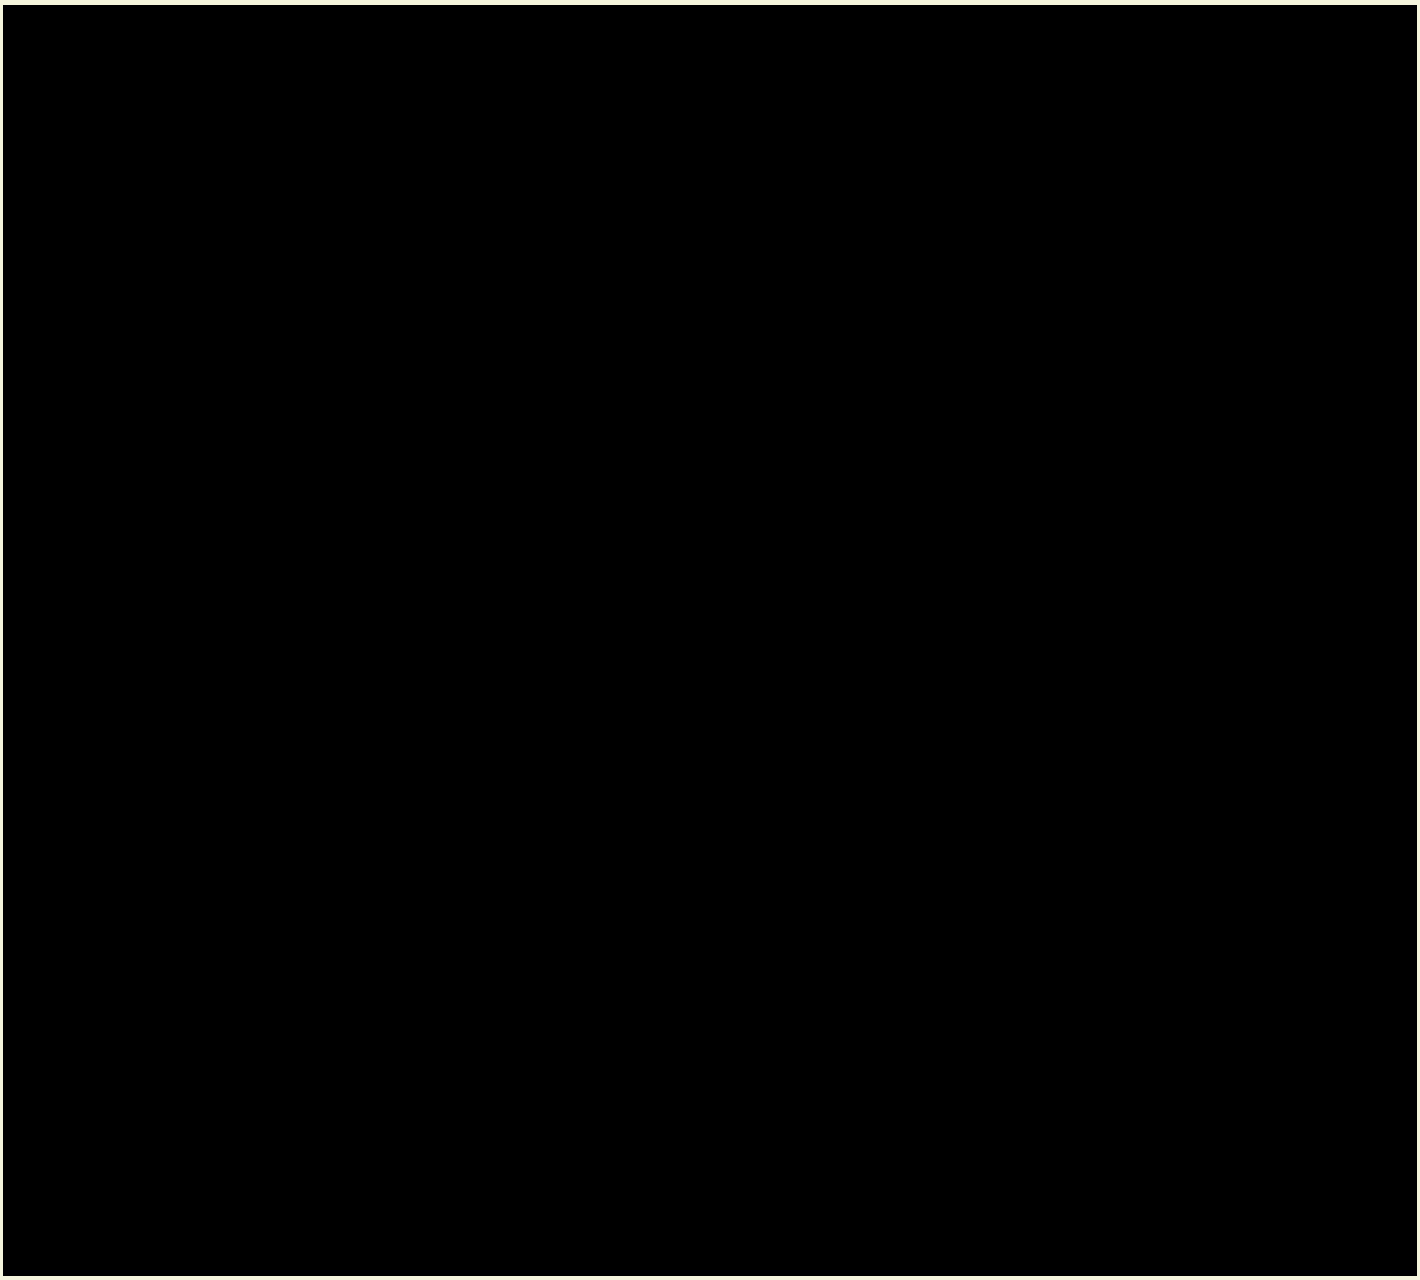
Mounted 24 feet high

An extended double zepp antenna for 15 meters is modeled mounted on two 24 foot poles spaced 60 feet apart. The antenna is cut for 15 meters and is 346 inches each side of center. It is feed in the center with 300 ohm twin lead. Typical feedpoint impedance is 119 ohms resistive and -692 ohms reactive. The EDZ is a fine antenna with several special properties.



Above we see a comparison of the broadside views of of the 15 meter EDZ loaded at 40 meters (grey), 20 meters (yellow) and 15 meters (pink). The 10 meter plot is not included here because it is split on the end as this approaches a long wire on 10 meters. Gain on 15 meters in the favored direction is 11 dbi with a launch angle of 26 degrees.

The EDZ is just about as long as a wire can get in terms of wavelength before the donut broadside pattern typical of a dipole quits sharpening and splits into two lobes. In fact you can see that already the split lobes are appearing at 15 meters. As frequency is increased further, these lobes grow rapidly and the broadside lobe shrinks rapidly. As wavelength is further shortened on a given wire length, it starts acting like a long wire with these split lobes getting closer and closer to the direction of the wire and multiple minor lobes appearing.



Viewed from above we see the 20 meter pattern (grey), the 15 meter pattern (pink) and the 10 meter pattern (yellow). Note how the 10 meter pattern has split and now has maximums that are 42 degrees off axis of the antenna broadside and an unfortunate null directly broadside to the antenna. This changes abruptly the favored angle of radiation of the antenna from dipole to long wire pattern. However, gain on 10 meters is excellent, being close to 12 dbi in the favored directions.

Another major consideration of the EDZ is mounting height. Since the dipole pattern is sharpened, it sends considerable energy towards the ground near the feedpoint. Thus the antenna changes pattern abruptly with height above RF ground. Optimum mounting height for such an antenna is close to .6 wavelength above RF ground. Below that there is some gain loss. Above that a vertical lobe starts to appear that saps energy from the desired low angle radiation.

This means an EDZ for 15 or 10 meters is a practical portable antenna. It can be loaded on the lower

bands, can be mounted only a 1/2 wave high which is just 21 feet at 15 meters and 16 feet at 10 meters, and it will perform adequately at lower bands while giving very worthwhile gain on the band it is specifically cut as an EDZ.

Of course the EDZ can be cut for lower frequency bands, but at 40 meters it now wants to be mounted about 70 feet high for best results. At 80 meters that climbs to 130 feet for optimum mounting height. Due to the fact the pattern will split just above the design frequency, the EDZ should be optimized for one of the higher bands you plan on using it on.

As long as you have a decent tuner designed to handle the reactive feedpoint which is highly capacitative and about 120 ohms resistive at the design frequency, you can effectively load an EDZ on many adjacent bands. The 15 meter one models as loading with a reasonable pattern on 40,20,17,15,12,10,6 meters. With the best results being broadside on 17,15 and 12 meters, though it works well on 20 meters.

DXpedition Antennas for Salt Water Locations

A study on 20m Antennas

By Kenny Silverman, K2KW

Which is better a 20m antenna for an island DXpedition: Yagi at 25', or a vertical or two on the beach? (Hint, You are on a web site dedicated to vertical antennas - this is a trick question!)

"Conventional Wisdom" would say that Yagi (typically a tribander or 2 element full-size Yagi) would be a great choice of antennas for a DXpedition on a beach. What makes the Yagi so great? Lets examine the reasons to use a Yagi…

The Top 10 Reasons to use a Yagi on a DXpedition, even when you are on the beach:

1. You have used Yagis at your home station
2. You understand how they work
3. Yagis have directivity
4. Everyone else uses Yagis on DXpeditions, so the *must* be great
5. and…

Hmm. I can't think of any other reasons! But everyone knows that *any* antenna by the ocean works great, or at least "conventional wisdom" tells you so.

O.K., lets examine the use of a Yagi for a serious DXpedition to a remote island. For this discussion, let's assume you are going on a DXpedition of a lifetime to Kingman Reef (KH5K) in the middle of the Pacific Ocean. Kingman is an interesting island which is about 25' wide, and 450' long. The entire island is made up of broken shells, rocks, and rubble. There is no sand, trees, or anything else. The wind typically blows at a steady 30 mph. You are days away from any kind of medical help.

Now imagine the difficulty of assembling a typical triband Yagi, where if you drop a nut, you won't likely find it again. Then your team has to armstrong the 35-40 pound Yagi, which is on top of a 25' mast, into the upright position. I'm assuming you aren't even going to consider a rotator, which would add another 25 lbs. to the top of the mast! Remember that the wind is blowing at least 30mph, and you are standing on loose rubble. To get the Yagi installed, you will probably need 3-4 people to walk the antenna up and hold it in position while securing the base in the shells, finding stable guy points (for 2 sets of guys, or 6 ropes total) in the rubble, and adding a tag line for rotating the Yagi. Any slip-up, and one could easily get cut on the rubble, or even possibly break a bone if you fell. Any relatively small problem like that in the tropics will likely become seriously infected in short order. Based on the wind and the hazardous conditions, you will probably need 4-6 people for a few hours to safely erect the antenna. This is looking like a lot of effort for just one antenna…Ahh, but waiting hams are worth the effort aren't they?

Maybe, but your health comes first. You may wonder - is there an easier and better way?

First, lets think a little more about propagation to Kingman Reef. Kingman is in the middle of no place, more precisely, in the middle of the Pacific Ocean. Based on the distances from the 3 main target areas, most take off angles are likely to be very low, usually under 10 degrees, and often below 2 degrees! Europe is the main target, and you will likely spend half your operating time on long path (typically very low take off angles). Most typical Yagi antennas have a beamwidth of around 60 degrees, which means that you will likely have to turn the Yagi for each of the main target areas:

Directions to target areas from KH5K:

JA: ~ 305 degrees

Europe: from ~355 degrees to 20 degrees (which is the main emphasis for the expedition)

USA: from ~43 degrees to 58 degrees

Continuing with our original "Yagis are the best" scenario, you remain convinced that the Yagi is still the best antenna. What if I told you that a simple 1/4 wave vertical on the ocean, or better yet a 2 element vertical dipole array, would be a far better performer! I can hear the pundits saying: "Verticals are for kids!" or "Real men use Yagis!" You believe there is no way that a Yagi could be inferior to a vertical!

So why do you think that verticals work so poorly? Because "conventional wisdom" says so? Unfortunately "Conventional Wisdom" on the performance of vertical antennas usually comes from comparing a Yagi at home to the trapped vertical in the back yard. At home the Yagi *will* be better, but not on the ocean! On the ocean, you will see that verticals are the clear choice for high-performance antennas, that just happen to be easier to install too!

First off, let me dispel one long-standing myth: Horizontal antennas over salt water do *not* get any enhancement from the salt water (from increased ground conductivity). Well, to be exact, almost all useful angles for HF propagation get little or no useful enhancement. The horizontal antenna (and so does the

vertical) receives a benefit from the ocean, because the ocean presents an undisturbed foreground for the incoming and out-going energy. Salt water also has less loss than typical ground for every reflection. To show you the impact of ground conductivity, the following two Figures were created: Figure 1 (below) shows that the take off angles in the 30-90 degree range (straight up) do get some limited enhancement from the salt water. Figure 2 (below) compares a 2-element vertical array over land and salt water. The only antenna that gets *significant* signal enhancement by being next to, or over, salt water is a vertical. In fact, verticals get about a 6 dB increase of gain when placed over salt water, and the radiation in the pseudo-Brewster angle is filled out (which is radiation under ~12 degrees). So the salt water is enhancing signals right were most DX signals are arriving - in the pseudo-Brewster angle!!

Figure 1: 2-element Yagi at 25' over land and salt water. Peak gain is 10.40 dBi (over salt water) at 38 degrees take off angle in this design.

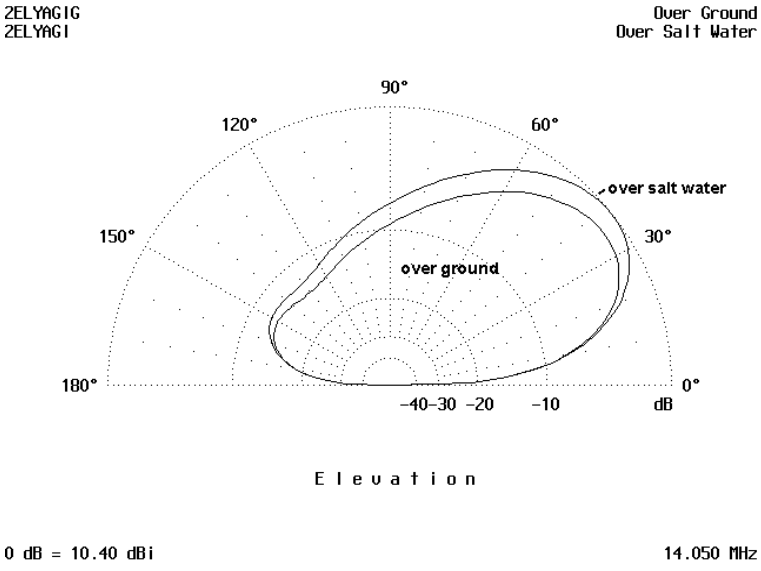

Figure 2: 2-element vertical dipole array (parasitic) over average land and salt water. Peak gain is 10.01 dBi (over salt water) at 8 degrees take off angle in this design.

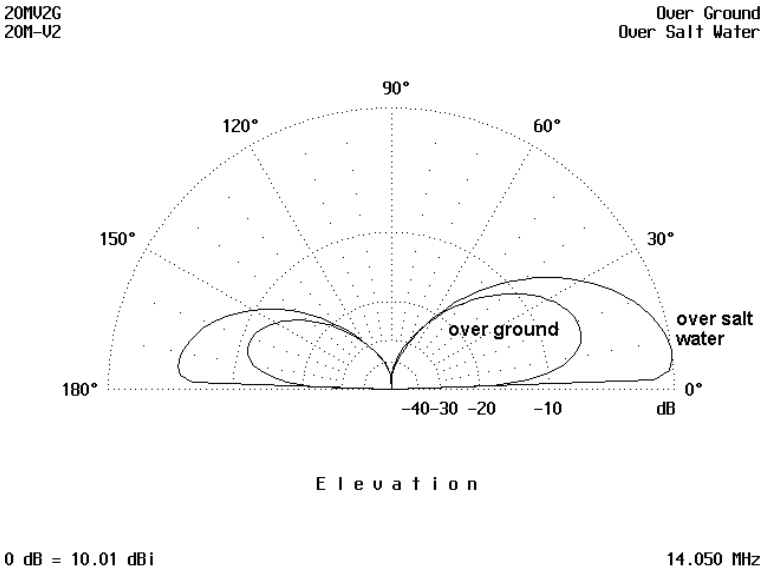
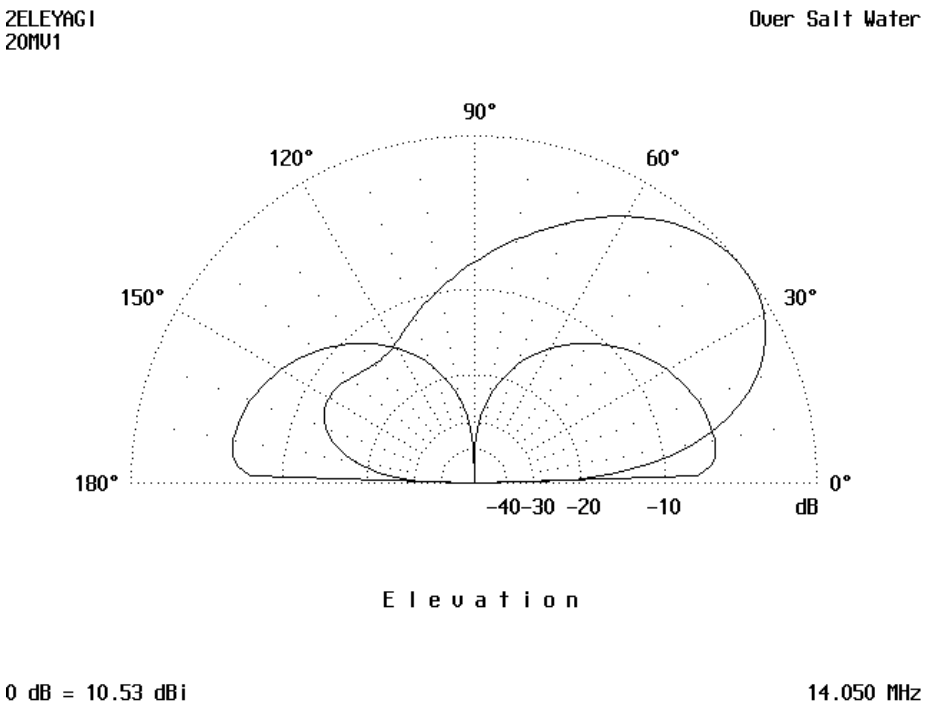


OK. Let's get back to Kingman.

I suggested that a simple vertical would be better for most useful take off angles… let me show you why. Figure 3 (below) compares a 2 ele Yagi at 25' height over salt water compared to a 1/4 wave vertical over salt water. The antenna with lots of gain at 40-degree take off angle is the 2-element Yagi at 25'. The other antenna is the 1/4 wave vertical. Notice, at take off angles below 10 degrees, the vertical is the hands down winner! You may point out that the Yagi has more "gain". This is true, but the extra dB or two gain is at take off angles that don't matter! A simple vertical by the ocean can and will usually outperform a Yagi on most typical DXpedition paths, because the energy from the vertical has fewer hops to the target! It's all a matter of the angles of the arriving signals.

Figure 3: Yagi at 25' compared to a 1/4 wave vertical over salt water

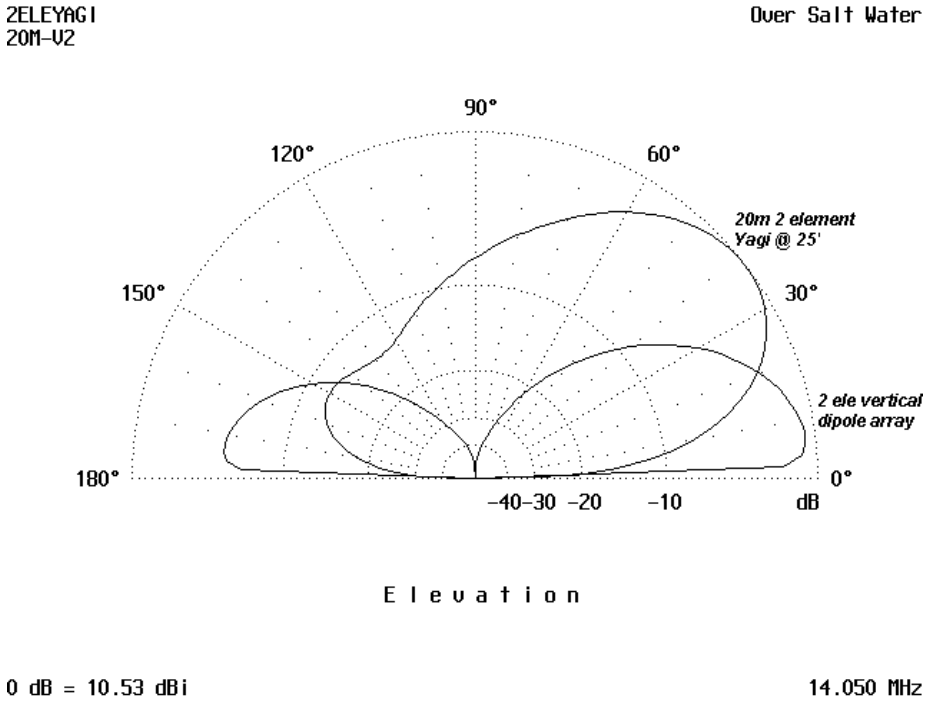


As you saw in Figure 3, the 1/4 wave vertical is a good performer. Even better for our Kingman Reef expedition is that a single vertical is really light weight (maybe 3-4 lbs for the 16' vertical), and can be assembled and installed in just a few minutes. Compared to the Yagi, the vertical only needs some rudimentary guying, and you don't have to worry about turning the antenna! And since you are going there to operate, you can be on the air in 30 minutes if you wanted! Try that with the Yagi.

I bet that some of you aren't convinced yet that a single 1/4 wave vertical is a good enough choice. OK, lets up the "vertical anti" a bit, and rather than a 1/4 wave vertical, lets examine a 2-element parasitic vertical array using 1/2 wavelength vertical dipoles. To better understand what this array looks like, picture a 2 element Yagi standing vertically, but minus the mast and boom to support it (much less overall weight). (see picture to right)

There are a few advantages of using vertical dipoles (vs. 1/4 wavelength elements): they eliminate the need for radials, and by raising the feedpoint, you achieve an additional 1.5-2.0 dB of gain at low take off angles. A parasitic vertical array (vs. a phased array) is an easy way to increase gain and directivity, yet is still very easy to install and tune up. The parasitic array needs less parts than phased array, which is an important aspect on DXpeditions. Figure 4 (below) compares the 2-element Yagi at 25' to the 2-element vertical array using vertical dipoles. You can see that the vertical array now has nearly the same peak gain as the Yagi, but the gain is focused right where most of the arriving signals are coming from: 0-10 degrees! And the verticals are now the clear winners from 0-20 degree take off angles - who could ask for more? Since many of the signals are arriving at around 1 degree take off angle, often the verticals can be 20 dB stronger than that Yagi! Talk about a band-opening antenna!

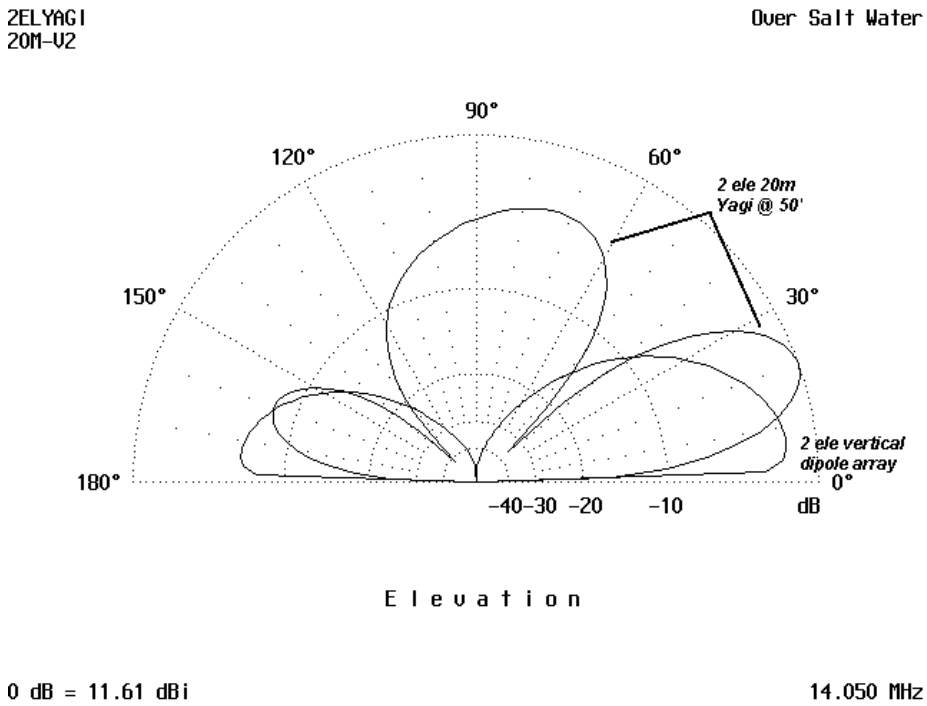
Figure 4: Yagi @ 25' compared to a 2-element vertical array using vertical dipoles



But I'm sure that the Yagi-lovers are saying: "I bet if you were able to get the Yagi up to a good height like 50', that it would surely beat the vertical array. Think again dude! First off, installing a Yagi at 50' on a DXpedition is difficult, if not impossible. Secondly, it still doesn't compare to the vertical array! Figure 5 (below) compares the 2-element 20m Yagi at 50' to the vertical array. Notice that the Yagi now has a large amount of energy being radiated straight up. Sure the main lobe is lowered, but the 2-element vertical will still be better on most DX signals.

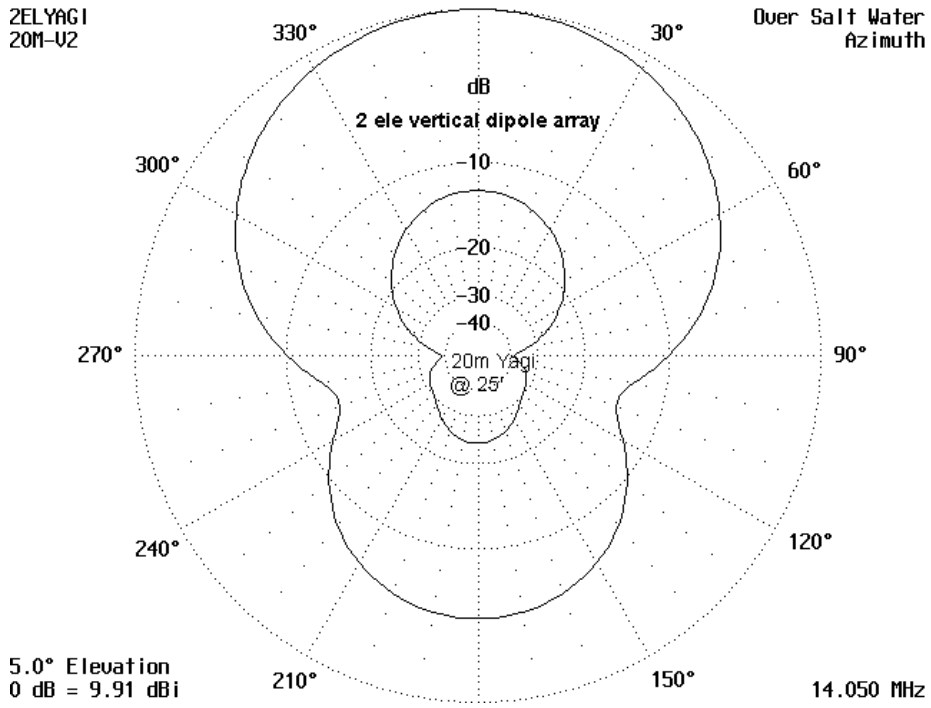
Remember, that a typical tribander weighs at least 35-40 lbs., and add another 20 pounds or so for the mast, for a total of at least 55-60 lbs. A two element full-size vertical dipole array for 20m weighs no more than 18 lbs. if properly built. A vertical array is much more efficient if you consider a key metric for DXpeditions: dB per Pound of Antenna.

Figure 5: Yagi @ 50' compared to 2-element vertical array using vertical dipoles



And you still need more convincing? OK, Figure 6 (below) is the energy at 5-degree take off angle. The antenna with all the signal (the big one) is the 2-element vertical array which has 9.9 dBi at 5 degree take off angles. The antenna that is down 12-20 dB in all directions is the good ole Yagi at 25'… Another key point is that a 2 element vertical array has a very wide pattern, which is on the order of 120 degrees for the -3dB points. Thus the 2-element vertical array can cover all 3 main target areas without turning the antenna!. In addition, if there are callers from other directions (assumes there is a water path in those directions), the vertical has more useful gain than the Yagi does on azimuths that are off the side or back of the antenna.

Figure 6: Energy at 5 degree take off angle of a Yagi @ 25' compared to a 2-element vertical array using vertical dipoles



Some of the pundits might still say this was a "Made up" example…Sorry to disappoint you, but the Kingman Reef example was real, and was based on the planning discussions for the upcoming Kingman Reef DXpedition. For many island DXpeditions, vertical arrays should be given more consideration on the high bands than they currently are receiving.

The computer models have been verified by empirical testing we did from salt flats while shooting over salt water. The measured data follows the model. Verticals were selected for the "Team Vertical" locations in the Caribbean and comparisons to full-size Yagis were made, confirming the models, as well. The comparisons were done over many continuous hours of switching back and forth, with differences of up to 9 S-units (on an 'MP meter), averaging 2-4 S-units, in favor of the verticals. The Team Vertical Yagis were occasionally used during the contests, but only to cover directions where the verticals has nulls. This might be one of those situations where if you haven't tried it, you don't realize what is happening. How good is a larger vertical array using vertical dipoles? Tom, N6BT, has commented that they are truly on par with the large commercial curtain arrays he used in Saipan. Salt water is the key to verticals. If you can get close to salt water, or literally sit right in it, such as at Kingman Reef, verticals are the answer to high performance antennas - besides being significantly easier to transport and set-up.

73, Kenny K2KW

Special thanks to Tom Schiller, N6BT, for offering input to this article.

E-H Antenna

[Home] [Up]

Background

Many antennas function because of common mode currents, rather than working in spite of them. Two popular examples are CFA and EH antennas. Another recent example, appearing in Antennex's compact antenna articles, is a thick stub "vertical" with no counterpoise.

All of these antennas become significantly poorer radiators if common-mode currents on feedlines are eliminated. Why? Because the feedline is the actual radiator, ***NOT*** *the tiny thing they call the antenna.*

Misunderstanding or misapplying Maxwell's equations and the principles behind radiation, in combination with missing some very key points of conventional circuit theory, causes problems. Some of us have unwittingly attributed increased feedpoint resistance and/or seemingly disproportionate amounts of radiation from very small structures to new methods of radiating EM waves. Reviewing these antennas and the theoretical or technical mistakes surrounding them will help us understand how antennas and transmission lines work. With that knowledge, we can build better antenna systems. The fastest and best way to learn is often to look in detail at mistakes!

What They Claim

Articles and user reports of CFA, EH, and thick stub verticals (without groundplanes) appearing in Antennex and other internet publications have one common thread, the operational descriptions almost always include strong indicators of problems with feedline common-mode current.

Authors commonly warn users to NEVER choke feedlines with baluns and to "be sure the feedline is straight and in the clear"! Authors lay blame for RF burns from feedlines or shack equipment on the antenna's "high radiation efficiency", claiming these small magical antennas radiate so efficiently they naturally excite the feedline and equipment more than full-size antennas.

For example, Ted Hart (of EH Antenna fame) claims the following at:

http://eh-antenna.com/documents/RF_on_the_Coax.pdf

"RF on the Coax

Due to the large radiation at the EH Antenna, there will be some RF coupling to the coax. Whether this is a problem is dependent on the radio you use. Some are subject to RF coupling into the audio system, which causes severe distortion while transmitting. On some field day setups with 100 watt transmitters we have had so much RF on the radio you can get an RF burn. Below we have suggested ways to eliminate the RF coupling problem."

In the above statement, Ted actually acknowledges current on the feedline shield and RF-voltage-on-chassis problems. The problem must be severe when a low-power 100-watt radio causes a burn. Like any good salesman, he turns a design shortfall into a feature! According to the author, unwanted RF on the feedline doesn't come from a feedpoint or antenna design problem like it does on other antennas, in this case it appears because the antenna works so well!

Here's what actually causes RF to appear on a coax shield and radio chassis. RF can only appear on the radio chassis through two methods:

1.) The antenna, from poor feedline or feedpoint design, can couple to the radio chassis through external wiring or cables attached to the radio.

2.) The radio chassis itself, being large in terms of the wavelength, can actually become an antenna and receive energy from actual desired "over the air" signals.

(Many of us have these problems. Click on this link to see one reason why.)

In this case, we can probably rule out reason two above. It is unlikely the chassis is a large portion of a wavelength long on 20-meters and that the antenna field is suddenly so strong it is "lighting up the house" with RF. After all, if power is radiating effectively it will all be going out to distant stations and NOT cooking you or the radio gear in your house! That only leaves reason one, poor feedpoint and antenna design, as the cause of common-mode feedline or wiring currents that excite the coax shield and eventually the radio chassis, as described in method one.

Actually someone has measured this, and posted it to a web page!

http://www.home.earthlink.net/~calvinf15/_technical/

When the time-varying current from the transmitter flows in any conductor, we will have charges accelerating in the cable. The outside of a shield is no exception. A feedline's shield will radiate proportionally by the ampere-feet of the cable. just as any other conductor will. Of course the antenna element will radiate also, but there is something else to consider.

A very small current flowing unopposed over a large linear distance will radiate quite a strong signal, because radiation resistance of a long antenna is generally very high compared to very short antennas. You can find this explained in the Radiation&Fields and Radiation Resistance articles on this site, and in engineering textbooks such as those written by Jasik, Kraus, and Jordan-Balmain. From all of this, we know the shield radiates.

The inventor of the E-H antenna goes on to say:

"If you use RF beads, since the coax shield is not a magnetic shield, the beads affect both the inner and outer conductors. Therefore, most of the transmitter power will be converted to heat. Not good."

Not a very knowledgeable statement at all, at least from the standpoint of how shields work!

Time-varying fields can not pass through a shield that is more than several skin depths thick. The inner part of the shield and outer part are isolated by the skin effect, and nothing passes through. The ARRL Handbook, Maxwell's book "Reflections", Reference Data for Radio Engineers, and dozens of other amateur radio and engineering texts describe this effect correctly. If we bring a time-varying electric field to zero in a system, the time-varying magnetic field is also by definition zero. The shield DOES isolate the center of the cable from time-varying magnetic fields on the outside of the cable!

If that is true, why then does a shielded cable passed through a current transformer used in a directional coupler appear to pass RF magnetic fields? Why does the RF magnetic field seem to "pass through" the shield of a shielded receiving loop antenna? The answer is quite simple. There is a gap or intentional break in the shield.

Current on the inside of the shield "spills over" the edge of the shield where the shield is broken, and causes a current on the outside of the shield. There is also a voltage across the gap at each end of the shield. We have both our time-varying voltage and current, via a circuitous path to the shield ends! Our Amateur texts explain that effect, as do all of the engineering texts dealing with shields on transmission lines. If the gap is closed and the shield's ends are shorted together, making voltage across the shield gap zero, the magnetic field no longer "seems to" penetrate the shield!

If a shield did not behave this way, we'd be in serious trouble in the radio world. Without the shield stopping both magnetic and electric time-varying fields, we could not shield our radios. We also could not shield our microwave ovens, with non-magnetic materials!

If anyone thinks a ferrite core affects the impedance inside a coaxial cable that does NOT have significant common mode current, they only need to slip some beads over a cable on a working normal "cold-for-RF" feedline. You will find absolutely no difference in system performance when

beads are added, proving Ted does not "have it right" in the text above that appeared on the E-H antenna web site.

The author and inventor of the E-H goes on to say:

"Use of a small choke made of several turns of the coax is good. We find that a wire connected to the ground side of the coax at the antenna and connected to either a ground rod or a wire laying on the ground will eliminate RF problems - in most cases. For some radios we also need to add a ground wire to the radio."

Of course adding a ground wire might help! The ground wire becomes the path for common-mode currents, or at least a portion of them. The additional wire to ground becomes part of a long-wire antenna (made by the cable shield) that actually does most of the radiating!

"A preferred method is to run the coax to ground then back to the radio. Near ground, connect the shield of the coax to a ground rod or radial. Another method is to connect a wire from the radio to ground. If the radio is very far from ground you will need to add a series resonant circuit in the ground wire to effectively cancel the inductive reactance."

It is understandable why this is a preferred method! The outside of the coax shield can remain the primary antenna, saving us the bother of installing the additional ground wire that becomes the antenna in the previous suggestion!

"It may take one or more of the above to solve your problem. Remember that if you have a good ground on the antenna, you have also minimized problems with lightning."

In the above text, we can see every solution carefully avoids installing an effective choke balun on the feedline. A properly designed and effective choke balun has no effect on a coaxial feeder or system SWR, unless the feedline is radiating!

Let's look at another E-H antenna experimenter and former proponent of the E-H antennas test of a 160-meter E-H antenna. You can read the text directly at:

http://www.qsl.net/iz7ath/web/02_brew/18_eh/english/pag11_eng.htm

Steve writes:

"With my short (and easy) tests I deduce the EH lose about 10 dB versus my short 10 mt vertical with capacitive hat in the top;
10 db is a big amount of power, but remember we are using 2 small cylinder of 37,5 cm on 160 mt band; my vertical performed better than a 40 mt long sloper, so, may be, loss versus full size dipole is not too much."

Steve claims the E-H antenna looses about 10dB compared to a 1/4wl sloper, which has an unpredictable efficiency. A typical sloper 1/4wl sloper is likely only around 50% efficient in the best situations, and more likely much worse! The actual range can be from 10 to nearly 100% efficiency. Steve's data repudiates Ted's claim and the CFA inventors claim that "crossed-field" antennas provide high efficiency.

"There seems to be something good;
May be optimizing something we can have more gain (or, better, we can lose less dB);
This antenna can be useful on the low band, expecially on 137 KHz (the EH cylinder should be 6 mt high with a 2mt diameter).
On the web I've seen an other similar antenna (ISOTRON), wich seems caming (as EH Antenna) from CFA antennas;
On the italian Radio Rivista (1995-1996) there were same informations about an "Antenna Toroidale" wich in same way remember the EH: will be interesting build and test one."

Steve seems to be saying something we all agree with. A short antenna will radiate, but not nearly as well as a full-size antenna.

"By the way, I think that my EH is not for Dxing; it will be useful for that radioamateur who have no possibility to install "long" antennas for low band, but want just to have local QSO or few contest-contact."

I agree! 10-20dB loss from a full size antenna would not make a good DX antenna! Now here come the current-on-the-feedline problems:

"Other point: tuning;
I think it's not as simple as others say; I've used an MFJ259B which tells me all about the antenna, but the tuning was critical. On the other side construction is easy;
I want suggest to you , when tuning, to connect the MFJ259B to the shack ground (if there's one). If not, EH will probably resonate higher (20-30 KHz)."

If grounding and ungrounding an antenna analyzer or any other piece of equipment connected to a coaxial cable causes resonant frequency or SWR of an antenna to change, the system has severe feedline radiation problems. See my article on testing baluns.

"Coaxial cable influence: inserting more coax cable, the resonance seems to vary a little; I suppose that's normal;

I don't know for certain if the line radiates or not; I've added two iron-powder coil forms back my TX and EH performance was unchanged. Then later I've added 2 big ferrite beads with a lot of turns on the roof (at the feed point of the EH) and all has changed. My signal was 3 S point weaker than before and S.W.R was very high.
I don't know if that loss is due to the changed resonance in EH (as I said before, outside the bandwidth performance goes down quickly)."

We see again that any attempt at reducing feedline radiation results in an antenna that does not radiate very well. With the feedline choked, Steve's EH antenna dropped 3 S-units in addition to the original 10dB from his sloper, or maybe 25dB or more!

There surely is a hidden message in all of the above contradictions!

How the E-H Antenna *Really* Works

There are many examples where designers intentionally use common-mode currents. Examples are found in textbooks, such as the "Antenna Engineering Handbook" by Jasik on and around page 22-6.

The antennas at the right, copied from Jasik's textbook, outline the derivation of a skirt collinear antenna from a simple feedline with the open end terminated into a conductor. (It could be a ground

Two or even three skirts may be added to the mast as shown in Fig. 22-5c, but reduced excitation of the lower sections diminishes the effectiveness of each additic skirt.[6] Thus, while the multiple-skirt coaxial antenna resembles a collinear arra in-phase half-wave elements, its gain is not as great. Typical gain values are ta lated in Table 22-2, but since no test data are available for this type of antenna, values given are merely engineering estimates.

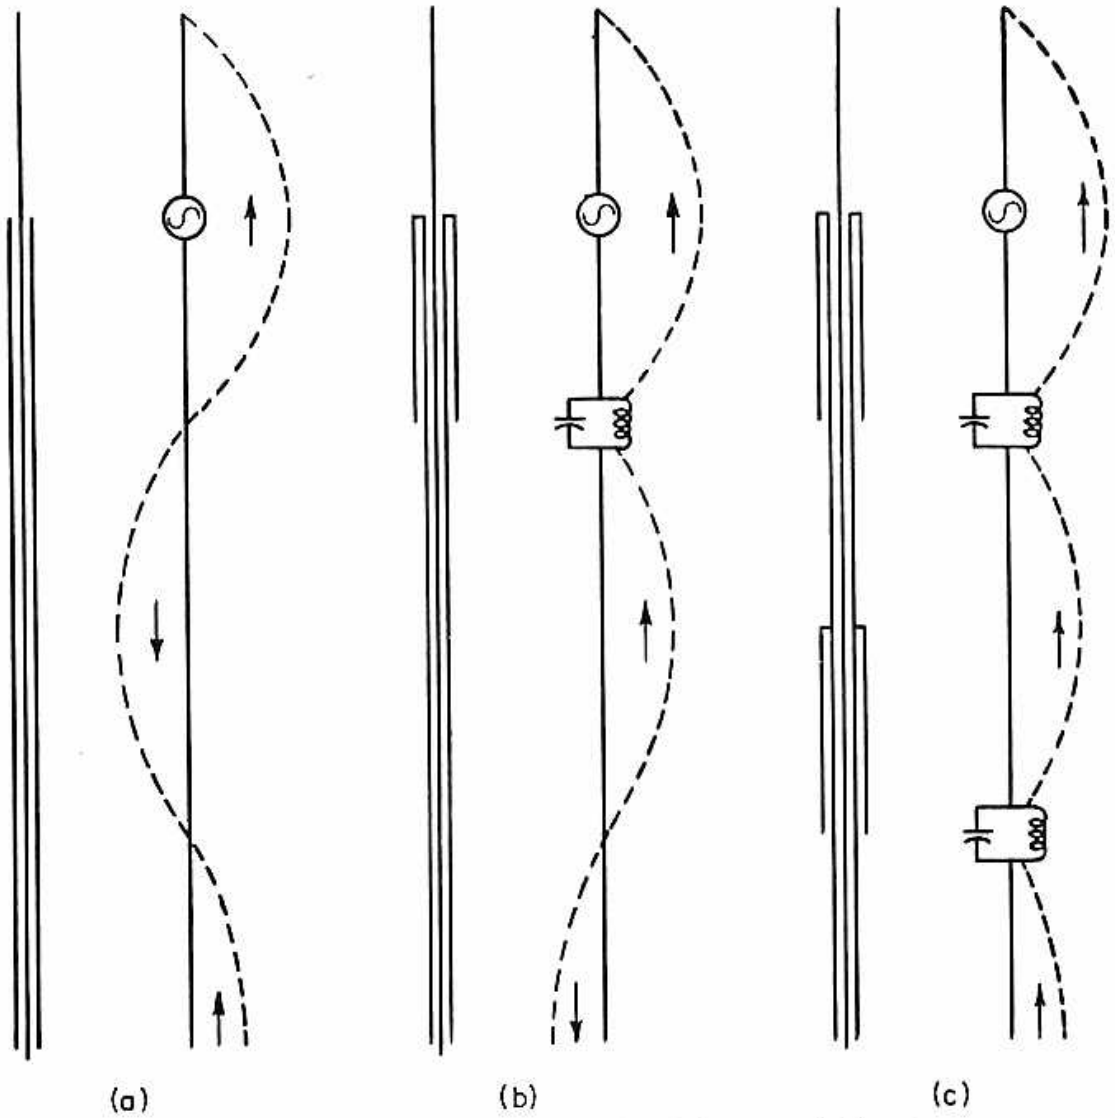

FIG. 22-5. Evolution of multiple-skirt coaxial antenna.

The relatively large diameter-to-length ratio of a practical skirt produces an effect which requires that the exterior length of the skirt be reduced by a factor of 0.8 to 0.9 and the interior length by from 0.95 to 0.98.[6] This is accomplishe cutting the skirt to the proper exterior length and inserting a dielectric slug ir skirt to increase its electrical length.

rod or an antenna, like a Beverage or large loop, the antenna does not have to be an "open circuit".

Looking at (a), we find by hanging any conductor from the end of a coaxial cable the shield is excited (on the outside) with common-mode current. The electrical equivalent of the OUTSIDE of the shield is just as if a generator located at the end of the shield was driving the outside of the shield as longwire antenna. This goes along with Kirchoff's Laws, that tell us the sum of currents entering a point must equal the sum of currents leaving that point. For any current to flow up into the antenna, and equal current must flow back down over the outside of the shield.

With one ampere flowing up the center conductor into the "stinger" at the coax's end-point, the same level of current flows back over the outside of the shield. (The shield's inside and outside are isolated by the skin-depth of the current at the operating frequency, an can be treated as two independent conductors that are connected over the open edge of the shield.) We *MUST* have this current simply because this is how coaxial cables work, the current on the inside of the shield is *ALWAYS* equal and opposite to current in the center conductor. There has to be some place for that shield current to flow, so it makes the bend over the end of the cable and flows back down the outside.

This is also why, when we use a cable's shield as a ground lead the center conductor and inside of the shield do nothing to reduce resistance. Any current that flows down the center conductor is cancelled by current flowing on the inner wall of the shield, the result is no current at all flows down the center conductor as long as the shield is several skin depths thick.

Many antennas intentionally and unintentionally use this principle, two examples are shown in (b) and (c).

A recent Antennex Article on a "magical" ultra-compact antennas claims an identical system, using a loaded fat cylinder, has an extremely high radiation resistance and excellent performance because some magical field-trickery increases the radiation resistance of a thick cylinder at the antenna end. Certainly radiation resistance is somewhat high...but not for the reason something magical or special is happening!

The small coil-loaded cylinder is actually only a fraction of the antenna length, and being so short has a very small radiation resistance. The point missed is the shield of the cable is very long, and is in series with that short section. Since the shield is long, it also has a reasonably high impedance both from radiation resistance and loss resistances. Shortening the length of the end-stub results in an insignificant reduction in radiation resistance, because the overall length of the radiating system is very long! We have a simple off-center fed dipole, with one very long leg and one very short leg!

The main radiator is the outside of the feedline shield, not the tiny thing being called an antenna!

Unless we make the coaxial shield an infinite length or pass it through what amounts to an infinite groundplane with zero resistance, current continues on down the cable shield. Looking at (c), we find even multiple sleeves appearing as parallel tuned high-impedance circuits do not fully decouple the

shield. Many collinear antennas work on this principle, yet E-H antennas and others attribute it to some form of electro-voodoo.

The *Texas Potato Masher II* Antennas at 10 m elevation

Welcome to my Home Page (best viewed at 1024x768). I have a few "home brew" antennas here as well as some links below to other sites that may be of interest to the amateur builder/experimenter. I hope you find something of value here. Please send me any comments or suggestions to at (insert my callsigne here)@amsat.org.

If you would like some information on amateur radio operation, please visit the American Radio Relay League (ARRL) for an introduction to this wonderful international fraternity. If you would like information on amateur satellite operation, please visit the Radio Amateur Satellite Corporation of North America (AMSAT-NA) for the latest in news and software. If you are new to amateur satellites, here is an introduction to the "EasySats" (slightly dated, but still useful). If you are wondering what kind of antenna(s) you might want or need, please read this introduction to amateur satellite antennas and this LEO satellite antenna cost/benefit analysis.

I live in Houston, Texas; about 90 km from the Gulf of Mexico (New! UPDATE: I am temporarily in Darwin, NT, Australia, operating as VK8OE (APRS). Weather here is hot and humid, just like Houston. My QTH in Houston was in a neighborhood with "deed restrictions," outlawing antennas of any kind. My response to this situation was to install "low visability" antennae that are hidden from the street and do not extend above my roof line. Please see my various antennas for examples.

The Gallery of the EME Arrays.

A Collection of EME Reflector Antennas and YAGI Arrays.

28-ft Dish at K2UYH.

The Majority of these pictures were provided to K2UYH for the 432 MHz And Above EME Newsletter.

Many of these antennae have been Designed, Constructed and Optimized by Radio Amateurs.
The Antenna represents a Major Module in a Moonbounce and/or Weaksignal System. It is an essential part in the receive as well in the transmit link.
A 1 dB increase in antenna gain delivers 1 dB increase in ERP and, depending on the frontend, it could deliver a more than 1 dB increase in system S/N ratio.
A significant improvement in an EME link Budget!

Antennae from the 432 MHz and Above Newsletter

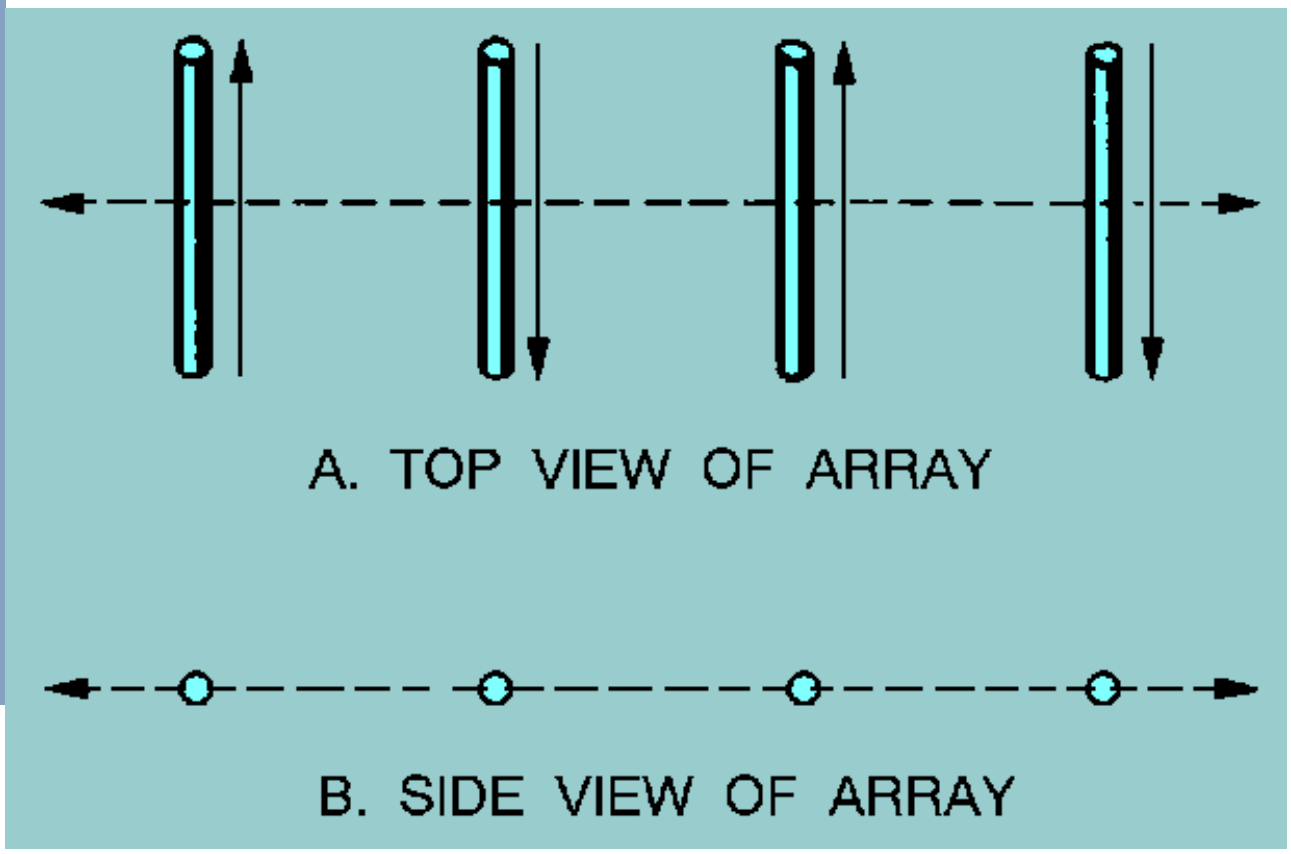
End-Fire Arrays

An end-fire array looks similar to a broadside array. The ladder-like appearance is characteristic of both (fig. 4-28, view A). The currents in the elements of the end-fire array, however, are usually 180 degrees out of phase with each other as indicated by the arrows. The construction of the end-fire array is like that of a ladder lying on its side (elements horizontal). The dipoles in an end-fire array are closer together (1/8-wavelength to 1/4-wavelength spacing) than they are for a broadside array.

Figure 4-28. - Typical end-fire array.

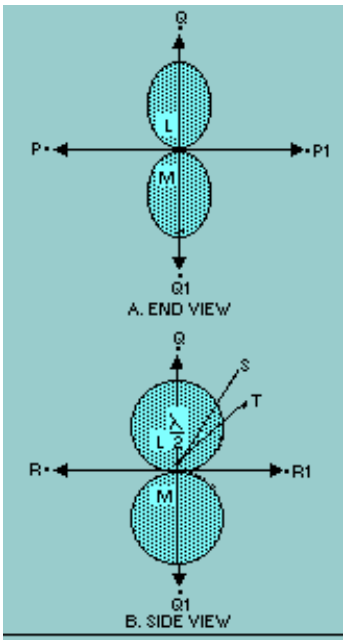


Closer spacing between elements permits compactness of construction. For this reason an end-fire array is preferred to other arrays when high gain or sharp directivity is desired in a confined space. However, the close coupling creates certain disadvantages. Radiation resistance is extremely low, sometimes as low as 10 ohms, making antenna losses greater. The end-fire array is confined to a single frequency. With changes in

climatic or atmospheric conditions, the danger of detuning exists.

RADIATION PATTERN. - The radiation pattern for a pair of parallel half-wave elements fed 180 degrees out of phase is shown in figure 4-29, view A. The elements shown are spaced 1/2 wavelength apart. In practice, smaller spacings are used. Radiation from elements L and M traveling toward point P begins 180 degrees out of phase. Moving the same distance over approximately parallel paths, the respective wavefronts from these elements remain 180 degrees out of phase. In other words, maximum cancellation takes place in the direction of P. The same condition is true for the opposite direction (toward P1). The P to P1 axis is the line of least radiation for the end-fire array.

Figure 4-29. - Parallel elements 180 degrees out of phase.



Consider what happens along the QQ1 axis. Energy radiating from element M toward Q reaches element L in about 1/2 cycle (180 degrees) after it leaves its source. Since element L was fed 180 degrees out of phase with element M, the wavefronts are now in the same phase and are both moving toward Q reinforcing each other. Similar reinforcement occurs along the same axis toward Q1. This simultaneous movement towards Q and Q1 develops a bidirectional pattern. This is not always true in end-fire operation. Another application of the end-fire principle is one in which the elements are spaced 1/4 wavelength apart and phased 90 degrees from each other to produce a unidirectional pattern.

In figure 4-29, view A, elements A and B are perpendicular to the plane represented by the page; therefore, only the ends of the antennas appear. In view B the antennas are rotated a quarter of a circle in space around the QQ1 axis so that they are seen in the plane of the elements themselves. Therefore, the PP1 axis, now perpendicular to the page, is not seen as a line. The RR1 axis, now seen as a line, is perpendicular to the PP1 axis as well as to the QQ1 axis. The end-fire array is directional in this plane also, although not quite as sharply. The reason for the greater broadness of the lobes can be seen by following the path of energy radiating from the midpoint of element B toward point S in view B. This energy passes the A element at one end after traveling slightly more than the perpendicular distance between the dipoles. Energy, therefore, does not combine in exact phase toward point S. Although maximum radiation cannot take place in this direction, energy from the two sources combines closely enough in phase to produce considerable reinforcement. A similar situation exists for wavefronts traveling toward T. However, the wider angle from Q to T produces a greater phase difference and results in a decrease in the strength of the combined wave.

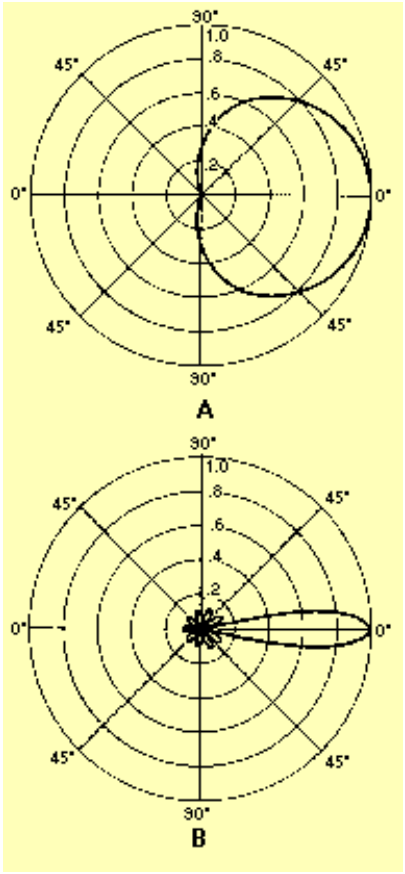
Directivity occurs from either one or both ends of the end-fire array, along the axis of the array, as shown by the broken arrows in figure 4-28, view A; hence, the term *end-fire* is used.

The major lobe or lobes occur along the axis of the array. The pattern is sharper in the plane that is at right angles to the plane containing the elements (figure 4-29, view A). If the elements are not exact half-wave dipoles, operation is not significantly affected. However, because of the required balance of phase relationships and critical feeding, the array must be symmetrical. Folded dipoles, such as the one shown in figure 4-20, view A, are used frequently because the impedance at their terminals is higher. This is an effective way of avoiding excessive antenna losses. Another expedient to reduce losses is the use of tubular elements of wide diameter.

GAIN AND DIRECTIVITY. - In end-fire arrays, directivity increases with the addition of more elements and with spacings approaching the optimum. The directive pattern for a two-element, bidirectional system is illustrated in figure 4-29. View A shows radiation along the array axis in a plane perpendicular to the dipoles, and view B shows radiation along the array axis in the plane of the elements. These patterns were developed with a 180-degree phase difference between the elements. Additional elements introduce small, minor lobes.

With a 90-degree phase difference in the energy fed to a pair of end-fire elements spaced approximately 1/4 wavelength apart, unidirectional radiation can be obtained. The pattern perpendicular to the plane of the two elements is shown in figure 4-30, view A. The pattern shown in view B, taken in the same plane, is for a six-element array with 90-degree phasing between adjacent elements. Since both patterns show relative gain only, the increase in gain produced by the six-element array is not evident. End-fire arrays are the only unidirectional arrays wholly made up of driven elements.

Figure 4-30. - Unidirectional end-fire arrays.



Q.35 What are some disadvantages of the end-fire array? Answer

Q.36 Where does the major lobe in the end-fire array occur? Answer

Q.37 To maintain the required balance of phase relationships and critical feeding, how must the end-fire array be constructed? Answer

Properties of Fiber Glass Rods and Tubes

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 2/25/2000)

Properties of Fiber Glass Rods and Tubes

At this point, I have obtained all of the fiberglass materials that have been using in my antenna projects from Max Gain Systems. These materials are all listed on their web page along with size, weight, color, and price. However, if you are planning to build light weight structures more information is probably required. In particular the bending properties associated with cantilever supports. The lightest weight material is the 1/8" rod, and an 8 ft length is easily bent into a full loop. Thus, this material can only support a small amount of weight at small lengths. The larger diameters of tubing can support increasing amounts of weight for a given deflection. The deflection information is particularly useful in predicting the total bending of a composite spreader and also for determining the amount of tension required in a guy line to re-establish specific position of the spreader.

The tables below give bending information for each of the rods and tubes I have tested. Each size of rod or tubing will bend a specific amount when loaded depending upon the size and length. These materials will also buckle when loaded axially. I concentrated mostly in determining the properties of the materials used as cantilever beams supported rigidly on one end in a horizontal position. Under this condition, the unsupported end will deflect downward due to the gravity load along the entire length of the beam. I measured the unloaded deflection as a function of length for each size material up to and including the 3/4" tubing. I also measured the 1/8" and 1/4" solid rods in the same manner. In general, all of these materials are formed from fiberglass of uniform density and modulus of elasticity, so the bending properties are predictable with a single equation. In general, the deflection increases with the cube of length for a given size and geometry. Further loading at the unsupported end increases the deflection in proportion to the loading, i.e., the lever acts as a linear spring about the rest position. This linear behavior is exhibited so long as the deflection angle is small (less than

about 15 degrees). An 8' span of the 1/8" rod material will deflect more than this angle, and the load no longer pulls perpendicular to the beam. For this reason, the smaller diameter materials are useful only in small lengths (as micro extensions). As an example, the table below shows the properties of the 1/2" tubing. Negative loading implies that the force is applied upward. Normally, I made some attempt to determine the amount of force required to bring the beam into horizontal position at the unsupported end.

grams loading at end of beam	displacement in inches	Comments
-160	0.00	Negative loading at tip
0	6.75	No loading
100	11.00	Positive loading at tip
200	16.50	
300	20.50	

Table 1
Deflection of 8' Cantilever Beam
0.5" OD 0.25 ID Tubing

It is clear from Table 1 that the useful range of loading is probably less than 200 grams for the 8' length. Further loading causes significant droop and such large distortions would be unable to support the wire beams in an acceptable manner. However, one way around this problem is to guy the beam into place. But, it may be more complicated to make a structure such that the beam is guyed from three or four sides. An other alternative is to deliberately bend the beam with a guy under tension from one direction such that this tension is much greater than the loading to be supported. This later procedure works well for making horizontal spreader structures for planar wire beams. The **Reflected M** beams pictured in that section are designed in this manner.

Table 2 below shows the deflection measurements for lengths of the 0.5" tubing for 2', 4' and 8' lengths supported horizontally and loaded at the free end. Note that some deflections were too small to measure, and some others were too large. In general the accuracy o f the deflection measurement is limited to about an 1/8 of an inch, and the gram loading is accurate to about 5%.

grams loading	2' length deflection	4' length deflection	8' length deflection

-160 (pulling up to level)			0.00
-120 (pulling up to level)		0.000	
0 (unloaded)	0.000	0.375	6.75
100 (pulling down)		1.250	11.00
200		1.375	16.50
300	0.313	2.625	20.50
400		3.500	
500	0.500	4.250	

Table 2
Deflection of 0.5" Diameter Tubing Under Loading for Various Lengths

At this point, it is probably best to try to make some sense of these measurements so that the standard equations for beam deflection and loading can be applied. Toward this end, several things are needed, and these include the weight per unit length of the materials, their second moments of inertia, and the modulus of elasticity. We have information on most of these except the latter item which is probably constant for the material. The deflection measurements permit us to get at this number using the deflection equation for uniformly loaded beams. If we let y be the downward deflection, then the equation is

$$y = w * L^4 / (8 * E * I)$$

where w is the weight per unit length (lbs/inch), L is the length (inches), E is the modulus of elasticity (lbs/inch^2) and I is the moment of inertia (inches^4). So, it is easy to see that we can solve for E given all the other parameters. Then, once we know E we can solve for deflections for many other cases. Table 3 is a summary of the data and resulting values of E determined for some of the smaller materials available. The value of the moment of inertia, I, can be calculated for these circular cross sections as

$$I = (pi/4) * (Ro^4 - Ri^4)$$

where Ro is the outside radius and Ri is the inside radius (not diameters). If you use diameters in this equation, you need to divide the result by 16 to get the correct answer. The weights for these materials are located in the MGS home page, but they can be calculated quickly by multiplying the the density of the material by the cross sectional area. This gives the weight per

unit length. The density of these fiber glass materials is about 6.72 x 10^-2 lbs/inch^3 or roughly 1.86 grams/cm^3. The white bicycle whip material in the table is about twice this dense (item # 3).

#	Outside Dia	Inside Dia	Length	y displacement	I	w	E
	(inches)	(inches)	(feet)	(inches)	(inches^4)	(lbs / inch)	(lbs/inch^2)
1	0.125	0.00	2.00	0.750	1.50x10^-5	8.33x10^-4	3.07x10^6
2 black	0.250	0.00	4.00	2.375	2.44x10^-4	3.23x10^-3	3.69x10^6
3 white	0.250	0.00	4.00	1.750	2.44x10^-4	6.43x10^-3	1.00x10^7
4	0.375	9/64	4.00	1.250	1.89x10^-3	6.72x10^-3	3.02x10^6
5	0.500	9/64	8.00	6.750	3.69x10^-3	8.72x10^-3	3.71x10^6
6	0.500	9/64	4.00	0.375	3.69x10^-3	8.72x10^-3	3.70x10^6
7	0.750	0.500	8.00	3.750	1.59x10^-2	1.56x10^-2	2.78x10^6

Table 3
Determination of Modulus of Elasticity from Deflection Measurements

Notice that the value of E is around 3x10^6 psi for all of the black fiber glass samples, but there is some variation that may indicate slight differences in the material. However, using a value near 3x10^6 will provide a good first estimate for engineering purposes, and the variation in the table can be used as an estimate of the expected variance. Note that the white bicycle whip

material is very different. It is twice a dense as the other materials in the table and has a modulus of elasticity that is 3 times as high (about equal to that of aluminum) as the other samples. The E values for the fiber glass are about 1/10 as large as structural steel (for perspective).

The tables that follow are measurements of loading applied to the ends of the horizontal cantilevers. So as long as the displacements are small, the beams respond as linear springs so that the displacement about the quiescent displacement is proportional to the applied load. So we can assume that y = K*W where W is the applied load. The spring constant, K, can be derived from the moment diagram of the loading, however, it may be adequate to know the dependence on the length of the beam is as K ~ L^3/(E*I), so the spring is very stiff for short lengths and gets loose rapidly as the length of the beam increases. So, y ~ L^3 * W / (E * I), and you can find the constant of proportionality for the data in the tables so that you can use W in what ever units you like. Also, note, the 0.5" tubing is given in Table 2 and is not repeated here.

Table 8
Displacements for 3/4" Fiber Glass Tubes

These tables are useful in determining the displacements of the beams when loading is applied and can be useful for estimating deflections when the supports are at differing angles, such as 45 degrees. In general, one should consider the wire load carefully, and choose materials strong enough to carry the load without serious distortion to the structure. The structures can be made more stable by using nylon monofilament guy lines, however, buckling, and other problems might appear if the guys or wires are too tight. Since the displacements depend upon the length cubed when loads are applied at the tips, the total displacement of compound or telescoping sections can be estimated from the tables above. More information on these topics will be added from time to time.

I have recently spent some time testing kevlar thread in place of the monofilament nylon fish line. This material is very strong and hardly stretches at all. However, this very property can also be a problem in getting the loading distributed equally in the various guy lines. This also means that the lengths must be measured and cut very exactly, and one must know exactly what length to cut. In systems with multiple guy lines, tension on one line affects the others, i.e., all parts of the structural system are coupled. Since these systems present considerable computational difficulty, you can save a lot of grief by including a small turnbuckle in each line. This allows individual adjustment of the tensions. The turnbuckles should be placed at the ends of the guys at the most stable point (for example the guy post). Alternatively, separate guy tie rings can be used for each guy set allowing adjustment of individual guy sets. This second method usually is lighter in weight. You should take care that each guy set is made with

identical lengths even though the actual lengths can depart slightly from those calculated.

The 1/8" material is useful for short extenders for either the 1/4" or 3/8" tubes. I found that terminal lugs can be crimped on to the 1/8" inch rods and grommets inserted to provide a wire guide. The wires can be secured in proper location using a 4" piece of #18 copper wire twisted around the lug and then to either side of the wire.

1/8" Extenders with Crimp Lugs

Flags and Pennants

Receive antennas for limited space with good noise rejection like the Ewe. They are ground independent, too, a big plus!

Here is a compendium of information about these excellent low-noise receive antennas. The Pennant was originated by EA3VY and optimized for 160 meters by K6SE, who first wrote about them on the Top Band Reflector in 1998. It also performs very well on 80 and 40 meters. I built a Flag antenna pointed at Europe and was pleased with the results. I plan to build more of them. K6SE has done a great job in refining and popularizing these antennas. JF1DMQ actually wrote an earlier article about the Flag antenna in November 1995 in a Japanese magazine. His was only 3.3 feet by 16.4 feet long (1 by 5 m). K6SE's 160m optimized versions are 14 by 29 feet (4.3 by 8.8m).

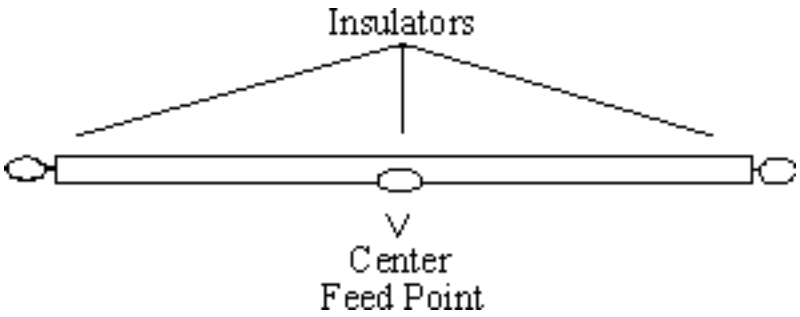
Folded Dipoles

A variation of the dipole is an antenna called a folded dipole. It radiates like a dipole but sort of looks like a **squashed** quad.

Having a folded dipole does **not** mean that you have an antenna that is folded in half and so you obtain an antenna that now takes up half the space of a regular dipole. No, the antenna is still approximately the same length as a regular dipole. It ***is*** however, an antenna that has a wire folded back over itself, hence its name. Below is a picture of a folded dipole.



The starting formula for the folded dipole calculation is the same as a dipole, 468 / Frequency (in MHz). Let's try an example: Design a folded dipole for the 40 meter band. The frequency that is chosen might be 7.15 MHz. Plugging this in to the formula (468 / 7.15) gives a folded dipole with a length of 65.45 feet. When I modeled a dipole on the computer at 30 feet, I came up with a length of 65.47 feet. When I added a second wire to make the folded dipole shown above, I designed the antenna with 1 inch spacing between the two wires. Note that this adds 1 more inch to each of the two antenna wires over that of a single wire dipole. This plus the fact that we are actually turning up the ends of the antenna, means that the horizontal length actually need to be a little shorter to be once again at resonance. The total length came to 64.38 feet, 1.09 feet shorter than the straight dipole. If you use a greater spacing, say 1 foot between the wires the length is 63.1 feet, 2.37 feet shorter. So be sure to shorten the antenna a bit or you'll find yourself operating lower down the band than you expected.

The feed point impedance is also modified by the second wire. Let's say the original dipole was 72 ohms. The step-up for a two wire folded dipole is 4 times which means 4 * 72 = ~288 ohms. (The computer shows 281 ohms on my example, but remember, we reduced the length slightly also.) This step up continues if you add more and more wires. A three wire antenna would provide a step-up of 9, and a four wire antenna provides a step-up of 16.

We can see why this step-up occurs by looking at the power formula P=(I*I) * R, this can be rewritten as R = P / (I*I). If the power to a regular dipole antenna was 100 watts and the current was 1.2 amps, we'd solve for R as R = 100 / (1.2*1.2), which is the same as R = 100 / 1.44, which is 69.44 ohms. In the folded dipole the wires are in parallel, the current must be divided between the two wires. The current in each is half and the total power has not changed, so now the formula is R = 100 / (.6*.6), which is the same as R = 100 / .36, which of course is 277.77 ohms, 4 times the normal dipole antenna.

So now you ask, why would anyone want an antenna with a feed point impedance of 277 ohms, my coax cable is 50 ohms!? Well let's say you wanted to feed the antenna, not with 50 ohm cable but with 300 ohm twin lead? Ah ha, now we have a decent match and a feed line that can also handle a higher SWR with low loss. You'd probably use a tuner (ATU) in the shack to match the 50 ohm radio to the 300 ohm feed line. You could also use the antenna on other bands with the tuner and have an efficient antenna system.

What are the drawbacks to the antenna? Well for one, the currents on each wire will begin to cancel each other out on even multiples of the *cut* frequency, so a 40 meter folded dipole should not be used on 14 MHz. On other bands even though the signal may cancel broad side to the antenna, you'll find that there is actually gain! This occurs about 45 degrees off broad side to the antenna. And this might make for interesting contacts.

Full Wave Delta Loop | 2 Meter Dipole Antenna
Portable 3-Band Yagi | Portable 6M Antennas

FULL WAVE LOOP ANTENNA

(Plus Halyard Building Instructions)

Are you looking for an inexpensive wire antenna that makes possible HF operation on all bands 10M through to 80M with wide bandwidth?

If yes, you may want to consider putting up this **Delta Loop** like Elizabeth, VE7TLK did on her single residential lot, with the help of amateur radio friends. Antenna apex is up approximately 82' tied to a cedar tree, while the two corners are tied to a shorter tree 25' high and a carport roof.

This Delta Loop is a three-sided antenna suspended high in the air by vertical supports, such as tall evergreen trees. Recommended height is 40 feet or more at highest point, but higher is better. It's one feed line eliminates the need for multiple antennas to cover the HF bands.

Diagram

The Delta Loop's feedpoint is located near one of the bottom corners providing a slight increase in gain and easy access when maintenance is required.

Directional Characteristics

The radiating element or wire position in relation to the ground determines polarization. If the wire is parallel to the ground, it radiates horizontally. If the wire is perpendicular to the ground, it radiates a vertical wave. If the wire is slanted, it radiates waves, which have both horizontal and vertical qualities.

Calculating Length Of Wire Needed For 80 M Loop

$$\text{Length (ft.)} = \frac{1005}{f\ (\text{MHz})}$$

Therefore, length of wire needed for an 80M loop antenna is:

$$\text{Length (ft.)} = \frac{1005}{3.7\text{MHz}} = 272 \text{ feet}$$

Materials Needed For Antenna

- Copper Stranded Wire #12
- 4 ceeramic or glass insulators (apex, two corners, and at feedpoint)
- RG58 or mini RG8 Coax (50 ohm) Calculate length from feed line to radio room plus a little extra.
- PL259 Connector (UHF male) - for end of coax which connects to radio.
- Support rope for corners and apex.
- Roll of coax seal to wrap.
- Polyester braided rope (3/8") needed for halyard and support ropes.

Step By Step Instructions

1. Draw to scale diagram of antenna and all supports with dimensions on lot.

2. Measure and cut wire length for antenna allowing 1' extra for securing insulators. Careful not to bend wire.

3. Lay the wire on the ground so that the sides can be measured and the insulators fixed to the apex and corners. To fix insulator cut a short piece of wire and twist it around the antenna wire for about 4" on one side and then cross over insulator end and repeat 4" up the other wire. This adds strength to the corners and apex ands keeps insulators in place when raising antenna.
4. Cut three pieces of support rope to clear and free antenna corners and apex from trees/buildings, etc. Connect ropes to the three insulators.

5. Feedpoint connection ¼ wavelength from bottom corner. (See diagram) With a sharp knife, carefully strip back (not cut) 3" of the exterior black jacket from one end of the 50 ohm coax being careful not to score the braid underneath. Pull the braid gently a part in one place and pull out the inner dielectric containing the center conductor. The coax is now split in two. Expose the center conductor by carefully cutting off 1" of the inner dielectric which is covering the center conductor.

6. Each wire end is then threaded through the closest insulator hole and then tightly twisted around antenna wire on that end. This is also repeated on the other end of the same insulator using the other antenna wire. Wrap prepared coax end around the middle of the insulator and secure with a clamp.

7. Once this is done and the materials have been cleaned

well, solder one of the #12 gauge copper wires to braid and the other to the center conductor. To avoid water and contamination in the feed line, the antenna end of the feed line must be adequately covered with coax seal . Remember, the feed line connection at the center insulator should not be done until after the antenna wire has been tied securely to the insulator.

8. Construct a 1:1 broadband balun. Wind or coil a length of coaxial feed line for 6-8 turns near point of connection and secure with electrical tape. Lengths are not critical. Diameter of coils approximately 8".

9. Pull the antenna wire carefully up in the air by pulling down on the rope end which will eventually be tied to the limb of the tree. Once desired height of highest corner or apex has been reached, tie rope to limb near ground and within reach by a ladder.

10. One of the two remaining insulators will have its rope now tied to the second tree (or other support) which also has a collar but no pulley. This insulator and the previous one are counterweighted (halyard) and allowed to move freely.

11. The delta loop is now ready to be raised using the pulley on the halyard at the top of the tree or pole. Once the apex is fastened at the correct height proceed to fasten securely the corner ropes to their tie supports.

12. Install the PL259 (UHF male) Connector on end of coax feedline in radio room. An adapter is available if using the smaller RG-58 size coax. Connect to transceiver and test for SWR.

Halyard Recommended

Introduces slack so that during high wind conditions the wire loop can move, thus reducing stress on wire avoiding breakage. See directions for making halyard.

Materials And Directions

1. Bucket (with several holes on bottom) with handle plus counterweight weighted with bricks or sand and rocks.

2. One pulley large enough for line to run through freely keeping in mind that rope can swell when wet. Buy a fast-eyed brass or bronze marine type pulley.

3. Polyester braided rope (3/8") needed to go up and down

full length of tree trunk from collar to ground. Allow for extra to tie around lower limb and to raise antenna without running out of rope.

4. Make a trunk collar to protect bark of tree. This is done by threading a short piece of rope through an old hose or other soft tubing, the diameter of the trunk, where the collar will be positioned up high on the tree. Thread the pulley onto collar rope where the two ends of collar will meet together and tie securely. Only an experienced tree climber, with safety climbing equipment, should do the climbing.

5. While climber is up on the tree have him take one end of the long rope and feed it through the pulley. As he comes down he can pull that end down with him to ground level. Do not cut rope yet until after the antenna has been raised up, otherwise you may find yourself with too short a rope.

6. One end of rope will be tied to the weighted bucket handle and the other end tied tightly to a low limb within your reach. Bucket should be suspended about six feet from ground floating freely. The antenna wire at this point is still lying on the ground.

7. Just before the antenna wire is ready to be raised, tie the appropriate support short rope to the insulator at the apex of the antenna to the halyard rope's mid-point. This rope enables the wire to position itself away from tree branches.

8. Raise the apex of the antenna by pulling on the rope without the bucket tied to it to the desired height. Then tie rope securely to one of the lower limbs within reach.

Grounding Antenna & Radio

Materials Needed

- 8 Feet Copper Ground Rods (1 to 3) five to six feet apart (?)
- Brass clamps (for each rod)
- Belden grounding braid or 2" copper ribbon
- Good Power Bar with filter and surge protector
- Copper Bar attached to back of station table-top

Take the next step and operate DX!

G5RV Multi-Band Antenna by Louis Varney,

CEng, MIEE, AIL, G5RV

***** taken from (RADIO COMMUNICATIONS, JULY 1984)

THE G5RV ANTENNA, with its special feeder arrangement, is a multiband centre-fed antenna capable of very efficient operation on all hf bands from 3.5 to 28mhz, specifically designed with dimensions which allow it to be installed in gardens which accommodate a reasonably-straight run of about 102ft (31.1m) for the "flat-top". However, because the most useful radiation from a horizontal or inverted-V resonant antenna takes place from the center two-thirds of its total length, up to one-sixth of this total length at each end of the antenna may be dropped vertically, semi-vertically, or bent at some convenient angle to the main body of the antenna without significant loss of effective radiation efficiency. For installation in a very limited space, the dimensions of both the "flat-top" and the matching section can be divided be a factor of two to make the half-size G5RV, which is a very efficient antenna from 7 to 28 mhz. The full-size G5RV will also function on 1.8mhz band if the station end of the feeder (either balanced or coaxial-type) is strapped and fed by a suitable antenna tuner using a good earth connection or a counterpoise wire. Similarly, the half-size version may be used thus on 3.5 and 1.8 mhz bands.

In contradistinction to multiband antennas in general, the full size G5RV antenna was not designed as a half-wave dipole on the lowest frequency of operation, but as a 1 1/2 wave centre-fed long-wire antenna on 14mhz, where the 34ft (10.36m) open-wire matching section functions as a 1:1 impedance transformer, enabling the 75ohm twinlead or 50/80ohm coaxial cable feeder to "see" a close impedance match on that band with a consequently low vswr on the feeder. However,on all the other hf bands the function of this section is to act as a " make-up" section to accommodate that part of the standing-wave (current and voltage components) which, on certain of the operating frequencies, cannot be completely accommodated on the "flat-top" (or inverted-V)radiation portion. The design centre frequency for the full-size version is 14,150khz, and the dimensions of 102ft (31.1m) is derived from the formula for long-wire antennas which is:

$$\text{Length (ft)} = \frac{492\,(n - 0{\cdot}05)}{f\text{MHz}} = \frac{492 \times 2{\cdot}95}{14{\cdot}15} = 102{\cdot}57\text{ft}\ (31{\cdot}27\text{m})$$

where n= number of half-wavelengths of the wire (flat-top).

In practice, since the whole system will be brought to resonance by the use of an antenna tuner, the antenna is cut to 102ft (31.1m).

As it does not make use of traps or ferrite beads, the "dipole" portion becomes progressively longer in electrical length with increasing frequency.

This effect confer certain advantages over a trap or ferrite-bead loaded dipole because, with increasing electrical length, the major lobes of the vertical component of the polar diagram tend to be lowered as the operating frequency is increased. Thus, from 14mhz up, most of the energy radiated in the vertical plane is at angles suitable for dx working. Furthermore, the polar diagram changes with increasing frequency from a typical half-wave dipole pattern at 3.5mhz

and a 2 1/2 wave in-phase pattern at 7 and 10mhz to that of a "long-wire" antenna at 14, 18, 21, 24 and 28mhz.Figure 1.

Although the impedance match for 75 ohm twinlead or 80 ohm coaxial cable at the base of the matching-section is very good at 14mhz, and even the use of 50 ohm coax cable results in only about 1.8:1 vswr on this band, the use of a suitable antenna tuner is necessary on all the other hf bands because, on those bands, the antenna plus the matching-section will present a reactive load to the feeder. thus the use of the correct type of antenna tuner (unbalanced input to balanced output if twin-wire feeder is used, or unbalanced to unbalanced if coaxial feeder is used) is essential in order to ensure the maximum transfer of power to the antenna from a typical transceiver having a 50 ohm coaxial (unbalanced) output. Also to satisfy the stringent load conditions demanded by such modern equipment employing an alc system which "senses" the vswr condition presented to the solidstate transmitter output stage so as to protect it from damage which could be caused by a reactive load having a vswr of more than about 2:1.

Figure 2

The above reasoning does not apply to the use of the fullsize G5RV antenna on 1.8mhz, or to the use of the half-size version on 3.5 and 1.8mhz. In these cases the station end of the feeder conductors should be "strapped" and the system tuned to resonance by a suitable series-connected inductance and capacitance circuit connected to a good earth or counterpoise wire. Alternately, an "unbalanced-to-unbalanced" type of antenna tuner such as a "T" or "L" matching circuit can be used. Under these conditions the "flat-top" (or inverted-V) portion of the antenna plus the matching section and feeder function as a "Marconi" or "T" antenna, with most of the effective radiation taking place from the vertical, or near vertical, portion of the system; the "flat-top" acting as a top-capacitance loading element. However, with the system fed as described above, very effective radiation on these two bands is obtainable even when the "flat-top" is as low as 25ft (7.6m) above ground.

Theory of Operation

The general theory of operation has been explained above; the detailed theory of operation on each band from 3.5 to 28mhz follows, aided by figures showing the current standing wave conditions on the "flat-top" and the matching (or make-up) section. The relevant theorical horizontal plane polar diagrams for each band may be found in any specialized antenna handbooks. However, it must be borne in mind that: (a) the polar diagrams generally shown in two dimensional form are, in fact, three dimensional (ie solid) figures around the plane of the antenna; and (b) all theoretical polar diagrams are modified by reflection and absorption effects of near-by conducting objects such as wire fences, metal house guttering, overhead electric power and telephone wires, house electric wiring system, house plumbing systems, metal masts and guy wires, and large trees. Also the local earth conductivity will materially affect the actual polar radiation pattern produced by an antenna. Theoretical polar diagrams are based on the assumptions that an antenna is supported in "free space" above a perfectly conducting ground. Such conditions are obviously impossible of attainment in the case of typical amateur installations. What this means in practice is that the reader should not be surprised if any particular antenna in a typical amateur location produces contacts in directions where a null is indicated in the theoretical polar diagram and perhaps not such effective radiation in the directions of the major lobes as theory would indicate.Figure 3

3.5Mhz. On this band each half of the "flat-top" plus about 17ft (5.18m) of each leg on the matching-section forms a fore-shortened or slightly folded up half-wave dipole. The remainder of the matching-section acts as an unwanted but unavoidable reactance between the electrical centre of the dipole and the feeder to the antenna tuner. The polar diagram is effectively that of a half-wave antenna. See figure 1.

7Mhz. The "flat-top" plus 16ft (4.87m) of the matching section now functions as a partially-folded-up "two half-wave in phase" antenna producing a polar diagram with a somewhat sharper lobe pattern than a half-wave dipole due to its colinear characteristics. Again, the matching to a 75 ohm twinlead or 50/80 ohm coaxial feeder at the base of the matching section is degraded somewhat by the unwanted reactance of the lower half of the matching section but, despite this, by using a suitable antenna tuner the system loads well and radiates very effectively on this band. See figure 2.

10Mhz. On this band the antenna functions as a two half-wave in-phase colinear array, producing a polar diagram virtually the same as on 7mhz. A reactive load is presented to the feeder at the base of the matching section but, as for 7mhz, the performance is very effective. See figure 3.

14Mhz. At this frequency the conditions are ideal. The "flat-top" forms a three-half-wave long centre-fed antenna which produces a multi-lobe polar diagram with most of its radiated energy in the vertical plane at an angle of about 14 degrees, which is very effective for dx working. Since the radiation resistance at the centre of a three-half-wave long-wire antenna supported at a height of half-wave above ground of average conductivity is about 90 ohm, and the 34ft (10.36m) matching section now functions as a 1:1 impedance transformer, a feeder of anything between 75 and 80 ohm characteristic impedance will "see" a non-reactive (ie resistive) load of about this value at the base of the matching section, so that the vswr on the feeder will be very nearly 1:1. Even the use of 50 ohm coaxial feeder will result in a vswr of only about 1.8:1. It is here assumed that 34ft (10.36m) is a reasonable average antenna height in amateur installations. See figure 4.

18Mhz. The antenna functions as two full-wave antennas fed in phase; combining the broadside gain of a two-element colinear array with somewhat lower zenith angle radiation than a half-wave dipole due to its long-wire characteristic. See figure 5

21Mhz. On this band the antenna works as a "long-wire" of five half-waves, producing a multilobe polar diagram with very effective low zenith angle radiation. Although a high resistive load is presented to the feeder at the base of the make-up section, the system loads very well when used in conjunction with a suitable antenna tuner and radiates very effectively for dx contacts. See figure 6.

24Mhz. The antenna again functions effectively as a five-half-wave "long-wire" but, because of the shift in the positions of the current anti-nodes on the flat-top and the matching section, as may be seen from figure 7, the matching

or "make-up" section now presents a much lower resistive load condition to the feeder connected to its lower end than it does on 21mhz. Again, the polar diagram is multilobed with low zenith angle radiation.

28Mhz. On this band, the antenna functions as two "long-wire" antenna, each of three half-waves, fed in-phase. The polar diagram is similar to that of a three half-wave "long-wire" but with even more gain over a half-wave dipole due to the colinear effect obtained by feeding two three-half-wave antennas, in line and in close proximity, in-phase. See figure 8.

Construction

The Antenna

The dimensions of the antenna and its matching section are shown in Figure 9. The "flat-top" should, if possible, be horizontal and run in a straight line, and should be erected as high as possible above ground. In describing the theory of operation, it has been assumed that it is generally possible to erect the antenna at an average height of about 34ft (10.36m), which happens to be the optimum radiation efficiency on 1.8, 3.5 and 7mhz for any horizontal type antenna, in practice few amateurs can install masts of the optimum height of half a wavelength at 3.5 or 7mhz, and certainly not at 1.8mhz.

If, due to limited space available, or to the shape of the garden, it is not possible to accommodate the 102ft (31.1m) top in a straight line, up to about 10ft (3m) of the antenna wire at each end may be allowed to hang vertically or at some convenient angle, or be bent in a horizontal plane, with little practical effect upon performance. This is because, for any resonant dipole antenna, most of the effective radiation takes place from the centre two-thirds of its length where the current antinodes are situated. Near to each end of such an antenna, the amplitude of the current standing wave falls rapidly to zero at the outer extremities; consequently, the effective radiation from these parts of the antenna is minimal.

The antenna may also be used in the form of an inverted-V. However, it should be borne in mind that, for such a configuration to radiate at maximum efficiency, the included angle at the apex of the V should not be less than about 120 degrees. The use of 14awg enameled copper wire is recommended for the flat-top or V, although thinner gauges such as 16 or even 18awg can be used.

The Matching Section

This should be, preferably, of open-wire feeder construction for minimum loss. Since this section always carries a standing-wave of current (and voltage) its actual impedance is unimportant. A typical, and very satisfactory, form of construction is shown in figure 10. The feeder spreaders may be made of any high-grade plastic strips or tubing; the clear plastic tubing sold for beer or wine siphoning is ideal.

If it is desired to use 300 ohm ribbon type feeder for this section, it is strongly recommended that the type with "windows" be used because of its much lower loss than that with solid insulation throughout its length, and its relative freedom from the "detuning" effect caused by rain or snow. If this type of feeder is used for the matching section, allowance must be made for its velocity factor (vf) in calculating the mechanical length required to resonate as a half-

wave section electrically at 14.15mhz. Since the vf of standard 300 ohm ribbon feeder is .82, the mechanical length should be 28ft (8.5m). However, if 300 ohm ribbon with "windows" is used, its vf will be almost that of open-wire feeder, say .90, so its mechanical length should be 30.6ft (9.3m). This section should hang vertically from the centre of the antenna for at least 20ft (6.1m) or more if possible. It can then be bent and tied off to a suitable post with a length of nylon or terylene cord so as to be supported at above head-height to the point where, supported by a second post, its lower end is connected to the feeder.

The Feeder

The antenna can be fed by any convenient type of feeder provided always that a suitable type of antenna tuner is used. In the original article describing the G5RV antenna, published in the , then, RSGB bulletin November 1966, it was suggested that if coaxial cable feeder was used, a balun might be employed to provide the necessary unbalanced-to-balanced transformation at the base of the matching section. This was because the antenna and its matching section constitute a balanced system, whereas a coaxial cable is an unbalanced type of feeder. However, later experiments and a better understanding of the theory of operation of the balun indicated that such a device was unsuitable because of the highly reactive load it would "see" at the base of the matching or "make-up" section on most hf bands.

It is now known that if a balun is connected to a reactive load presenting a vswr of more than about 2:1, its internal losses increase, resulting in heating of the windings and saturation of its core (if used). In extreme cases, with relatively high power operation, the heat generated due to the power dissipated in the device can cause it to burn out. However, the main reason for not employing a balun in the case of the G5RV antenna is that, unlike un antenna tuner which employs a tuned circuit, the balun cannot compensate for the reactive load condition presented to it by the antenna on most of the hf bands, whereas a suitable type of antenna tuner can do this most effectively and efficiently.

Recent experiments by the author to determine the importance or otherwise of "unbalance" effects caused by the direct connection of a coaxial feeder to the base of the matching section had a rather surprising result. They proved that, in fact, the hf currents measured at the junction of the inner conductor or the coaxial cable with one side of the (balanced) matching section and at the junction of the outer coaxial conductor (the shield) with the other side of this section are virtually identical on all bands up to 28mhz, where a slight but inconsequential difference in these currents has been observed. There is, therefore, no need to provide an unbalanced-to-balanced device at this junction when using coaxial feeder.

However, the use of an unbalanced-to-unbalanced type of antenna tuner between the coaxial output of a modern transmitter (or transceiver) and the coaxial feeder is essential because of the reactive condition presented at the station end of this feeder which, on all but the 14mhz band, will have a fairly high to high vswr on it. This vswr, however, will result in insignificant losses on a good-quality coaxial feeder of reasonable length; say, up to about 70ft (21.3m). Because it will, inevitably, have standing waves on it, the actual characteristic impedance of the coaxial cable is unimportant, so that either 50 ohm or 80 ohm type can be used.

Another very convenient type of feeder that may be used is 75 ohm twinlead. However, because of the relatively high loss in this type of feeder at frequencies above about 7mhz, especially when it has a high vswr on it, it is recommended that not more than about 50 to 60ft (15.2 to 18.3m) of this type feeder be used between the base of the matching section and the antenna tuner. Unfortunately the 75 ohm twinlead in the UK is the receiver type; the much less lossy transmitter type is available in the USA. By far the most efficient feeder is the "open wire" type. A suitable length of such feeder can be constructed in exactly the same way as that described for the open-wire matching section. If this form of feeder is employed, almost any convenient length may be used from the centre of the antenna right to the antenna tuner (balanced) output terminals. In this case, of course, the matching section becomes an integral part of the feeder. A particularly convenient length of open-wire feeder is 84ft (25.6m), because such a length permits parallel tuning of the

antenna tuner circuit on all bands from 3.5 to 28mhz with conveniently located coil taps in the antenna tuner coils for each band, or, where the alternative form of antenna tuner employing a three-gang 500pf/section variable coupling capacitor is used the optimum loading condition can be achieved for each band. However, this is not a rigid feeder length requirement and almost any length that is mechanically convenient may be used. Since this type of feeder will always carry a standing wave, its characteristic impedance is unimportant, and sharp bends, if necessary, may be used without detriment to its efficiency. It is only when this type of feeder is correctly terminated by a resistive load equal to its characteristic impedance that such bends must be avoided.

Coaxial cable hf choke

Under certain conditions, either due to the inherent "unbalanced-to-balanced" effect caused by the direct connection of a coaxial feeder to the base of the (balanced) matching section, or to pick-up of energy radiated by the antenna, a current may flow on the outside of the coaxial outer conductor. This effect may be considerably reduced, or eliminated, by winding the coaxial cable feeder into a coil of 8 to 10 turns about 6in in diameter immediately below the point of connection of the coaxial cable to the base of the matching section. the turns may be taped together or secured by nylon cord.

It is important, of course, that the junction of the coaxial cable to the matching section be made thoroughly water-proof by any of the accepted methods; binding with several layers of plastic insulating tape or self-amalgamating tape and then applying two or three coats of polyurethane varnish, or totally enclosing the end of the coaxial cable and the connections to the base of the matching section in a sealant such as epoxy resin.

LOW REACTANCE MULTIBAND CENTER FED WIRES

An antenna system is more easily interfaced to a radio when the input reactance at the feedline terminals is low or close to series resonance. If a center fed dipole is fed with a length of low loss balanced transmission line, the input reactance is a function of both transmission line length and antenna length, and to reduce the reactance at selected frequencies there are optimum lengths of dipole and feedline. The G5RV antenna design is an example of selecting these lengths to produce near-series resonances at amateur operating frequencies from 3.5-28MHz. There are other combinations of feedline length and dipole length which reduce the overall reactance as shown below. The red regions of Figure 1 have low RMS reactance over the frequencies shown to the right of the figure.

Grounding is key to good reception

From: jpd@space.mit.edu (John Doty)
Newsgroups: rec.radio.shortwave
Subject: Grounding is key to good reception, was: Experience w/NRD-535
Date: 16 Feb 1995 16:36:40 GMT

In article <825_9502140342@tor250.org> Larry.Picard@odxabbs.tor250.org (Larry Picard) writes:

> In your recent post you advised that coax should be grounded at two sites, first at the antenna and then just before entering the house. Is there an advantage in grounding at more than these sites?

With grounds the most common experience is "the more the merrier". As you add more, however, you usually reach a diminishing returns (no pun intended) situation where there is no *observable* improvement: that's usually a good place to stop. There are also exceptional circumstances where grounding increases noise problems, but these, in my experience, are much rarer than the pundits who preach against "ground loops" seem to think.

Even a semi-quantitative theoretical treatment of grounding in oversimplified situations requires heavy math at RF. Experimentation is thus required even if one has done elaborate calculations. It's often easier to use the theory as a guide to what to try, and then experiment.

> I would also assume that the antenna is grounded when it is connected to the receiver as the outer braid of the coax is in continuity with the receiver chassis.

What's ground? If connect the shield of my coax (which is grounded outside) to the antenna input of my R8, I hear lots of junk, indicating that there is an RF voltage difference between the coax shield and the R8 chassis. Last night this measured about S5.5, which is about -93 dBm (preamp off, 6KHz bandwidth). That's a lot of noise: it was 18 dB above my antenna's "noise floor", and 26 dB above the receiver's noise floor.

This sort of disagreement about ground potential is characteristic of electrically noisy environments. The receiver will, of course, respond to any voltage input that differs from its chassis ground. The antenna, on the other hand, is in a very different environment, and will have its own idea of what ground potential is. If you want to avoid noise pickup, you need to deliver a signal, referenced at the antenna to whatever its ground potential is, in such a way that when it arrives at the receiver, the reference potential is now the

receiver's chassis potential.

Coaxial cable represents one way to do this. Coax has two key properties:

1. The voltage between the inner conductor and the shield depends only on the state of the electromagnetic field within the shield.

2. The shield prevents the external electromagnetic field from influencing the internal electromagnetic field (but watch out at the ends of the cable!).

So, it's easy, right? Run coax from the antenna to the receiver. Ground at the antenna end will be whatever the antenna thinks it is, while ground at the receiver end will be whatever the receiver thinks it is. The antenna will produce the appropriate voltage difference at the input side, and the receiver will see that voltage difference uncontaminated by external fields, according to the properties given above.

Unfortunately, it doesn't quite work that way. It's all true as far as it goes, but it neglects the fact that the coax can also guide noise from your house to your antenna, where it can couple back into the cable and into your receiver. To see how this works, let me first describe how this noise gets around.

The noise I'm talking about here is more properly called "broadband electromagnetic interference" (EMI). It's made by computers, lamp dimmers, televisions, motors and other modern gadgets. I have all these things. In many cases, I can't get them turned off, because it would provoke intrafamilal rebellion. However, even when I turn them off, the noise in the house doesn't go down very much, because my neighbors all have them too. In any case, one of the worst offenders is my computer, which is such a handy radio companion I'm not about to turn *it* off.

Some of this noise is radiated, but the more troublesome component of this is conducted noise that follows utility wires. Any sort of cable supports a "common mode" of electromagnetic energy transport in which all of the conductors in the cable are at the some potential, but that potential differs from the potential of other nearby conductors ("ground"). The noise sources of concern generate common mode waves on power, telephone, and CATV cables which then distribute these waves around your neighborhood. They also generate "differential" mode waves, but simple filters can block these so they aren't normally a problem.

So, let's say you have a longwire antenna attached to a coaxial cable through an MLB ("Magnetic Longwire Balun" [sic]). Suppose your next door neighbor turns on a dimmer switch. The resulting RF interference travels out his power lines, in through yours, through your receiver's power cord to its chassis, and out your coaxial cable to your MLB. Now on coax, a common mode wave is associated with a current on the shield only, while the mode we want the signal to be in, the "differential" mode, has equal but opposite currents flowing on shield and inner conductor. The MLB works by coupling energy from a current flowing between the antenna wire and the coax shield into into the differential mode. But wait a second: the current from the antenna flows on the coax shield just like the common mode current

does. Does this mean that the antenna mode is contaminated with the noise from your neighbor's dimmer?

The answer is a resounding (and unpleasant) yes! The way wire receiving antennas work is by first moving energy from free space into a common mode moving along the antenna wire, and then picking some of that off and coupling it into a mode on the feedline. In this case, the common mode current moving along the antenna wire flows into the common mode of the coax, and vice versa. The coax is not just feedline: it's an intimate part of the antenna! Furthermore, as we've seen, it's connected back through your electrical wiring to your neighbor's dimmer switch. You have a circuitous but electrically direct connection to this infernal noise source. No wonder it's such a nuisance!

The solution is to somehow isolate the antenna from the common mode currents on the feedline. One common way to do this is with a balanced "dipole" antenna. Instead of connecting the feedline to the wire at the end, connect it to the middle. Now the antenna current can flow from one side of the antenna to the other, without having to involve the coax shield. Unfortunately, removing the necessity of having the coax be part of the antenna doesn't automatically isolate it: a coax-fed dipole is often only slightly quieter than an end-fed longwire. A "balun", a device which blocks common mode currents from the feedline, is often employed. This can improve the situation considerably. Note that this is not the same device as the miscalled "Magnetic Longwire Balun".

Another way is to ground the coaxial shield, "short circuiting" the common mode. Antenna currents flow into such a ground freely, in principle not interacting with noise currents. The best ground for such a purpose will be a earth ground near the antenna and far from utility lines.

Still another way is to block common mode waves by burying the cable. Soil is a very effective absorber of RF energy at close range.

Unfortunately, none of these methods is generally adequate by itself in the toughest cases. Baluns are not perfectly effective at blocking common mode currents. Even the best balun can be partially defeated if there's any other unsymmetrical coupling between the antenna and feedline. Such coupling can occur if the feedline doesn't come away from the antenna at a right angle. Grounds are not perfect either. Cable burial generally lets some energy leak through. A combination of methods is usually required, both encouraging the common mode currents to take harmless paths (grounding) and blocking them from the harmful paths (baluns and/or burial).

The required isolation to reach the true reception potential of the site can be large. According to the measurements I quoted above, for my site the antenna noise floor is 18 dB below the conducted noise level at 10 MHz. 18 dB of isolation would thus make the levels equal, but we want to do better than that: we want the pickup of common mode EMI to be insignificant, at least 5 dB down from the antenna's floor. In my location the situation gets worse at higher frequencies as the natural noise level drops and therefore I become more sensitive: even 30 dB of isolation isn't enough to completely silence the common mode noise (but 36 dB *is* enough, except at my computer's CPU clock frequency of 25 MHz).

Getting rid of the conducted noise can make a huge difference in the number and kinds of stations you can pick up: the 18 dB difference between the conducted and natural noise levels in the case above corresponds to the power difference between a 300 kW major world broadcaster and a modest 5 kW regional station.

The method I use is to ground the cable shield at two ground stakes and bury the cable in between. The scheme of alternating blocking methods with grounds will generally be the most effective. The ground stake near the house provides a place for the common mode noise current to go, far from the antenna where it cannot couple significantly. The ground stake at the base of my inverted-L antenna provides a place for the antenna current to flow, at a true ground potential relative to the antenna potential. The buried coax between these two points blocks noise currents.

> There has been some discussion of grounding problems on this and related echos. I believe it has been mentioned that electrical codes require that all grounds be tied together with heavy guage wire.

I'm no expert on electrical codes, and codes differ in different countries. However, I believe that any such requirement must refer only to grounds used for safety in an electric power distribution system: I do not believe this applies to RF grounds.

Remember that proper grounding practice for electrical wiring has very little to do with RF grounding. The purpose of an electrical ground is to be at a safe potential (a few volts) relative to non-electrical grounded objects like plumbing. At an operating frequency of 50/60 Hz, it needs to have a low enough impedance (a fraction of an ohm) that in case of a short circuit a fuse or breaker will blow immediately.

At RF such low impedances are essentially impossible: even a few centimeters of thick wire is likely to exhibit an inductive impedance in the ohm range at 10 MHz (depends sensitively on the locations and connections of nearby conductors). Actual ground connections to real soil may exhibit resistive impedances in the tens of ohms. Despite this, a quiet RF ground needs to be within a fraction of a microvolt of the potential of the surrounding soil. This is difficult, and that's why a single ground is often not enough.

> A little experimentation with my radio showed that the chassis was directly connected to the third (grounding) prong of the wall plug. I am concerned that by connecting my receiver to an outside ground I am creating a ground loop that involves my house wiring. Can you comment on this?

Yes, you have a "ground loop". It's harmless. In case of a nearby lightning strike it may actually save your receiver. My R8 isn't grounded like that, so I had to take steps to prevent the coax ground potential from getting wildly out of kilter with the line potential and arcing through the power supply. I'm using a surge supressor designed to protect video equipment: it has both AC outlets and feedthroughs with varistor or gas tube clamps to keep the various relative voltages in check. Of course the best lightning protection is to disconnect the receiver, but I'm a bit absent minded so I need a backup.

> This may seem like a trivial point but I recently discovered that the main ground from the electrical service panel in my house was attached to a water pipe which had been painted over. I stripped the paint from the pipe and re-attached the grounding clamp and I noticed a reduction in noise from my receiver.

Not trivial. Not only did you improve reception, but your wiring is safer for having a good ground.

I suspect part of the reason I see so much noise from neighbors' appliances on my electric lines may be that my house's main ground wire is quite long. The electrical service comes in at the south corner of the house (which is where the breaker box is), while the water (to which the ground wire is clamped) enters at the east corner. All perfectly up to code and okay at 60 Hz, but lousy at RF: if it was shorter, presumably more of the noise current would want to go that way, and stay away from my receiver.

> I am also a little confused by what constitues an adequate ground. I have read that a conducting stake driven into the ground will divert lightning and provides for electrical safety but that RF grounding systems have to be a lot more complex with multiple radials with lengths related to the frequencies of interest. Is this true?

Depends on what you're doing. If you're trying to get maximum signal transfer with a short loaded (resonant) vertical antenna with a radiation resistance of, say, 10 ohms, 20 ohms of ground resistance is going to be a big deal. If you're transmitting 50 kW, your ground resistance had better be *really* tiny or things are going to smoke, melt or arc.

On the other hand, a ground with a resistance of 20 ohms is going to be fairly effective at grounding a cable with a common mode characteristic impedance of a few hundred ohms (the characteristic impedance printed on the cable is for the differential mode; the common mode characteristic impedance depends somewhat on the distance of the cable from other conductors, but is usually in the range of hundreds of ohms). Of course, if it was lower a single ground might do the whole job (but watch out for mutual inductance coupling separate conductors as they approach your single ground).

In addition, a ground with a resistance of 20 ohms is fine for an unbalanced antenna fed with a high

impedance transformer to supress resonance. Such a nonresonant antenna isn't particularly efficient, but high efficiency is not required for good reception at HF and below (not true for VHF and especially microwave frequencies).

Much antenna lore comes from folks with transmitters who, armed with the "reciprocity" principle, assume that reception is the same problem. The reciprocity principle says that an antenna's transmission and reception properties are closely related: it's good physics, but it ignores the fact that the virtues required of a transmitting and receiving antenna are somewhat different. Inefficiency in a transmitting antenna has a direct, proportional effect on the received signal to noise ratio. On the other hand, moderate inefficiency in an HF receiving antenna usually has a negligible effect on the final result. A few picowatts of excess noise on a transmitting antenna has no effect on its function, but is a big deal if you're receiving (of course, one might not want to have transmitter power going out via unintended paths like utility lines: this is indeed the "reciprocal" of the conducted noise problem, and has similar solutions).

Appendix: Absolute RF measurements with an R8.

Although the Drake R8's signal strength meter is marked with silly "S" units, the alignment procedure in the service manual actually sets up the meter to an absolute standard, at least sort of. A 60% modulated signal with a carrier level of -73 dBm (which is really closer to -72 dBm in total power including sidebands) is S9. One S unit is 5 dB. This is with 6 kHz bandwidth and with neither the RF preamp or attenuator engaged. I assume this is what they do at the factory.

Now, I don't really know how accurately this calibration is performed, and it certainly can't be more accurate than the flatness of the input passband filters (spec'd at <2 dB p-p). There are also problems because the measurement is actually being made by a peak-responding AGC system rather than an RMS meter. Based on experience with other peak sensing systems, I estimate that the meter probably reads noise power too high by about 3 dB, relative to the carrier power in the test waveform. Therefore, for noise, S9 is about -76 dBm.

On my R8, the linearity of the S-meter calibration is poor at the very low end: S1 is much less than 10 dB below S3. Therefore, for measurements below S3 I do relative measurements and refer them to stronger signals. I have on my NeXT computer an old demo application that gives the RMS amplitude of a signal on the audio input jack. With the R8's AGC turned off and the RF gain set low enough to insure good linearity, this may be used to make quite accurate relative power measurements. You could, of course, use an ordinary AC voltmeter to do this if you have one sensitive enough to read the level of the Drake's audio output (I don't have one).

Considering all of the uncertainties, the numbers hold together remarkably well, better than the likely accuracies in this case (just dumb luck).

For the measurements quoted in my previous message, the receiver's noise floor is -119 dBm. Drake's specs imply that for a 6 kHz bandwidth the noise floor should be below -118 dBm with the preamp off.

According to "Reference Data for Radio Engineers" (Sams, 1975), the wintertime level of natural noise in my area at 10 MHz should be about 32 dB above the thermal reference level: this would produce a noise floor of -104 dBm in this bandwidth with a perfectly efficient antenna. A calculation for a 17 m vertical antenna feeding a high impedance transformer predicts a loss due to mismatch/lack of resonance of 4.5 dB at 10 MHz. My antenna is not a vertical but an inverted L which I presume is slightly less efficient (difficult to calculate). There are also presumably some modest losses in the transformer, the grounds, the cables and the connectors. I wouldn't be surprised if these added up to 3 dB or so. With a total antenna system inefficiency of 7 dB, I'd therefore expect to see an antenna noise floor of -111 dBm, which is, in fact, just what I measure.

Grounding Systems for Amateur Radio Stations

By: John Wendt WA6BFH

There is quite a bit of talk these days between Amateur **(Ham)** Radio operators about the desirability for **"good grounding systems"** for their home radio stations. I can tell you honestly that this was not so fervently discussed on the radio in earlier decades. My suspicion for this is that there was a better understanding in earlier times, before the advent of our rapid increase in new operators, of the conditions under which a **"grounding system"** would do some good. Lets look at this carefully and critically so that we can assess the desirability of a grounding system for our radio stations.

Safety Grounds vs. Radio Frequency (RF) Grounds

First of all realize that there are two discreet types of ground systems and reasons why a Ham might desire to provide a **"station ground"**. These are for the most part mutually exclusive! In other words one does one job for which it is specifically designed, and one does a different job. You must design your grounding system with this in mind, or one function may inhibit or nullify the other!

One of these grounding systems is what I will generally describe as a **"safety ground"**. This safety ground is installed to reduce the risk of electrocution or radio equipment damage by short circuited **"power mains"**, or from lightening strikes to the antenna or **"feedline"** system. A safety grounding system is certainly a good Ham Radio **"engineering practice",** although it is usually considered as of secondary importance to an **"RF ground"!** In portions of our country where dramatic lightening storms are common this preference is probably reversed. I can tell you that even in the portion of Southern California that I live in, lightening strikes from annual spring storms, or even the thought of accidental **"short circuit"** electrocution are enough of a concern that I have a safety ground system for my station. I have designed it though to operate in conjunction with the RF grounding system I use! Lets talk about the considerations of properly designing an RF grounding system. Through the course of this discussion I

will explain how an RF ground can be utilized as a safety ground, and also that a safety ground **should never** be used as an RF ground!

The RF or Radio Frequency Grounding System

A popular misconception is that all radio antenna systems should be grounded to enhance their radio performance. If grounding these antennas was for the purpose of safety, as I have clarified in the earlier paragraphs, this might be true. To think though that grounding an antenna will automatically make it a better communications device is completely wrong! To appreciate this we must think in terms of **"radio frequency wavelength"**, or fractions of wavelength at 1/4 wavelength increments.

On certain lower frequency longer wavelength bands an RF ground is not only a reasonable consideration but, it is fundamental to getting the best communications performance from your radio station. At other higher frequency and shorter **"wavelength bands"** however, RF grounds are either superfluous, or even harmful to overall communications performance! Lets look at this carefully as illustrated in typical and practical scenarios. Keep in mind the concept of thinking about the physical length of the **"grounding conductor"** in relationship to its comparative **"wavelength dimension"!**

The Practical Station Ground

Living in a typical single story ranch style home my choices and availability for a good RF ground installation are relatively simple. The first **"ground rod"** of my grounding system is within 4 feet 2 inches or 1.27 meters of my station equipment. This 50 inch dimension is the entire or total length of the conductor to this first grounding rod. From this first 10 foot deep ground rod, a # 6 AWG. (American Wire Gauge) bare copper wire is buried and runs under ground in a one foot deep trench to a second 10 foot long rod about 15 feet distant. This second rod is then connected to a very elaborately designed grounding system at the base of my antenna tower's foundation. The length of this conductor between the second ground rod and the tower base is 16 feet. The entirety of these ground rods, and the interconnecting conductors, are buried at about 12 inches deep. Take a look at Figure 1 to see this system drawn to scale.

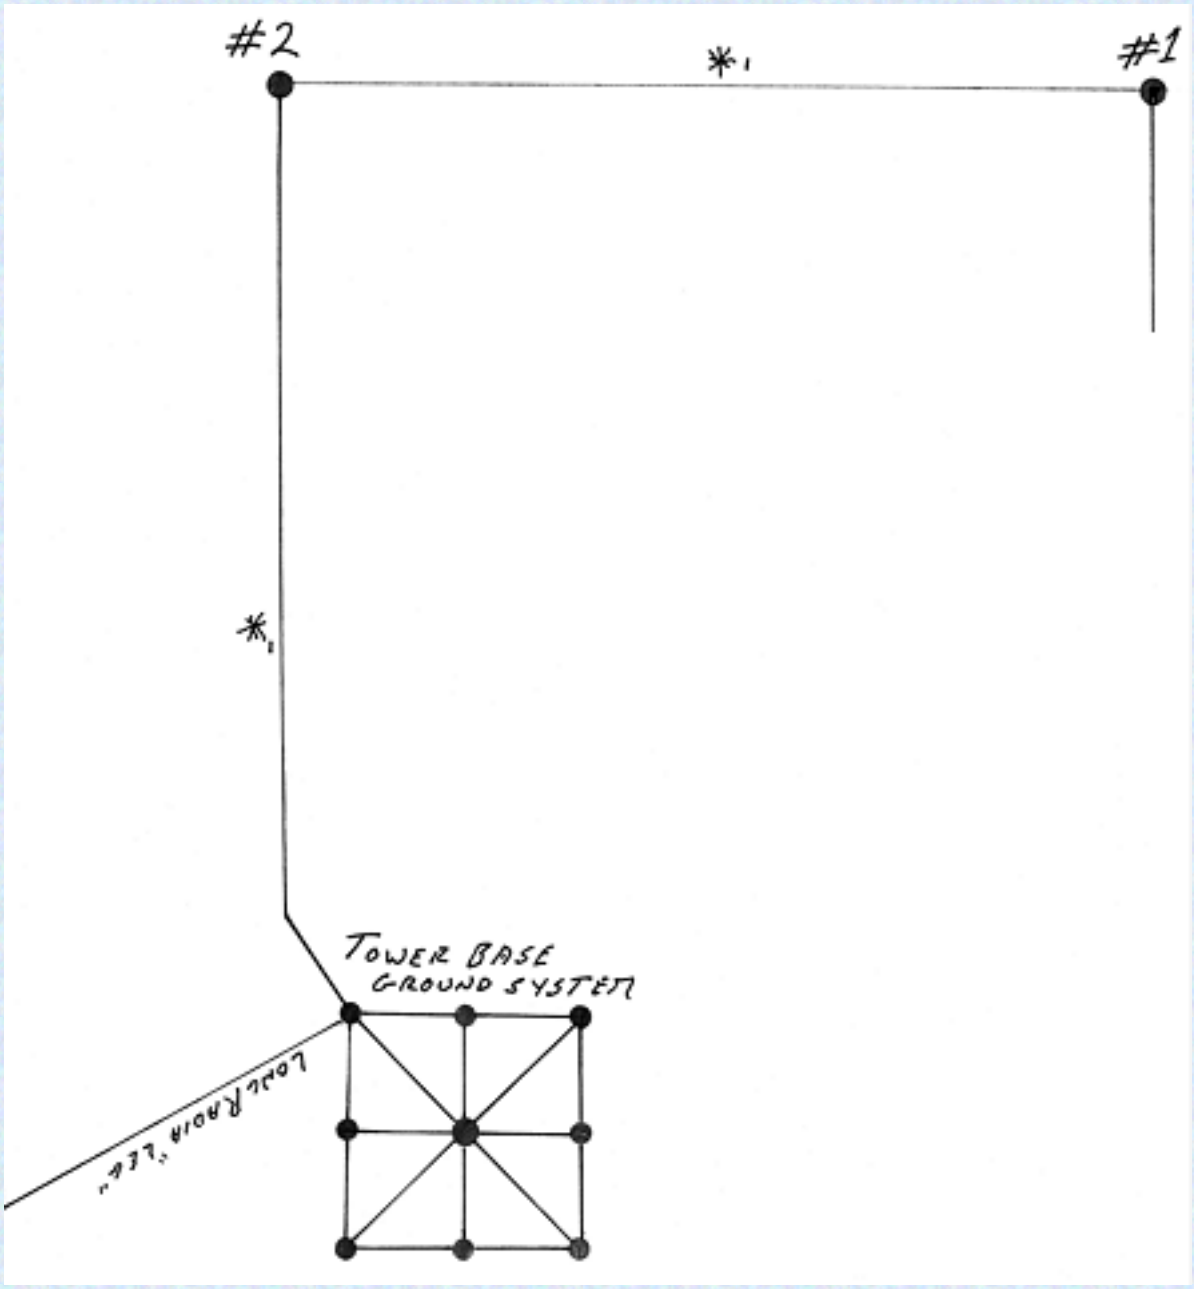

Figure 1.

When you look over this drawing you might think, gee if he says its important to keep the ground conductor as short as possible, why does he have almost 5 meters (15.5 feet) of separation between ground rods. He could have even run a wire from ground rod number 1, straight to the tower base! Well believe me, if I could have, I would have! The combined 15 and 16 foot dimensions surround the perimeter of a building, so that I was forced to take this longer circuitous route! This really though isn't such a bad happenstance!

Having the ground rods this far apart is actually a desirable feature. What is being achieved by this system is to make a **"large surface contact area"** to earth ground. It also functions to reduce **"ground loops"** as well as is possible. Even though I can't prevent all ground loop conditions, I can keep them manageable! I had thought that in my original design that I might also place 10 foot deep rods at the points where asterisks are shown. After testing the system on the MF (Medium Frequency) and HF (High

Frequency) wave-length bands, I found these additional rods to be unnecessary.

Ground Loops (and the worst case scenario)

Ground loops are the major concern and worry to be dealt with as you lay out an RF ground system! Lets lay out a worst possible case scenario of what would be a terrible way to ground a 20 meter (and all harmonically related bands) home station.

Lets say that our 20 meter Ham has his "Ham Shack" in approximately the middle of his house, up on the second story of the house. He uses a nice low resistance and low inductance flat braided strap (lets let him do at least one thing right), which runs from his 1500 Watt amplifier to a 2 foot deep ground rod in his front yard. This braided conductor runs between the floor of the second story and the ceiling of the lower story. It then runs down the outside of his stucco covered home to the ground rod. Its total length is 33 feet long from the amplifier to the ground rod.

Fifty feet (15.24 meters) of coaxial cable goes up between the walls of the second story, is draped over to the top of his tower, and terminates at his TH6DXX beam on this 65 foot tall tower. Lets break down these dimensions in terms of wavelength, and even look at them as they may appear to form a **"current loop"**!

Our rueful Ham friend is using a ground conductor that is almost exactly one half wavelength long and is raised in the air by the buildings structure. Even if this length were reduced to about a quarter wavelength, it would still very nicely couple energy into other wiring in the house, and also the wire mesh beneath the stucco walls. This other wiring could be telephone wires, television cabling, and the 110 volt power wiring in the house. His coax cables shield is a nice **"odd order harmonic"** radiator, as it is 3/4 wavelength long! The ungrounded tower is about a half wavelength tall.

This last point about the tower must be viewed carefully. He might want to ground it as an RF consideration, and he might not! Think about it this way. One ground rod is in the front yard at the end of a half wavelength wire. The shield of the coax cable ultimately goes to ground in the back yard at the tower base at an electrical length of about 7 quarter wavelengths (50 + 65 = 115 feet). This makes another sort of odd order harmonic radiator! If you add into this loop circuit the length of the front yard ground rod conductor, the loop circumference becomes 9 quarter wavelengths. Yet another odd order radiator dimension!

My assessment of this Ham's station would inform me that he is throwing away some of the advantage of his beam and the height of his tower because, all of the radiating conductors strung around the house raise the **"angle of radiation"** considerably higher than it could otherwise be! He is also enhancing the prospects of **"audio rectification"** to his own and to neighbors telephones. He is also enhancing the possibility of **"TVI"** to his television, and maybe to the neighbors as well if they all use a cable TV system.

The Absolute Worst Thing To Do

Maybe though this isn't the worst case scenario? The worst case would be the Ham that tries to use the 3rd wire ground within the 110 volt AC power system that runs though out his house. Then he could really couple RF energy around his house and the neighborhood! **Never ever use this 3rd. wire ground as an RF ground!**

How Should our Ham have done it

1) His station should be on the ground floor of the house.

2) His low inductance low resistance grounding conductor should have considerably less than a quarter wavelength of total length between his amplifier and the first ground rod.

3) If the soil or other conditions in his yard allowed only short length rods, he should have used several of them all tied in a line, and ultimately connected to a **"grounding cage"** or rods near the **outside** of the tower's concrete base.

Important Tip: Don't install the ground cage within the concrete! One reason is that it is connected to the earth via the high resistance of the concrete. The other reason is that a lightening strike to the tower may well blow the concrete block to bits!

When Should an RF Ground Be Used and When is it a Bad Thing

With the advent of the many new MF/HF/VHF transceivers on the market these days, Hams are flocking to frequency bands on which they have little or no experience. Additionally because of the licensing structure, one of the most popular Ham bands in use is the 10 Meter band. I'm sure also that within the coming years, 6 Meters will become even more popular. On 6 meters at least, RFI is very simply controlled.

On one of these two mentioned bands, and also on most bands above 20 Meters, television interference from harmonic radiation becomes a concern that grounding will not fix. In fact most practical possibilities for grounding systems at a typical residential home, will enhance this TVI (Television Interference) problem!

Think about it this way, the 2nd. Harmonic of the 28 MHz. band falls right at TV channel 2 (2 X 28 = 56 MHz.)! This is the fourth harmonic of the 20 Meter band (4 X 14 = 56 MHz.)! From this description and the other worst case scenarios that I outlined, you may be thinking, so is he saying not to bother with installing a ground system? Well, that's not at all what I'm saying! I am telling you though that you must appreciate and design your grounding system so that it cannot possibly contribute to either **"fundamental frequency"** radiation, and also not contribute to the re-radiation of harmonics of these upper HF bands.

The prime methods for accomplishing this are to (1) keep the ground conductor shorter than a quarter wavelength on 10 Meters, which is of course the highest frequency HF band. Next we must, (2) make this conductor be at the lowest AC resistance (impedance) possible! We do this by using large surface area (fat) conductors, and **SOLDER** all connections. After soldering, seal them from the eroding effects of weather by using electricians tape and silicon sealers. Anti-oxidizing compounds such as "No-Ox", which are available at most electrical suppliers, are a must for any connection of dissimilar metals! A simpler way to deal with this last mentioned concern is to simply use non-alloy baring copper for the entire system. Copper tubing typically used for plumbing meets all of the above requirement perfectly. Don't use steel or iron pipe for ground rods! Always (3) connect multiple ground rods in a line. This line can bend or zigzag but, it must extend from the nearest to the furthest ground rod or screen in a line. The last physical consideration (4) is to cover as much ground surface area as is practical within the constraints of your yard or acreage. A minimum RF ground system will use at least three 8 foot or longer ground rods. If you can't sink a rod that long, than you must use many more shorter rods, or bury a splayed out radial system of wires. In this last case you must terminate this wire radial screen within less than a quarter wavelength at 29.7 MHz. (which is 94.5 inches or 2.4 meters).

Thinking conversely, if a grounding system becomes a touchy prospect at the higher bands, might it be a better consideration and benefit at the lower bands such as 160 meters? If you answered this question absolutely, you win a gold star, and Ham of the year award!

On lower frequency bands, both RF noise level, and also **"ground wave"** signal propagation become an important concern. Just to give you a clue, AM broadcast stations invest huge amounts of money in designing and installing their antenna grounding systems. Of course, we are nearby neighbors, almost kissing cousins you might say of the Broadcast band that ends just below 160 meters! On this band doing everything you can to enhance the signal is preeminent within the stations design. It even becomes easier to install a good grounding system than it is to install good antennas!

Think about it. Even if you could put an antenna that is 260 feet long, 100 feet above the ground, it would still be only .19 wavelengths above the ground. That would be the equivalent of installing a 2 meter antenna at about 15.6 inches above the ground! My 160 meter **"Zep"** is 48 feet up at its highest point, this equates to .18 wavelengths. This actually places the **"high current point"**, which is main working point of the antenna, at 37 feet. Thirty-seven feet is about .14 wavelengths above the ground at 1.8 MHz. Pretty low, little more than 1/10th of a wavelength! By contrast, a good ground system is easy! Good RF ground systems really come into their own, as far as showing worthwhile value, on the bands below 30 meters!

Lets wrap up these concepts

An RF ground can be used as a safety ground but, a safety ground is often the worst sort of RF ground.

Multiple ground rods provide the most earth area covered, and consequently, the best sort of grounding

system.

If soil is so rocky that even hydrologically installed ground rod tubes aren't possible, a screen or web of wires below the ground surface will work well. Always use metalurgically sound, true copper wire. No alloys! Cover the largest surface area possible.

Tip: These wires can be installed in a radial fashion, by making slits in the earth or lawn with a sidewalk gardening edger. You then stuff bare copper wire in the slits. In this sort of installation wire size can be reduced to save cost. Use large enough wire to provide good physical strength, lets say #16 AWG.. Be certain that it is **"soft copper"**. A good test is to heat the wire with a gas flame, a propane cigarette lighter works great. If the wire is truly soft copper non-alloy wire, it will quickly turn green, then black, and loose all of its tensile strength. Another test would be to bury a piece of this wire for a week or more. When you dig it up, if it shows signs of oxidation or pitting, its not pure copper!

A ground cage surrounding a tower foundation provides a good final terminus point for the grounding system. It also provides for the prospect of **"shunt feeding"** the tower as a multi-band vertical antenna.

Why use a Ground Cage

For the Ham that is dedicated enough to our avocation to want the best engineered station possible, an antenna tower of considerable height is a must! The best radios in the world will not out perform poorer radios using an efficient antenna!

If you are going to install a tall tower (at least a half wavelength tall in the center of the HF spectrum) your going to have to dig a deep hole for the towers concrete base. The kind of tower I'm speaking of as a minimum will require at least a 6 foot deep hole that is 3 feet per side. I think its advisable though to install a foundation for a larger tower. You never know, you may someday want a nice 90 or 120 foot tall tower. This sort of tower requires at least a 9 foot deep hole that is 4 or 5 feet square. After such a hole has been dug, putting in a ground cage is simple!

First install the longest feasible ground rod in the center of this hole. Hopefully this rod will be at least 8 feet long. Even if you can't install a rod this long into the center bottom of the hole, a shorter rod still adds its length to the wire cage that will reside in the hole.

The cage itself is fabricated from #8 AWG. copper wire. You may visualize this cage as 8 lengths of wire that extend upward from the central ground rod, and reside at each corner of the hole, and the four sides of the hole. It is best to keep the wire contiguous however. If you were to section it into individual lengths, its net resistance (or AC impedance) would be higher than if it is kept as a continuous length. I hope that my verbal description will reveal an assembly that extends 17 feet into the ground (assuming a 9 foot deep foundation hole, and 8 foot rod) and covers a large surface area around the sides of the hole.

After this wire assembly is in place, install the towers steel work base frame. Next before filling the hole

with concrete, install plastic sheeting over the wire. Now when the hole is filled with concrete, the plastic sheeting will insure that the wire is pressed against the dirt sides of the hole, and not encased by concrete. Two ends of the wire can be left to extend above the top of the hole. These will later be attached to the bottom of the tower.

The rod at the bottom center of the hole also provides a solid anchor, to keep the steel work from "floating" or moving about while the concrete is being poured. To accomplish this use Nylon rope and turnbuckles to tension down the steel frame. Nylon rope is used so that no metal work encased within the concrete is electrically connected to the ground system. High voltage static or lightening will now flow only to dirt earth surrounding the concrete. Raise the steel frame above the dirt bottom of the hole with cement foundation piller blocks. If the ends of the steel frame contact the dirt at any point, they will eventually rust and totally disintegrate!

Let's review the best things to do

1) Always use the shortest and largest surface area conductor feasible. This can be wide metal strap material, or large diameter wire or tubing.

Helpful Tip: I use 1/2 inch diameter copper tubing as my ground conductor between rod #1 and the radios. The **"ground bus"** at the back of the radio bench is yet another piece of tubing, with short braided cables soldered to it for attachment to the radios, amplifiers, and antenna **"Trans-Match"**. The ground rods themselves are also copper tubing which were hydrologically sunken (this is a technical way of saying, hook up a garden hose to the tube and let the water suck it into the ground). This method will push aside even grapefruit size rocks as it burrows into the ground.

Copper tubing is much less expensive per foot than is large diameter copper wire (I wish I had thought of that when I installed my system, because it's easier to solder as well). It has a larger diameter than most wire which lowers both its impedance and inductance. It can be easily soldered together using plumbing fittings, just as you would install water pipes. If you want to make a real bang up job of things use Silver solder to lower the impedance even more! Seal and weather proof all soldered joints!

2) Use several ground rods, and cover a large surface area. A large surface area is more important than ground rod depth! Longer rods are desirable though when possible. If it is possible, place ground rods in an area that is often irrigated. Wet soil improves soil conductivity, and helps reduce radio frequency noise.

3) Think about and sort out possible ground loops on various wavelength bands. Design your system to avoid ground loops on any band on which you operate.

Terms you should become convivial with, and use in your conceptual thinking process

Angle of radiation: The term "angle of radiation" and "signal gain" are virtually the same thing. A good

antenna that is high in the air, and also isolated from other random radiators provides the lowest radiation angle, and consequently, the furthest signal propagation.

Audio rectification: This is the condition that prevails when transistor and diode circuitry within telephones or other audio devices are within the "near field" of a radio signal. This same sort of diode junction detection can even be observed with the false switching of infrared detector outdoor lighting. In this last example, the RF signals forward bias the lamps switching circuitry.

****Current loop:*** Any time a wire or assembly of wires form a loop, a current generator is formed. Whenever you impose generated current across a resistance, you produce voltage. In the case of this articles premise, this voltage represents unwanted signal radiation!

Feedline: This term depicts the generic and proper description of conductors that connect an antenna to the radio station. This "feedline" might be either coaxial cable, balanced "Ladder line", or even single conductor line (as in the feed system for a "Windom" antenna, and also "G-line").

Fundamental frequency: The fundamental or prime frequency at which an oscillator or "Exciter" operates. An example might be an oscillator or Exciter operating at 3.5 MHz. (See Harmonic)

Ham: The name by which radio experimenters identified themselves, prior to the implementation of Amateur Radio pursuant to the Federal Radio Bureaus, "Communications Act of 1934".

Harmonic: The multiple of some fundamental frequency. The second harmonic of

3.5 MHz. is 7.0 Mhz., or 2 X 3.5 MHz. = 7.0 MHz.

High current point: Radio frequency currents reverse every half wavelength. The high current point of maximum signal radiation is at the center of a half wavelength antenna.

Good engineering practice: Amateur Radio operators are required by law to construct and maintain their radio stations to the best "state of the art" good engineering practice.

Good grounding system: A grounding system that provides the lowest possible resistance or Alternating Current (AC) impedance, has the lowest AC inductance possible, and is designed so as to limit the re-radiation of fundamental or harmonic frequency energy.

Ground bus: A common point connection terminus that embodies the design criterion of a good grounding system.

Grounding conductor: This is the connecting link between the radio station equipment bus, and the nearest point of earth grounding connection.

Ground rod: The term used to describe the simplest device associated with any sort of electrical "earthing" practice.

****Ground loops:*** Intrinsically the same thing as a Current Loop.

Grounding system: The entirety of a conceived and engineered plan for providing "earthing" perameters for radio or other electrical requirements.

Ground wave: One electrical component of the physics of low frequency radio propagation. In Amateur Radio practices, the 160 band is the only wavelength band that exhibits significant ground wave signal propagation.

Large surface contact area: In the context of this article, this term implies the best "current conductivity" to earth ground. In Alternating Current (AC) circuits (ergo radio) large surface contact provides both low inductance, and low impedance. (See also "Skin Effect")

Near field: The near field of radio frequency energy is that radiated energy within a several wavelengths of an antenna or other radiating source.

Odd order harmonic: The direct definition relates to the third, fifth, seventh, ninth, eleventh, and thirteenth multiples of a fundamental signal etc. A readily available example of an odd order harmonic in Amateur Radio practice is the means by which a 441 MHz. signal can be generated from a 147 MHz. source (147 X 3 = 441). Another way of saying this is, the 70 centimeter band falls at the 3rd. Harmonic of the 2 meter Amateur Radio wavelength band. Odd order harmonics are easily propagated in contrast to "Even Order" harmonics which will self cancel.

Power mains: The generic description of the primary power distribution source (117 Volt Alternating Current, or 220 VAC etc.)

Radio frequency wavelength: The unit of radio signal measurement that embodies both the legal requirement of Amateur Radio station operation, and also depicts the physics by which radio signals propagate. Radio wavelength is determined by deviding frequency into the velocity by which that signal energy travels. Where V = Velocity or 300,000,000 meters per second, and f = Frequency (of oscillation) of the frequency in use. Example: V f = λ 300 / 50 MHz. = 6 meters

RF ground: A grounding system that by inference implies the qualities of low impedance, and low inductance.

Safety ground: A grounding system that by inference implies only a better electrical path to ground than the person or equipment being protected.

Skin effect: Alternating Currents, such as radio frequencies, flow only on the outside surface of conductors. By inference in this application, larger surface area equates to lower impedance and improved conductivity.

Short circuit: The situation that arises when a person or other conducting object is exposed to an electrical circuit between that circuits source and load. The "short circuiting" object in this case, becomes the interim load.

Shunt feed: In the context of this article, this implies a system for "feeding" radio signal energy into a grounded metal tower, to make that tower function as an antenna.

Soft copper: The term soft copper refers to copper that is not produced with other metal content. In other words, it is just plain copper, not an alloy.

Hint: To expand upon the conceptual idea contained within the use of such metals, think about the concept of using other metals of low resistance! Just as a thought teaser, if the cost was not so exorbitant, would using silver plating on antennas or other RF conductors be desirable?

Station ground: A radio station grounding system where both electrical safety precautions as well as radio frequency transmission optimization have been provided.

Trans-match: This is the proper term for a transmitter to antenna system impedance matching coupler. This is often errantly referred to as an "Antenna Tuner". If the word Antenna *System* Tuner was inserted, the errant quality of the term would be mitigated.

Wavelength bands: A political distinction for allotting and cataloging portions of radio frequency spectrum. This term though embodies the physics by which radio signals propagate. (See: radio frequency wavelength)

Wavelength dimension: This term refers not only to unitary or single units of frequency wavelength such as 10 meters or 2 meters, it more importantly refers to thinking in terms of a dimension length. Example: 10 feet is .28 wavelengths at 28 MHz. (or a bit longer than a 1/4 wavelength).

The formula to calculate this is:

V f =

300 / 28 MHz. = 10.7 meters

10.7 X 39.37 = 421.8 inches

421.8 / 12 = 35.15 feet

10 feet / 35.15 = .28 wavelength

Where V = Velocity of signal propagation, or 300,000,000 meters per second, and 39.37 = 1 meter as measured in inches

This same 10 foot physical length of wire becomes .253 wavelengths (still a bit over a quarter wavelength) at the 12 meter band, .508 wavelengths on the 6 meter band, and 1.46 wavelengths on the 2 meter band.

For our purposes in this article, anytime a piece of wire at your station approaches a 1/4 (.25) wavelength or longer, it isn't a ground conductor anymore! In fact it becomes a **"radiating element"**, or you might say an antenna in its own right. This is bad news for a ground system!

Radiating element: a radiating element is any metallic conductor that is within the **"near field"** of a radio frequency energy source. This is usually specific length component elements of an antenna. It can be any piece of metal that is a significant percentage of the energizing wavelength frequency. Examples of such **unwanted** radiating elements might be, rain gutters, wire guy lines, or grounding conductors, any of which would have to be a quarter wavelength or longer at the energizing frequency.

K3MT
presents . . .

The *GRASSWIRE*
another approach to hidden HF antennas

April, 1997

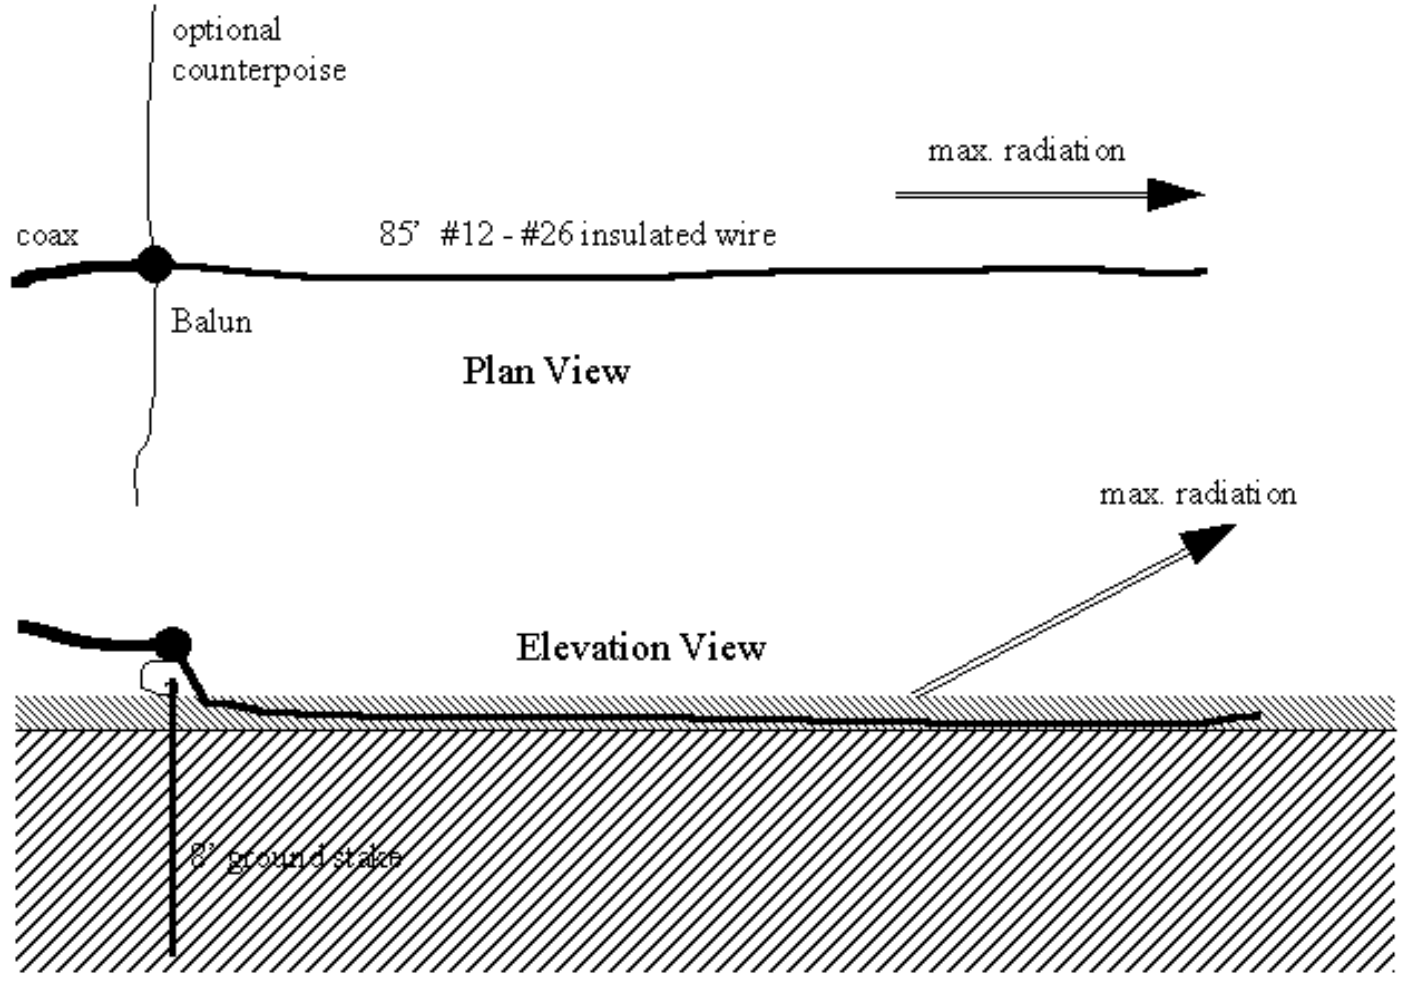
Deed restrictions got you down? Neighbors intimidating your tower plans? Need a really *easy* portable HF antenna? Then the *grasswire* may be the answer! Virtually invisible, lightweight, and compact (you can carry one in your hip pocket), this antenna works! It has been used by K3MT in various installations for more than 10 years.

Read on - and listen to the "experts" telling you that this is hogwash, that an antenna like this can't work. But it does. And *true* experts, who have taken a decade or more to come to grips with the intricasies of Maxwell's Math, know *why* it works.

This antenna will *not* out-perform a yagi, or a decent dipole up a half wavelength. Not in gain or signal strength, at least. But it will survive an ice storm, wind storm, and is practically immune to lightning. And it doesn't need a large tower or tall support. I deploy one from my hip pocket at times - the balun to match it is larger than the antenna!

THE GRASSWIRE - IN BRIEF

What is it? Put simply, it is an end-fed, longwire antenna that is laid right on the grass. Hence the name. The original grasswire used by K3MT in the summer of 1988 was just 204' of #18 AWG magnet wire laid along the property line, anywhere from 1" to 6" above the ground. This sketch shows plan and elevation views of a typical installation. Both an 8' ground rod and optional counterpoise wires are shown. Use one or the other. Both are not needed.



These antennas are largely resistive, with values ranging from 150 to 500 ohms or so on average ground. They have been used successfully on the average soils northwest of Washington, DC, on the sandy soils of the Cape Canaveral, Florida area, in the rocky, shale soils of the mountains in Somerset county, PA, and on river bottomland of Allegheny County, PA. One was used with great success by K3MT/VP9 in Southampton, Bermuda - the object of nightly pileups on 30 m CW for four nights.

REFLECTION AND THE BREWSTER ANGLE

The skeptic in you will doubt that such low antennas can work. After all, its image in the ground radiates and cancels out all radiation. True - if the ground is perfect. But nothing is perfect! The grasswire radiates *vertically polarized* off the *end* of the wire. Extensive monitoring tests with wires laid along the great circle route toward WWV, and perpendicular to that line, demonstrate the end-fire nature of the antenna. So why does it work?

When a plane wave reflects from an air-earth boundary, an incoming ray reflects, giving an outgoing ray. These two, and the line normal to the boundary plane, form

a *plane of incidence.* Solutions of Maxwell's equations differ for the case of the E-field being perpendicular to this plane (i.e., horizontally polarized), and the case when the E-field vector is *in* the plane of incidence. You will probably call the latter "vertical" polarization, although this is technically not correct. Electromagneticists (a.k.a those who practice Electromagical effects) refer to these cases as *normal* incidence (horizontal polarization) and *planar* incidence (vertical polarization.)

For the normal incidence case, reflection is nearly total, with a nearly 180 degree phase reversal. Thus very low antennas neither respond to, nor generate, appreciable amounts of horizontally polarized radiation. But for the planar incidence case, the reflection varies in strength considerably. At some *takeoff angle* (angle between outgoing ray and the ground) the reflection becomes quite weak, and has a 90 degree phase shift. Near this angle, the sum of direct and reflected rays will have a magnitude as if the antenna were in free space! Of course, at other angles, ground reflection largely cancels the direct ray, and the antenna does not radiate well at all.

A *reflection coefficient* is calculated as the ratio of the electric field in the incoming ray to the electric field in the reflected ray. It varies from one (total reflection without loss) to zero (no reflection at all.) It depends on the takeoff angle, frequency, and the soil parameters (dielectric constant and conductivity.) Here are plots of planar incident (vertical polarization) reflection for typical "good" and "poor" soils.

Reflection Coefficient,
vertical polarization
Good soil:
dielectric constant =20
conductivity = 30 mS/m
3.75 MHz
10.1 MHz
29 MHz
coefficient
takeoff angle, degrees
0
0.1

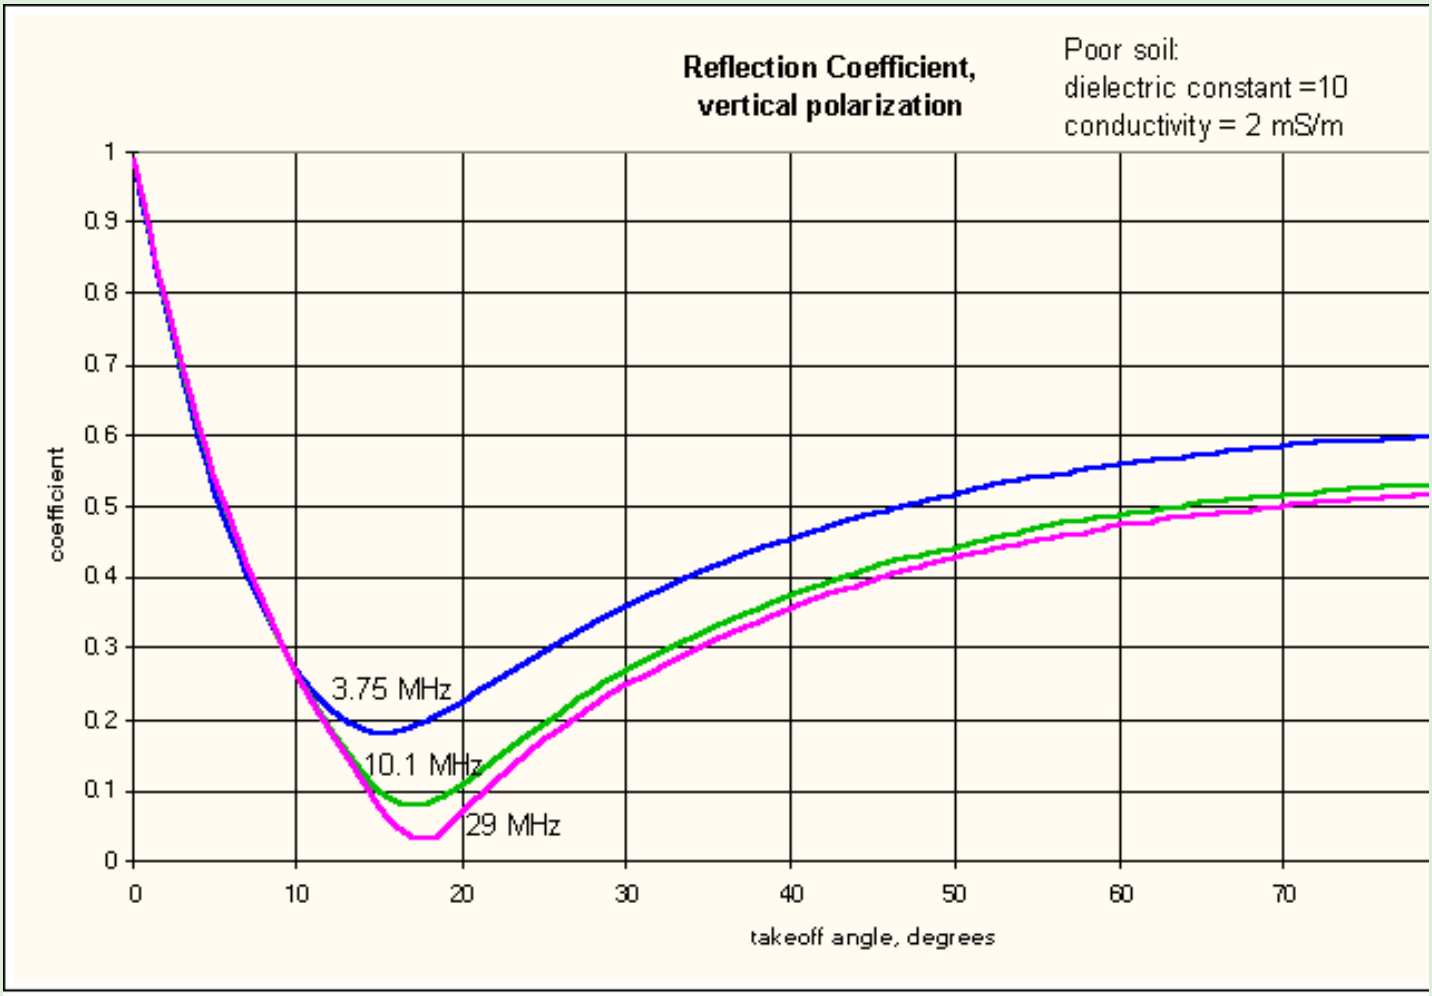
50
60
70



Notice that, at 10 to 25 degrees, the ground reflection is very weak. It also is shifted 90 degrees in phase from the incident ray. Therefore, radiation from the grasswire, off the ends will be about the same as if the ground were not present.

But launching a ray at, say, 15 to 20 degrees takeoff angle, in a direction toward Europe, can be useful! That's what a grasswire does. It is lossy in all directions, but least lossy when exciting the ionosphere for a long-haul DX contact. To demonstrate the point, here's an extract of K3MT's log, for October of 1988, (ahh, glory! Yes, the SSN was good then!) using a grasswire:

```
Date     GMT      CALL     his/my RST     FREQ     Power

OCTOBER

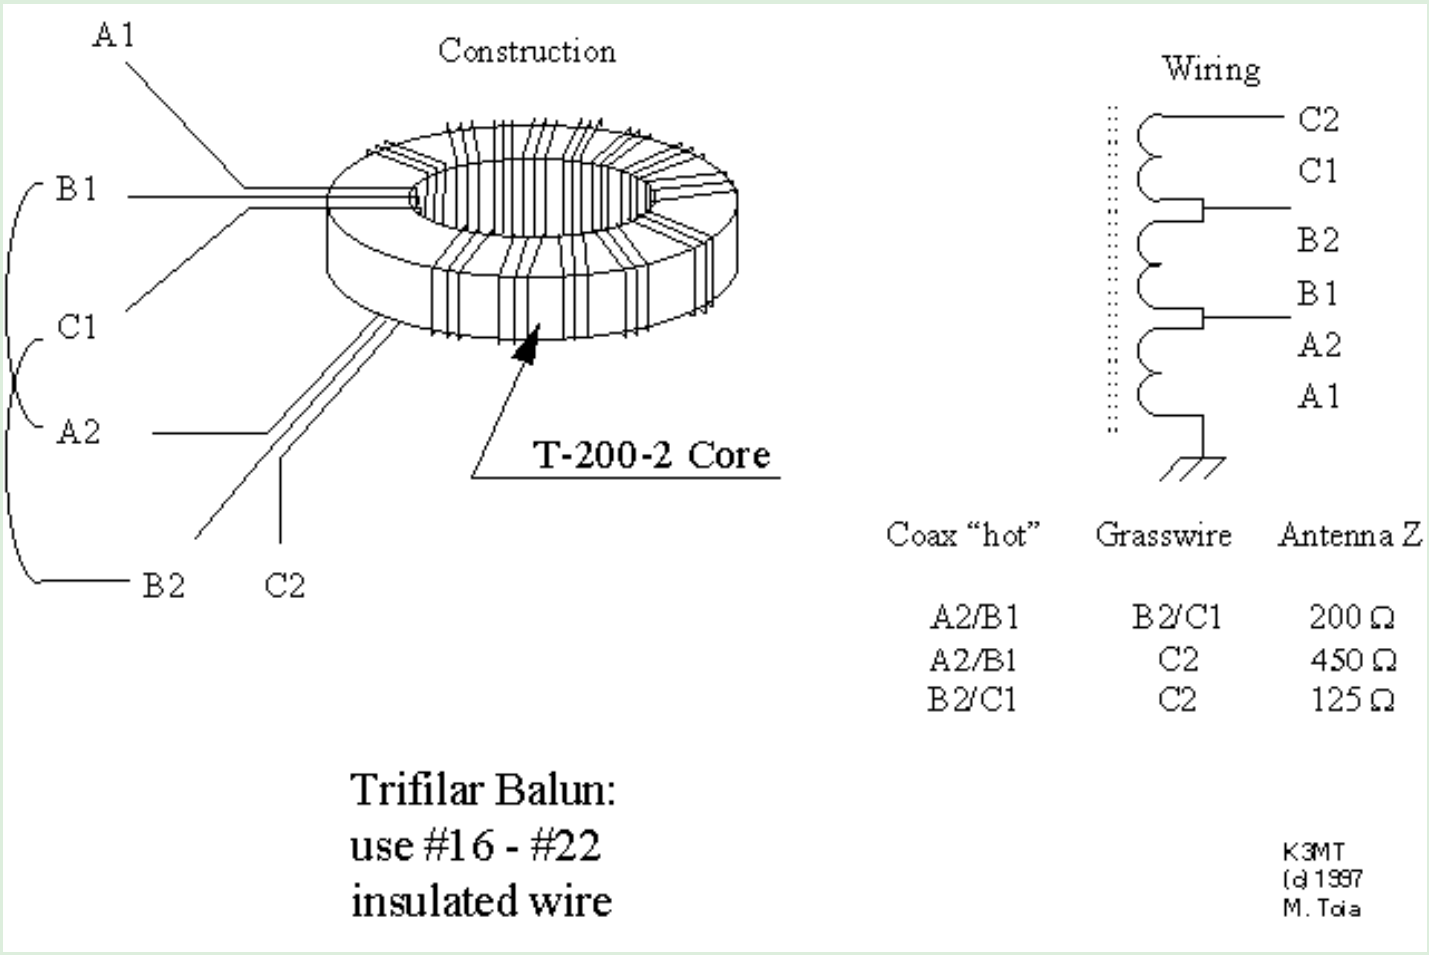
29	2105	WA200JXT	599 / 599	28015	80	ND

Not bad, for a wire on the ground. Notice that contacts were made on 80, 40, 20, 15, and 10 meters. The signal reports are not fantastic. But contacts were made, and ham radio was enjoyed! Five countries were worked in 3 days. And the best part of this setup: *the neighbors never knew that a ham station was on the air!*

FEEDING THE GRASSWIRE

Since this antenna is largely resistive, a simple trifilar balun is all that I have ever had to use. This sketch shows how to make a balun that works:

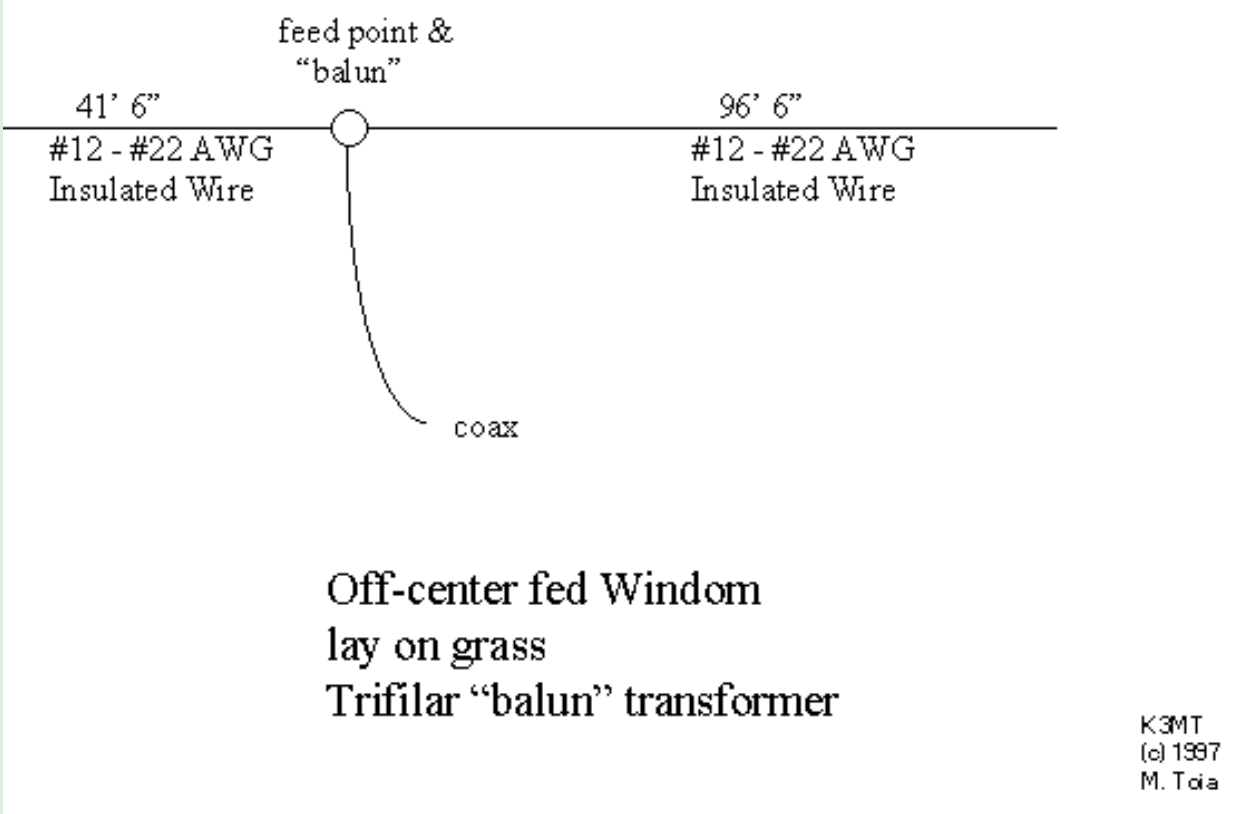


Typically I pull the insulation off of some indoor telephone wiring cable. Four insulated #22 copper wires are inside: discard one of these and use the remaining three. Wind about 16 turns on the core, without allowing the wire to twist (keep the three conductors parallel at all times.)

Notice that this "balun" really matches an unbalanced antenna to an unbalanced transmission line. It is basically a wide-band, three-winding autotransformer. Impedance ratios are as shown on the drawing. Generally it is necessary to connect the coax to either A2/B1 or B2/C1, and the antenna to B2/C1 or to C2. This may change from one band to another, and usually does.

WINDOM IN THE GRASS

I have elsewhere described a windom antenna. While it is usually hung from a pole or in a tree, it works when used in a "grasswire" mode. Just lay it on the ground. Dimensions are repeated here for ready reference.



When I travel, I take one of these made of #22 insulated hookup wire. Since I often set up beside motel parking lots, and often after a day's work, the longer wire is black, and the shorter one is red. This helps me determine which way to point the windom. Remember, though, that it fires *off the long end*. Of course, it fires the other way, too, but usually works best off the long end.

I hope this has given some of you a good case of curiosity. Go out and try one of these ground - mounted wires. They're easy to build. Even the balun is easy to build.

If you must, contact us: we can supply a core, a whole balun, or a whole grasswire windom setup.

For more unusual antennas, visit my web page.

And check out my Book for a dozen topics about HF antennas.
that includes the grasswire and other beverage antennas.

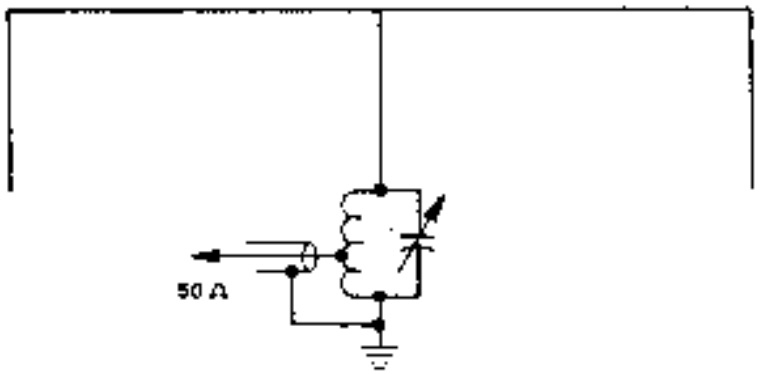
K3MT

Bobtails and Half Squares

These antennas offer big gun DX performance on the low bands, yet they are surprisingly simple to build. Try one- you will like it!

ABOUT THESE ANTENNAS

Bobtails are vertical arrays that look like the letter "E" turned 90° clockwise onto its tails. They have 3 quarter wave vertical elements and are one wavelength long. The Half Square is a shortened Bobtail- it has 2 quarter wave vertical elements and is a half wave long. The tops of the verticals are all connected together by a wire or other conductor. The bottoms of the verticals are all insulated from ground. Bobtails are fed from the bottom of the middle element. Half squares may be fed at either end- it matters very little in the resulting pattern.



These antennas belong to the 'inverted ground plane' family. They work best *voltage-fed,* rather than current-fed. You should not connect coax directly to the tails. Current-fed antennas like the dipole have low impedance feedpoints and are a good match to coax. The impedance at the tips of a dipole is high, however- in the thousands of ohms, like the bobtail. Fortunately it is easy to voltage-feed the bobtail with a simple LC parallel resonant circuit connected between the element tip and ground. With the point of highest RF current a quarter wave up in the air, ground requirements are much less stringent than with ground-driven, current-fed verticals which need many radial wires to work well.

It is customary to use only a small ground screen as the feedpoint counterpoise. A 3 by 5 foot piece of wire cloth is often enough, even on 80 meters. It can be supported a few feet up or it can be laid directly on the ground or even on a roof. It works much better than a ground rod, which may be connecteded to the counterpoise but should be thought of only as a lightning ground. A coax feedline can be connected to a tap near the grounded end of the coil and the tap adjusted for best SWR, or even better, inductive link coupling can be used.

The horizontal pattern of a bobtail is a bidirectional figure 8 broadside to the plane of the antenna. The two lobes are rather narrow- only about 50°. It has a respectable gain of about 5dB over a

single vertical. The half square has a beamwidth of about 60° and a gain of about 4dB. *Apparent* gain for DX (over single verticals or low horizontal antennas) will seem to be greater. Both antennas have good side rejection that helps hear the DX better. The bobtail has a cleaner pattern that better rejects close-in noise and signals (some of your competition in the pileups.) The vertical angle of radiation is low, in the 20° to 30° range, depending on the conductivity of the local earth.

Note that the bobtail is primarily a low bands antenna useful on 30 meters and below. 30 is a transitional band where vertical and horizontal antennas both do well for DXing. For 20 meters and up, almost any horizontal antenna at reasonable height will usually do better than a vertical (unless your location happens to be over salt water.) I did build a 20 meter bobtail once in an emergency when the yagi atop my tower had failed and there was a DXpedition to a rare country coming up. The center tail was voltage-fed, with the feedpoint on my roof at about 17 feet. The stations I worked reported it had a potent signal. There have been favorable reports in the literature as well. Perhaps these antennas are underrated and underappreciated on the high bands. I doubt it is worth bothering with one for 20 meters and above, however, if you are able to put up a tower and yagi.

New bobtail owners often report great success with their antenna. It is designed for DXing, not for close-in work where low, horizontally polarized antennas are more appropriate. Mounted at heights of about 25-30 feet for 30 meters and 35-40 feet for 40 meters, these simple antennas deliver DX performance that rivals horizontal antennas in the 100+ foot class. Furthermore, at these heights it is practical to use trees or simple wood or metal masts to support the wires. Metal tubing or pipe masts can also double as the vertical elements. If you have tall trees as I do, 80 meters is not out of the question. Mounted at 70 feet, the tails of a wire 80m half square will be a few feet off the ground. I have used both a 40 meter bobtail and 80 meter half squares and was very pleased with them. I would not hesitate to build some again, under the right circumstances. They are a hard-to-beat combination of DX punch and simplicity.

Elevated Half Square

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 2/25/2000)

Elevated Half Square

The elevated half square antenna is a very simple antenna that can be constructed from common materials yet gives significant improvement over a dipole at the same elevation. Ground mounted versions of this antenna are commonly used in amateur radio for 75/80 and 160 meter bands. The elevated version described here provides even greater performance. The Half Square antenna is bi-directional, has a low angles of radiation, is self supporting, is easily erected, and can be rotated with a TV antenna rotator. The Elevated Half Square antenna achieves its high level of performance by not radiating power at high angles of elevation where is leaks through the ionosphere and by having its high current regions near the top of the antenna. Figures 1 and 2 show the radiation patterns in azimuth and elevation.

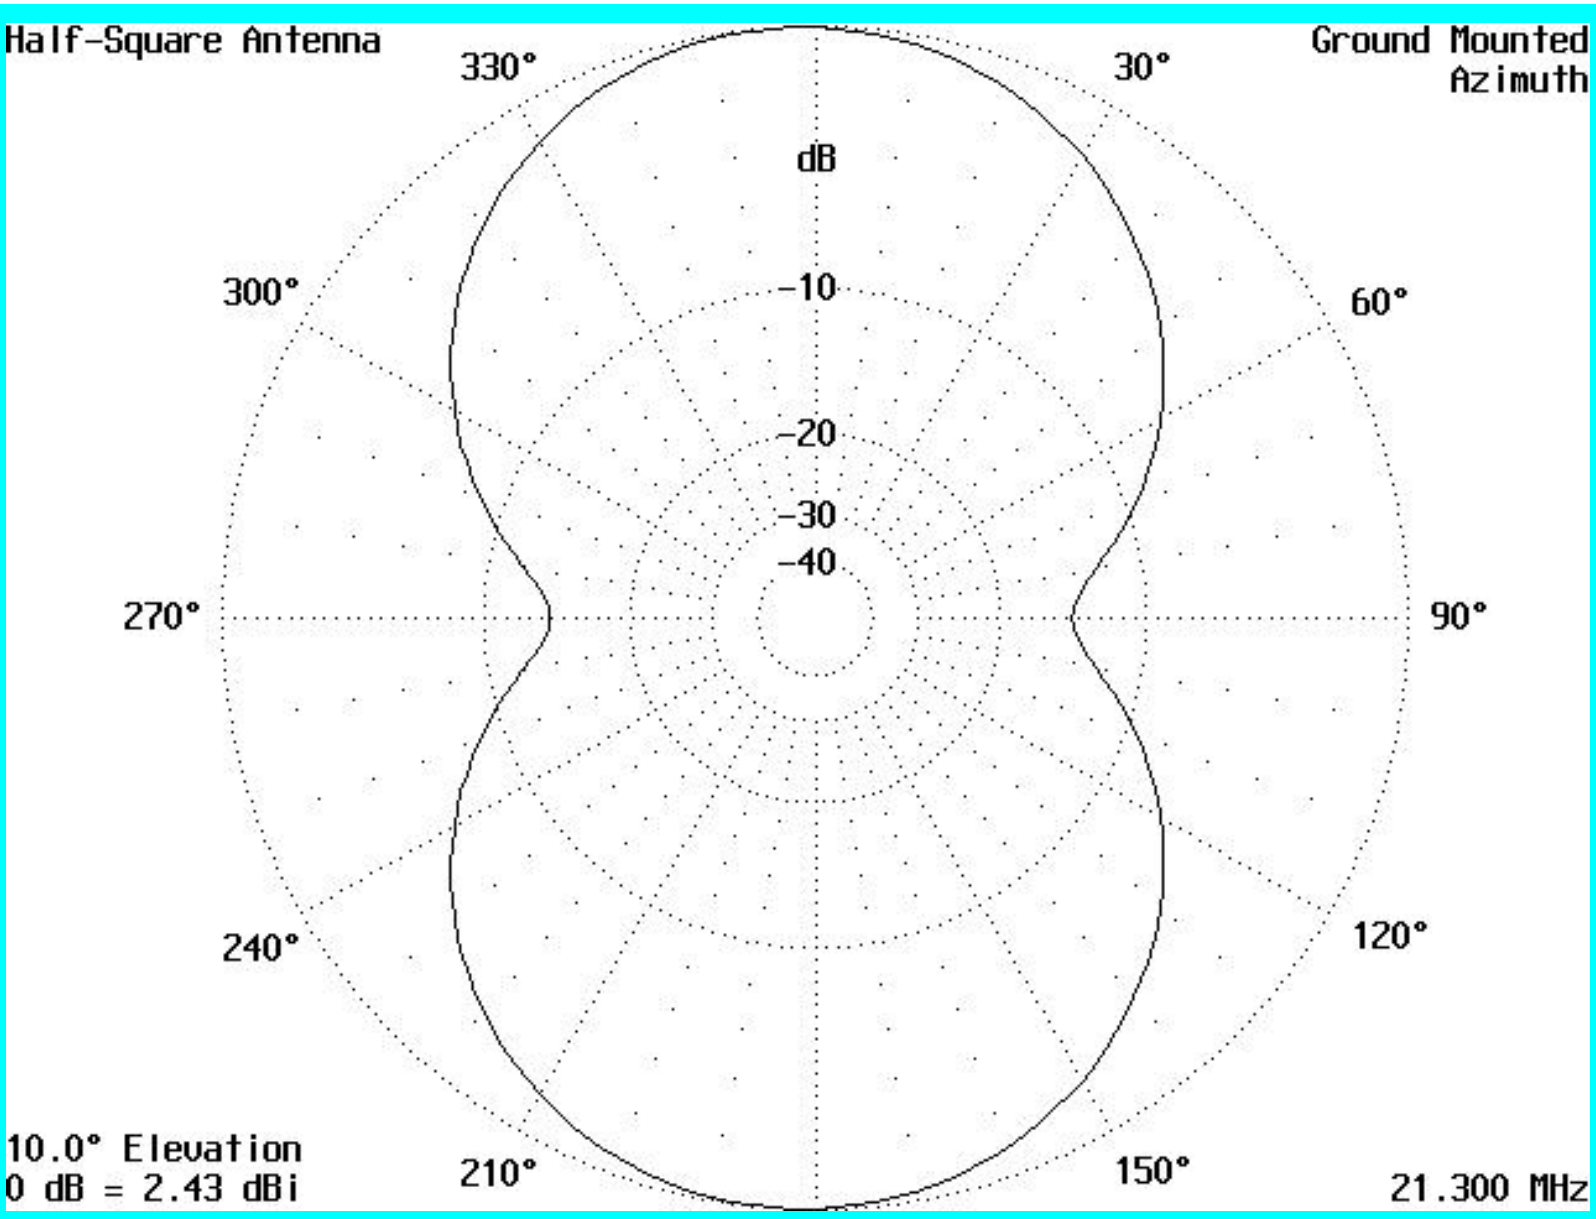

Figure 1

Azimuth Pattern at 10 Degrees Elevation

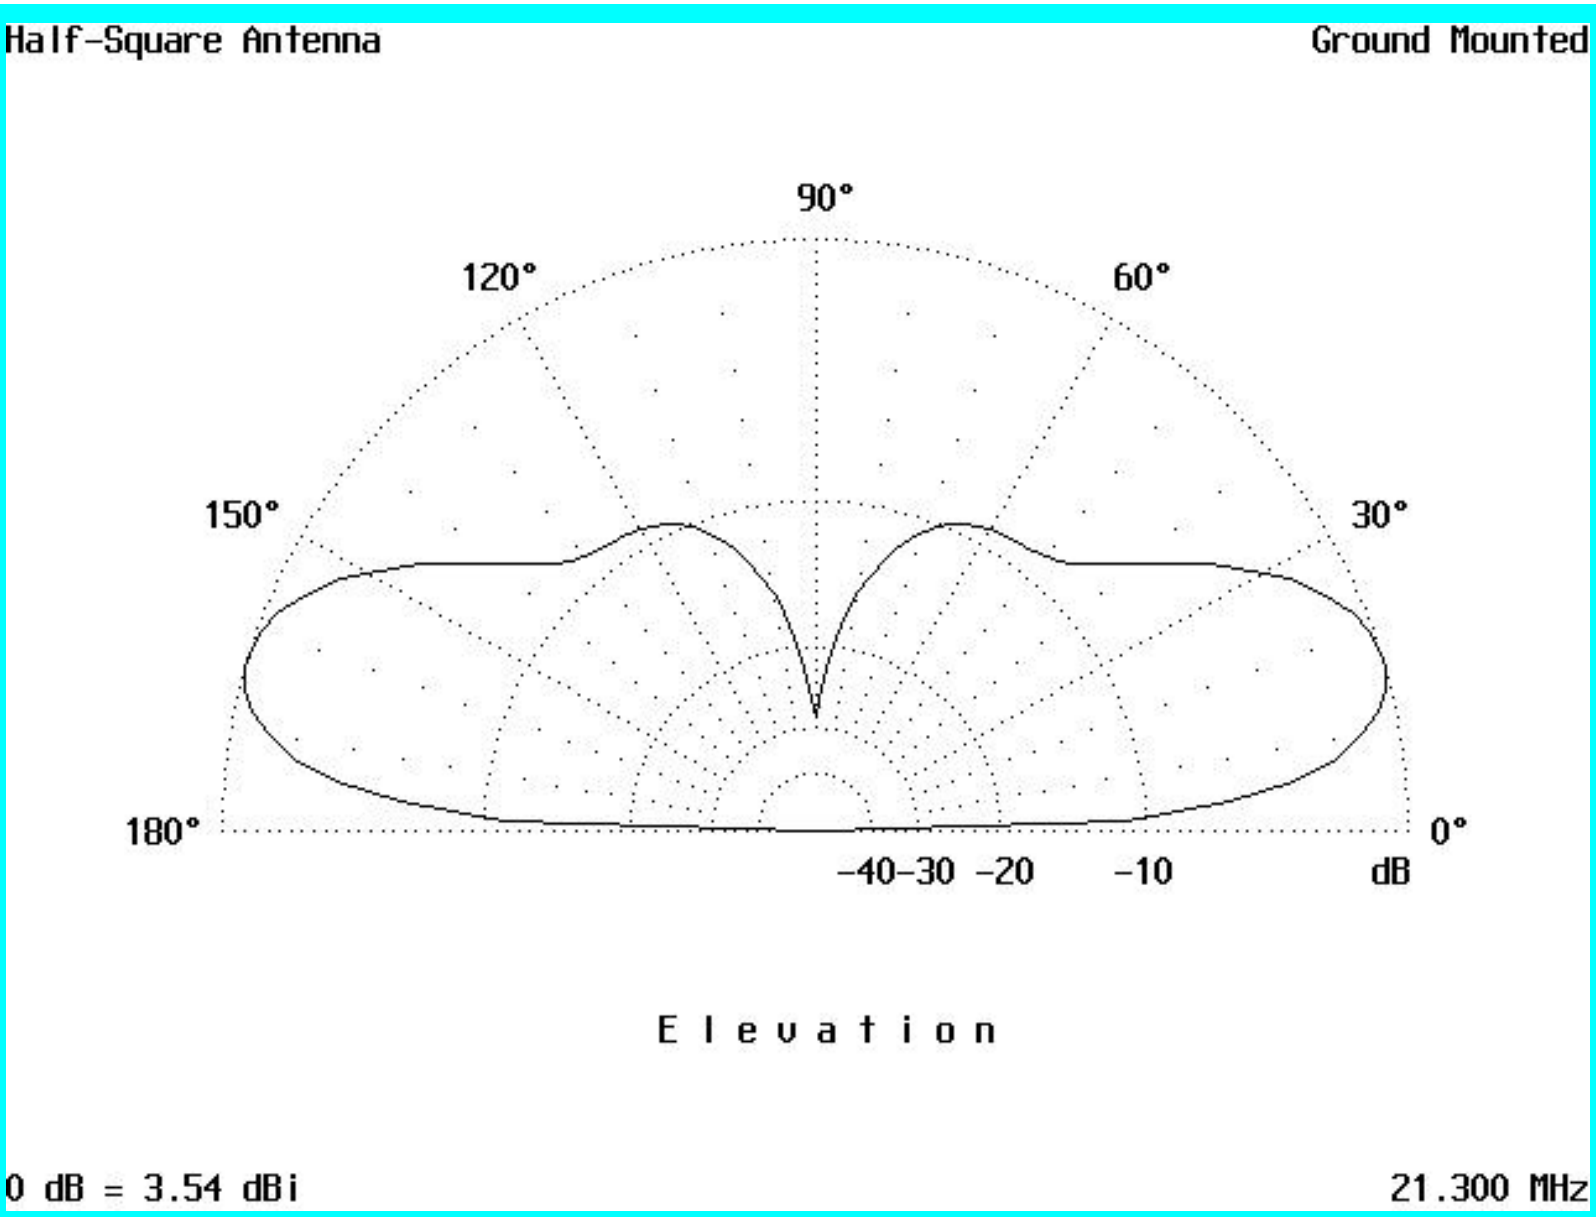

Figure 2

Elevation Pattern for the Elevated Half Square Antenna at 0 Degrees Azimuth

This is one of the best DX antennas you can find unless you just happen to be able to put a 3 element Yagi at 90 to 120 feet in the air. Note that high angle radiation (local QRM) is attenuated by as much as 10 dB, so if you are in the central US, coastal stations will be attenuated, and the Europeans and western Pacific regions will be given 3.54 dBi gain. Forget about using this antenna for local work.

The pictures below show two ways to construct this antenna. There is the neat and light version made with fiberglass structures and the cheap, heavy and ugly PVC version. So take your pick.

Figure 3

Fiberglass Version of the Elevated Half Square Showing Structure and Feed

Figure 4

PVC Version of the Elevated Half Square Showing the Structure

There are a number of tricks to the design of the Elevated Half Square, and our Guide to the Elevated Half Square gives the complete details of the corrections for propagation velocity in dielectric tubes, methods of decoupling the feed line from the radiating structure, the construction of light weight structures to support the antenna and a complete parts list for both fiberglass and PVC structures. These topics are too extensive to cover on a web site, so this guide is listed in our Products Page.

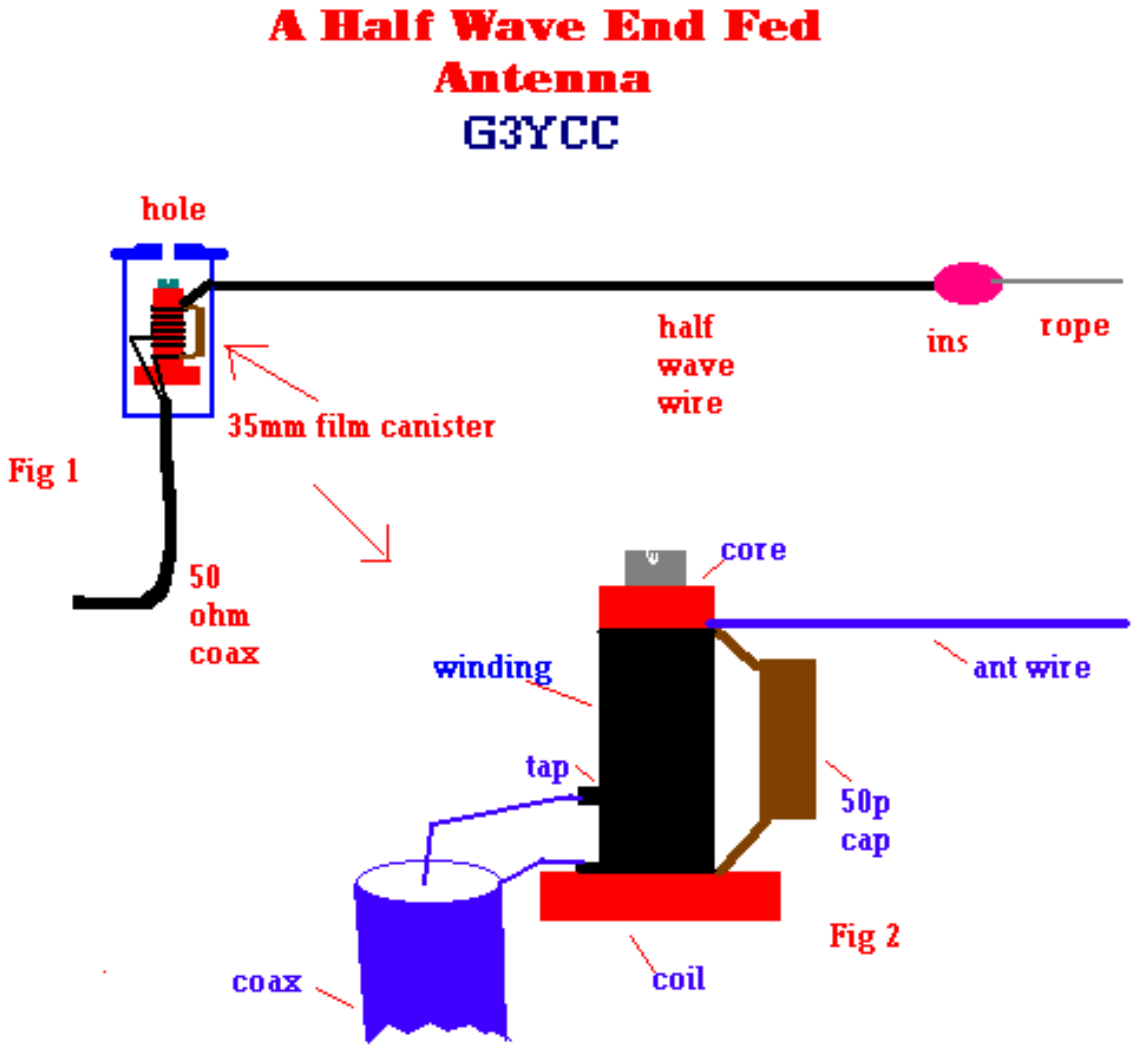
An End Fed Half Wave Antenna

Useful for portable work



This end fed type of antenna was marketted in the UK and is a useful system for the portable set-up. Being a half wave, no radials or counterpose wires are needed.

As the impedance will be high at the end of the wire, some form of matching unit is needed and a simple parallel tuned circuit housed in a plastic film container is fine (figure 1). A hole in the container allows for tuning, by adjusting the ferrite core in the coil for maximum reading on a field strength meter nearby.

The inner of the coax goes to a tap about 1/4 of the way from the earthy end of the winding, to which the braid of the coax is soldered.

As a rough guide, a capacitor of 50pf across a winding of say 30 turns is a starting point for 40m. Some experimenting with turns and tapping point is necessary. The coil former used was about 1/4 inches in diameter as found in old IF transformers.

The antenna wire (1/2 wave long) is soldered to the top of the coil as shown in figure 2.

The drawings illustrate the set up, I hope.

For portable use, throw the wire into a tree or whatever, using thin cord or rope onto the insulator (figure 1), tune for best filed strength reading and off you go!

Try it - it works!

Want to work two bands? Use a slightly bigger container with two tuned circuits which have some sort of terminal each, to which one of their respective wires can be connected.

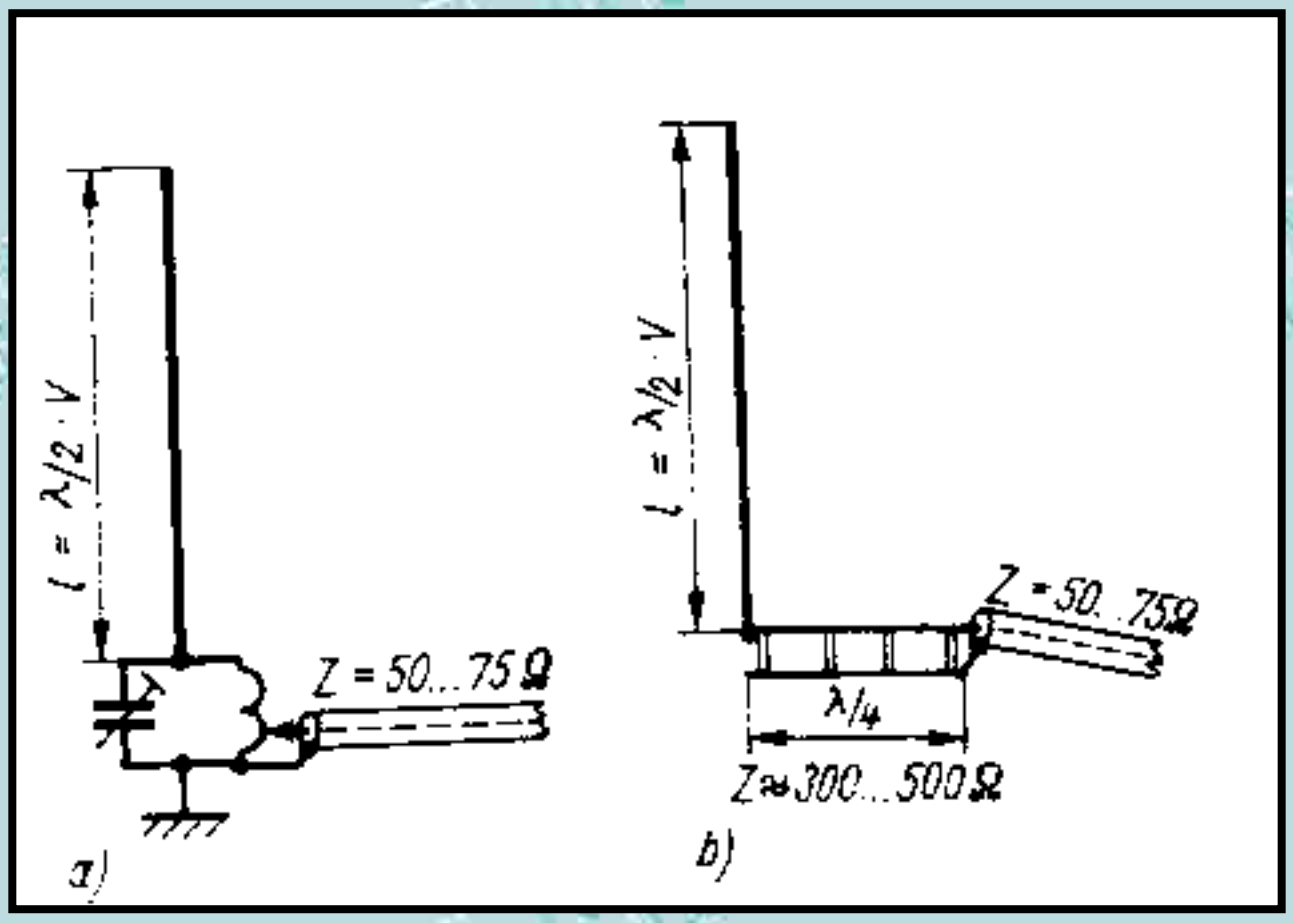
Rough lengths of half wave wires:

80m - 132 feet, 40m - 66 feet, 20m - 33 feet.

Enjoy your portable working and how about telling me what you thought of the above idea - when you have used it?

Back to the first page

End fed-Halfe-wave antenna



This type of antenna has same performance as a dipole, but requires only one single mounting point, which makes this concept ideal for portabel stations. Actual bandwith is more than 2 Mhz with VSWR better than 1:1,7 !
For 14 Mhz you need approx. 10 meters of wire, abt. 4,7m coax-cable 50Ohm or 300Ohm with a connector about 30cm from the shortend end. No tuner is required. We used this antenna on all our holiday - Dxpeditions : 8Q7BZ and in SV8, EA8, SV9, ...

Build this antenna system in less than 30 minutes and have fun and good DX.

Here are the building instructions on the 2 meter square loop.

Credit is given to K0FF for most of this design.

We have added modifications that proved useful in the design.

The mods will be presented under modifications in the design instructions. Special thanks to **W6ARQ** and, **KC5BBP** for thier input on this Antenna.

2 Meter Square Dipole by K0FF

Here is the parts list and dim. sheet for the 2 meter square dipole, made of copper water pipe.

Parts List

1/2 Inch Copper Water Pipe
Long Sides 9 1/2 inches
Open Ends 3 1/4
2 Short Pieces on each side of "T" 4 7/16

4-90 Degree Elbows
2-Copper Caps
1 Copper Tee
Brass Plate for SO239
Gama Tube 4 3/4 of 3/8 Copper Tubing
RG8 is 5 1/2 iches long
Copper or Brass Gama Tube Bracket
SO239

Modification Parts (DO NOT USE STAINLESS STEEL)

6 Brass Nuts-Note Any size
2 Brass Screws at least 1 1/2 long

Instructions The mounting array to be affixed to a standard mobile
mast that presents 3/8 X 24 threads.
Run coaxial cable right to the antenna and connect it to the built in SO-239.
Their are two adjusments on the Antenna to match the coax Imp.
Adjust the Gamma Match Tube for Lowest SWR, then the tuneable stubs move in or out for lower swr.
Do not use Stainless Steel Screws, Soldering them to the end caps is almost impossible.

The 2 meter square loop is a folded Dipole around itself.
The shape is 11" X 11".

Solder the antenna parts together using 90 degree elbows at the corner open ends and mind the gap.
All measurements are critical. The brass plate to hold them form an "L" 1-3/4" tall with a 1/2" lip.
A 5/8" hole is provided 1-1/4 inch from the bend, and attached using stainless steel or brass hardware.
Two small holes are drilled in the lip and mounted to the copper TEE with #6 self taping screws.
Solder the 5 1/2 inch piece of RG8 to the SO-239.
When using the RG8 discard the outer shield and use only the Dielectric. Slip the RG8 inside the 4-3/4 Gamma Tube.
The Gamma bracket should be at least 1 1/2" long brass or copper.
Secure with stainless steel screws right before the 90 degree elbow.
Either side doesn't matter.
The Gap between the Open Ends is 2-3/8".
Adjustments to the gap in or out can be made with the modification
of installing the brass screws on the end caps.

The Antenna is more or less Omni Directional and horizontally
polarized.
It presents a high takeoff angle and is intended for use in the 144.200mhz area.
The Antenna can handle 100 Watts and has proved useful in working some satellites such as AO-27.
The Antenna provides excellant SSB results while mobile and have talked with other stations 200 miles with simularly equipped Antennas.

HOME BREW 6M HALO

Built for Mobile Use

Jonesy
W3DHJ

The Jones version of the Lawn Chair 6M Halo as viewed thru the rear window of the mobile.
Ain't that just the sexiest thing you've ever seen on the outside of a vehicle?

I read the article: Six Meters from Your Easy Chair by Dick Stroud, W9SR in the January, 2002 QST with some interest. Dick described a 6M Halo antenna that was built from the aluminum frame of a 'generic' lawn chair. It is always a pleasure to peer into the working mind of another homebrewer and scrounger.

However, I put the article and the idea aside, because I had no interest in a 6M *vertical* antenna for this QTH (nor, for mobile operation, either.) And, that was how the antenna was 'portrayed' in the article. However, later in the Summer of 2002, I became Very Interested in improving my meager 6M mobile operation. Heretofore, I had been running 10W out of an ancient IC-551 into a 2M 5/8 wavelength whip -- which 'worked' well as a base-loaded 6M 1/4 wave vertical -- but, probably radiated like crap. I knew deep in my heart that it was not 'fair' to the other op to have to try to copy my peanut whistle.

Harmonic Convergence: It came to pass that one day I was

A: Pondering a better antenna for 6M mobile.

B: Thinking of a better transceiver for 6M mobile.

C: Feeling that the stock market hadn't really hurt me **that**much.

D: Reading the email copy of the "AURORA REPEATER ASSOCIATION SWAPLIST"

There was a used IC-706II listed for sale. Whoa!, I thought. That'll give me 100W on 6M -- it'll do mobile Quite Nicely -- and, to boot, I could dabble in HF mobile. I whipped out my checkbook and became the proud owner of the newest rig in my collection. (I had been using 2 TS-520's, an IC-551, and an IC-251A. I am soooo Last Century.)

While waiting for the UPS Man to drop off my new rig, I had time to ponder just exactly how I was going to 'solve' the 6M mobile antenna problem. I looked at several of the 'commercial' 6M halos that are available. They all looked FB, and the prices were not out of line. But, the Olde Home Brewer and Scrounger was already feeling guilty for **buying** a transceiver. So, I toyed some with the idea of homebrewing the antenna. I played mental games with a few ideas, and eventually circled back to the January, 2002 QST article. Hmmmmmm.... I wondered if I couldn't scratch out something along those lines that would both: radiate horizontally and do 85 MPH?

Well, I think I succeeded. And that explains this website. On the following web pages I hope to explain my thinking, design, material selection, construction techniques, and (yes) mistakes.

These web pages about my homebrew construction of a
Six Meter Mobile Halo are dedicated to the first Jonesy, W3DHJ.
Nearly all my homebrewing and scrounging skills were taught to me by my dad.
I'd like to think he'd be proud of this antenna.

Constructive comments and/or discussions:

6M Halo - Project Beginnings.

HAM UNIVERSE

THE HENTENNA RE-VISITED

The Hentenna was developed by Japanese 6 Meter Hams, JE1DEU / JH1FCZ/ JH1YST in the 1970's and can be designed and built for hf thru uhf and possibly beyond!

After much experimentation, finally, the antenna was developed with good performance, however, it was difficult to explain why the performance was so good, or how it is worked basically at that time. So it was named Hentenna , "Hen" means strange in Japanese.

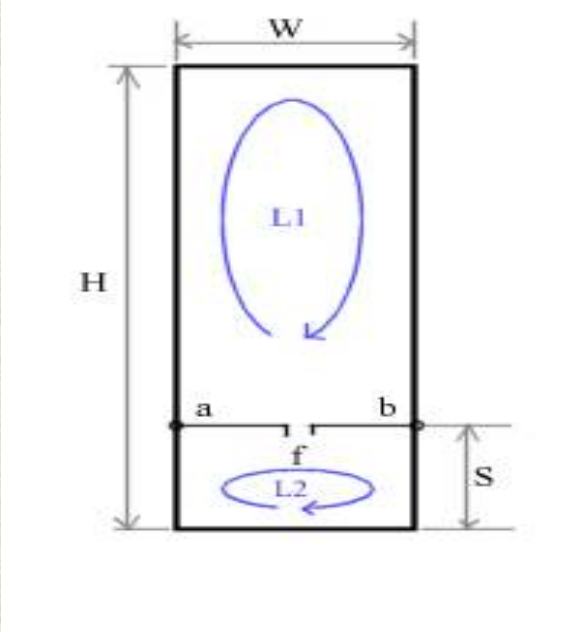
The antenna has good performance and many advantages and it has become very popular in Japan. Many JA stations make it and enjoy it at home or in the field. Some Japanese 6m beacon stations are using the Hentenna antenna.

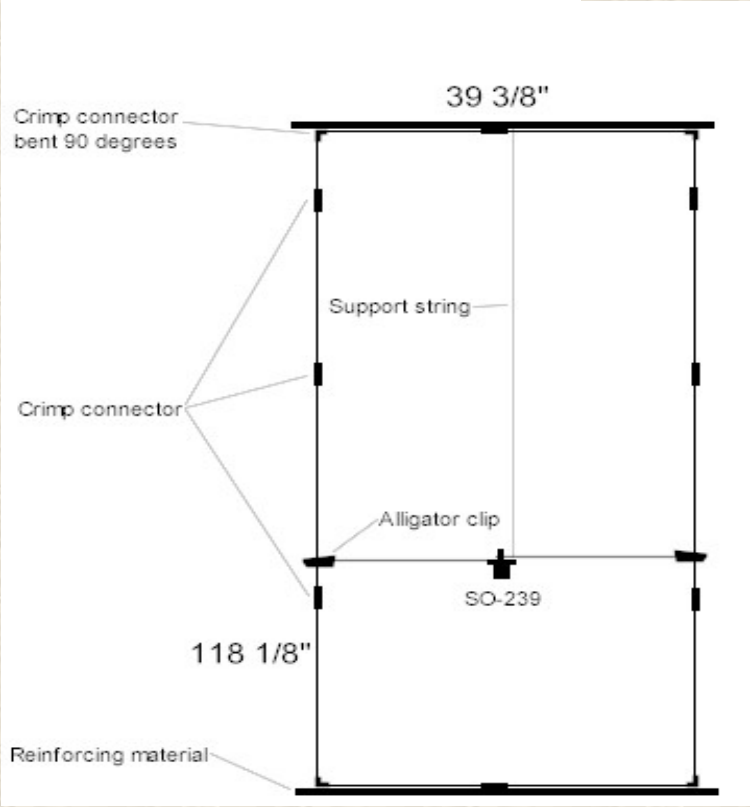
HERE ARE SOME GOOD POINTS FOR THE HENTENNA

1. Good performance
2.5-3 dBd gain
Low angle radiation
*** Total performance is equivalent to 2-3 element Yagi-uda antenna,**
Wide band width
2. Easy to make
It is possible to adjust impedance and SWR perfectly, This means, not so difficult to make!
No special parts are required. You can use any electrical conductor to make the main rectangle.
Broad adjustment ....wide bandwidth
3. Easy to build up
If you use thin aluminum pipe and thin wire, you can make this antenna for 6m very light.
This means, it is easy to put it in a higher position in the air. You can also use light mast for it.
As this is a vertically long antenna, it is easy to install the antenna on a veranda or small space.
It appears to be a vertical antenna but has mainly Horizontal radiation: This is one of the reasons this antenna is "Hen".(STRANGE)

"The following article has been re-edited for the English language from the Japanese site and we discovered some minor errors so corrections were made."

N4UJW





Japan version

English version

Please note in the above English drawings that the Hentenna is basically a loop fed about 1/10 wavelength from the bottom element with 50 or 75 ohm coax attached to the top element of the bottom loop at the center point.

Hentenna Basics

1. Basically 1 1/3 WL Loop antenna around outer edge of antenna
2. L1 works as 1 loop antenna
3. L2 works as matching section
4. Vertical long rectangle has more gain than ordinary square loop and has less impedance. L2 helps the matching and low angle radiation.
5. 3D pattern is like shell of peanut (maximum gain directions looking at you and away from you) so it will be somewhat bi-directional.

How to Adjust

1. Move the "a" and "b" points to adjust swr. (move in equal amounts)
S1 >S Matching Frequency UP (move towards top to increase resonant frequency)
S1 <S (move towards bottom to decrease resonant frequency.

2. SWR may be higher than 1:1.5 at first so move matching points "a" and "b" in small increments up or down the loop until lowest swr is obtained and secure at these points with whatever method you choose depending on your construction materials.

Putting it in the air and on the air

The construction materials you use for the loop will determine how the antenna is supported. It will weigh more if made from aluminum or copper tube and will require a non conductive support mast or structure to attach it even if made from wire. Nylon cord or rope or other non conductive material can be used for support at the four corners.
A length of pvc pipe can be used as support for the top, bottom and coax feed point elements with the side wires strung between them or can be used to completly enclose the wire. Use your own design. Most JA hams use wire construction.
The final configeration in the air should be as close to a vertical rectangle as possible.
This antenna is horizontally polarized.....lay it on it's side for vertical polarity!
Experiment with your favorite support and try to keep conductor size under 1/4 inch.
See the Japan site link below for more info.

6 Meter Version

THE MATH

Calculating the lengths for the Hentenna is simple and straightforward and can be used for HF THRU UHF and possibly beyond.
Just start with 1 meter = 39.36 inches
1 inch = 2.54 cm
1 wavelength = 6 meters = 6 x 39.36 = 236.16 inches

1/2 wavelength per side = 3 x 39.36 =118.08 inches
1/6 wavelength = 6/6 =1 wavelength = 39.36 inches
1/10 wavelength = 236.16 x .1 = 23.61 inches
Some adjustment of lengths may be required for peaking at design frequency. Experiment!

From the above calculations we arrive at the lengths for the Hentenna:

1/2 wavelength sides = 118.08 inches each
1/6 wavelength top, bottom and coax connection element = 39.36 inches
1/10 wavelength matching point = 23.61 inches up from each side of bottom element.

Please note that this is not just a full wave loop. the total length around the outside of it is 314.88 inches which comes out to be 1 1/3 wavelength long. AT first glance the above measurements make this antenna to be HUGE! IT IS NOT. It is only about 9.8 feet tall by 3.28 feet wide! A scaled down Hentenna for 2 meters would be 1/3 it's size or about 39 inches by 13 inches!

EXPERIMENT! EXPERIMENT!

editors comments:

" I personally have not built this antenna YET and cannot warrenty it's performance....make sure you use low power when adjusting the swr and send me any comments you desire about this "strange" Hentenna. IF YOU HAVE EXPERIENCE WITH THIS ANTENNA AND HAVE ANYTHING TO ADD, PLEASE LET ME KNOW."

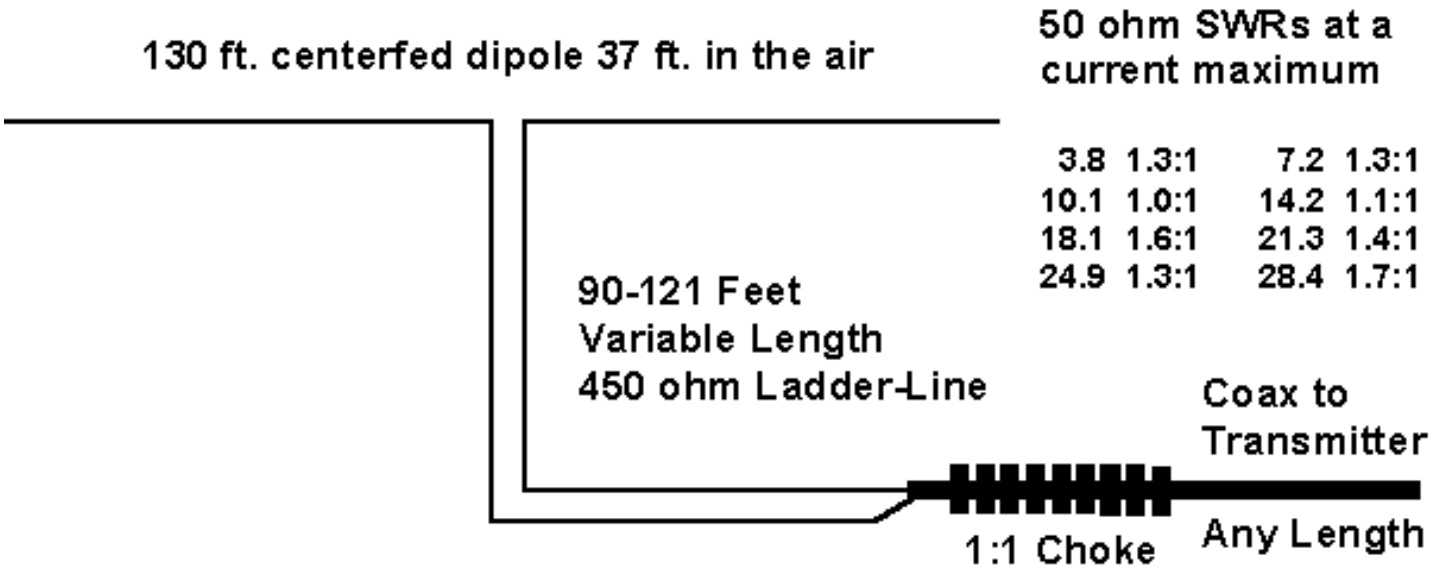
W5DXP's No-Tuner, All-HF-Band, Horizontal, Center-Fed Antenna

No-Tuner All-HF-Band Antenna

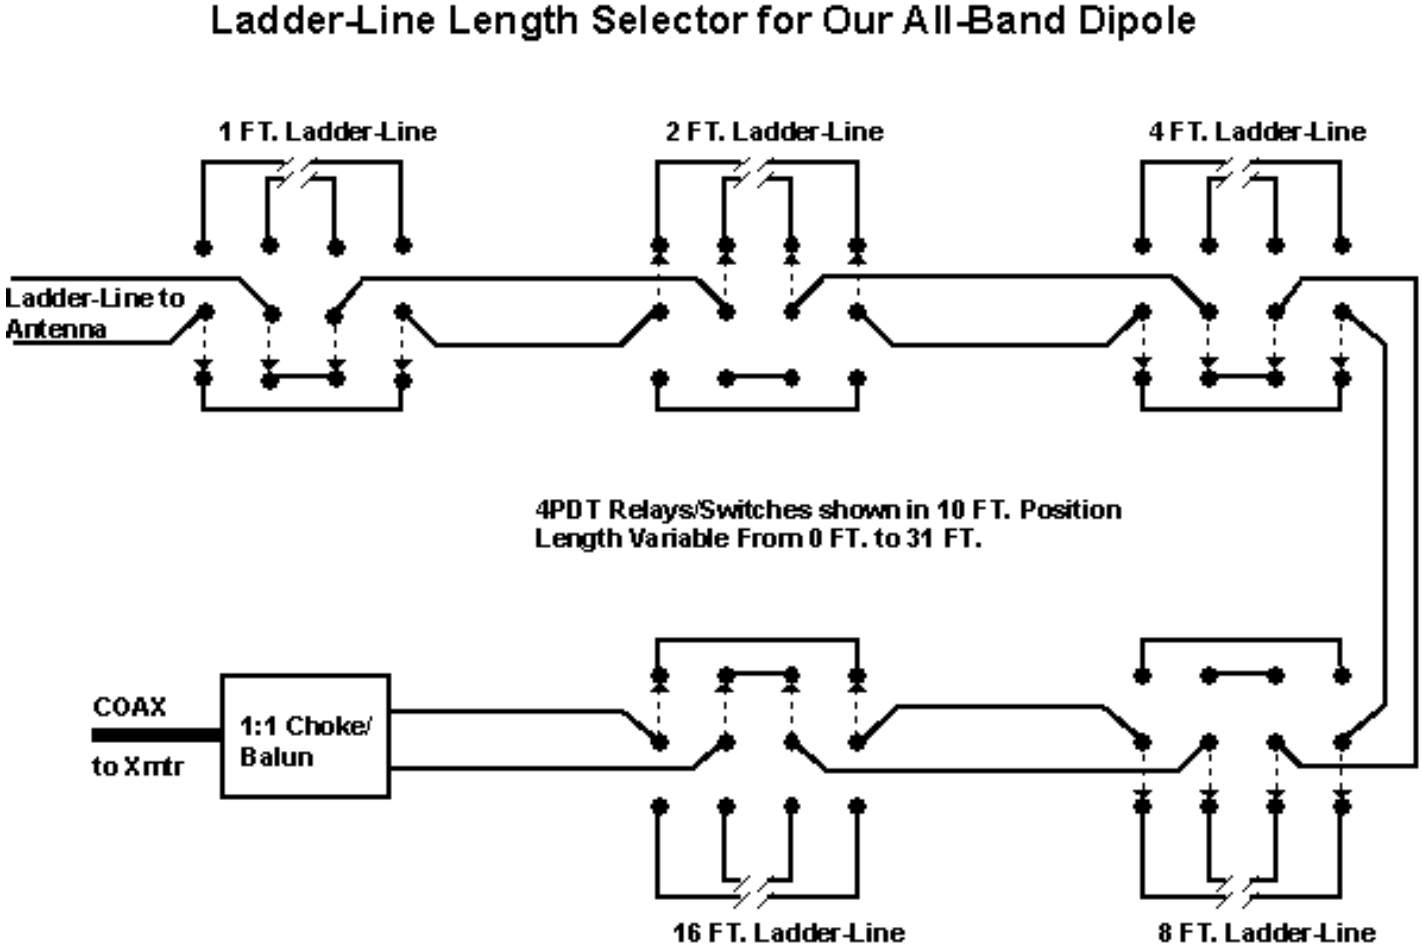


Ferrite beads for the 1:1 choke are available from Amidon Associates
Ten of the FB-77-5621 beads will work for RG-58
Fourteen of the FB-77-1024 beads will work for RG-213
Thirty of the FB-77-6301 beads will work for RG-174 or RG-316 (Teflon)

The No-Tuner, All-HF-Band, Horizontal, Center-Fed Antenna is our old friend, the 80 meter halfwave dipole dressed up a bit. By varying the length of the 450 ohm ladder-line feeding the antenna, we can achieve an SWR of less than 2:1 on all frequencies on all HF bands with the exception of the lowest part of 80m. On 75m, we are feeding the antenna with a half-wavelength of ladder-line. On 40m, we are feeding it with 3/4 wavelength of ladder-line.

No antenna pruning required. My transmission line really does tune my antenna system.

Special thanks to Walt Maxwell, W2DU and Jim Bromley, K7JEB.



The Ladder-Line Length Selector actually does tune the antenna system so no conventional "antenna tuner" is needed - no coils and no capacitors. Switches or relays (remote control) can be used for the switching function and should be sized according to the RF power levels involved. W5DXP presently uses ten DPDT Knife switches attached to a piece of plexiglas mounted in the hamshack window. For portable or backpacking use, the length selector function can be performed simply by 1/2/4/8/16 foot pieces of ladder-line with mating connectors on the end. The proper length of ladder-line is selected to cause resonance in the antenna system.

Here's a table that explains it all. The transmission line always consists of a

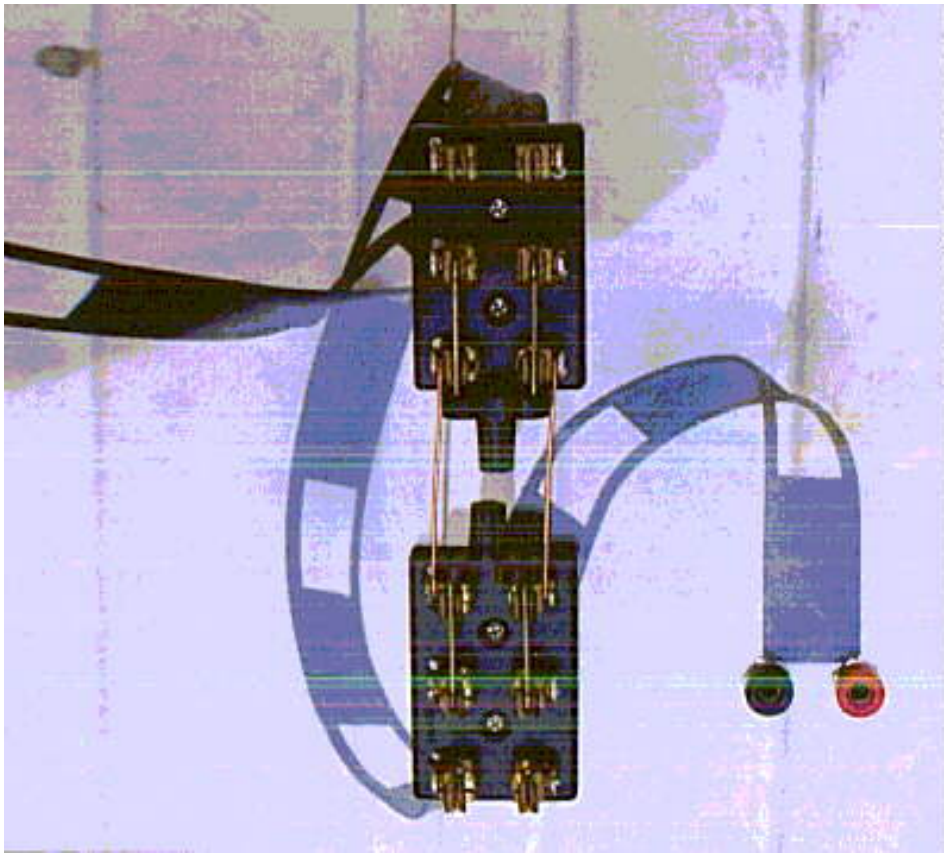
matching section and from zero to six halfwavelengths of ladder-line. The impedance at the antenna is shown along with the 450 ohm SWR and the impedance at the transmitter is shown along with the 50 ohm SWR, i.e. the SWR seen by the transmitter.

..Freq-MHz..	..T-line length = Matching Section + 1/2WL's..	..Impedance at XMTR..	..50 ohm SWR..	..Impedance at Antenna..	..450 ohm SWR..
3.8	109.5' = 109.5' + 0	69 ohms	1.4:1	71+j84	6.6:1
7.2	92.0' = 30.5' + 1x61.5'	40 ohms	1.2:1	4939-j716	11.2:1
10.125	99.4' = 12.0' + 2x43.7'	50 ohms	1.0:1	116-j510	9.1:1
14.2	110.2" = 16.6' + 3x31.2'	53 ohms	1.1:1	2120+j1886	8.5:1
18.14	101.9' = 4.3' + 4x24.4'	81 ohms	1.6:1	111-j267	5.5:1
21.3	94.8' = 11.6' + 4x20.8'	70 ohms	1.4:1	1210+j1378	6.4:1
24.95	94.1' = 5.35' + 5x17.75'	65 ohms	1.3:1	186-j593	6.9:1
28.4	102.8' = 9.2' + 6x15.6'	87 ohms	1.7:1	721+j1009	5.2:1

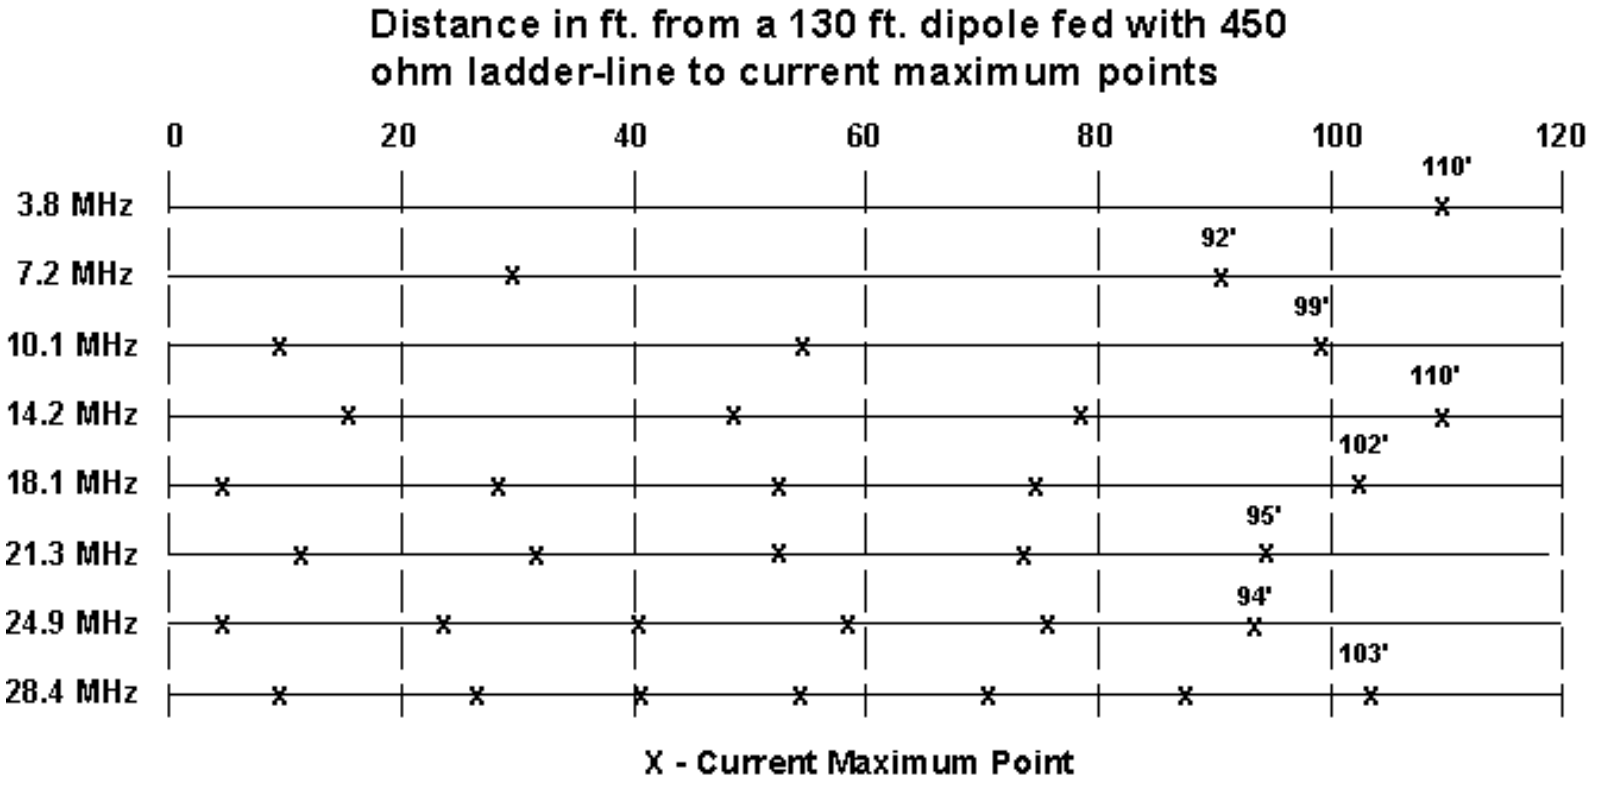
75M Graphs 40M Graphs 30M Graphs 20M Graphs 17M Graphs 15M Graphs 12M Graphs 10M Graphs

---

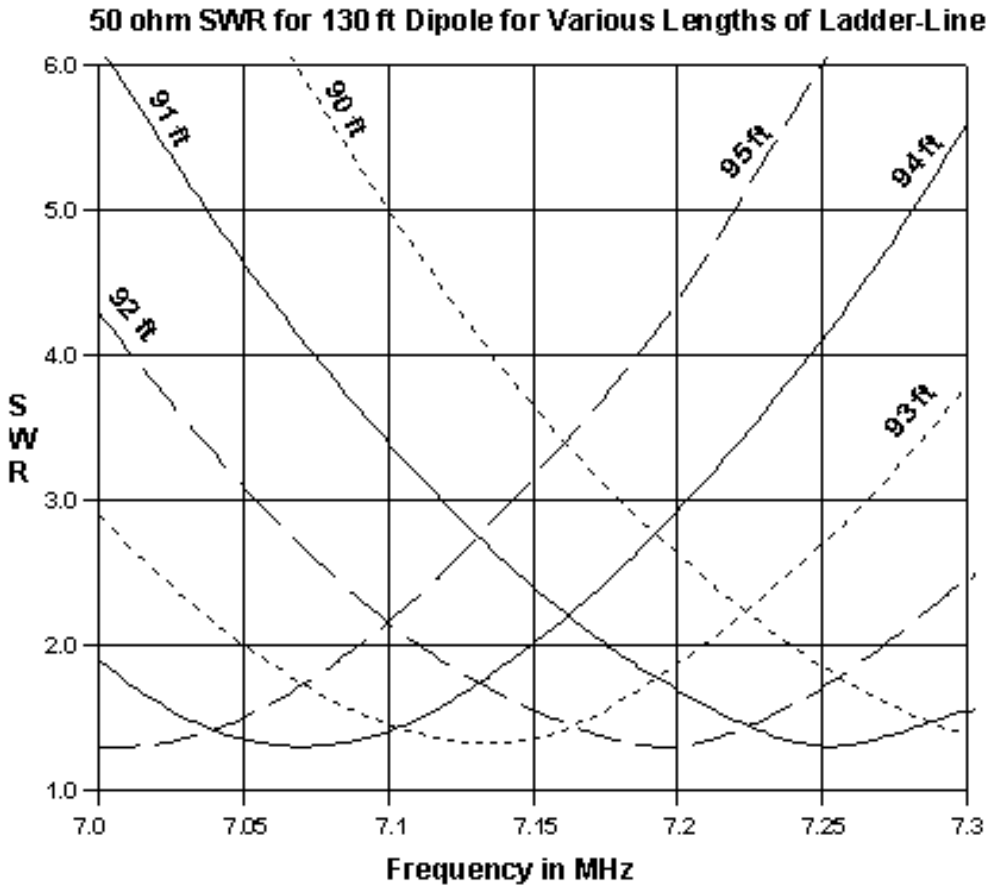
Here are the ten DPDT switches mounted on a piece of plexiglas that mounts in W5DXP's hamshack window. It shows the ten DPDT switches with the one foot, two feet, and four feet loops installed. The eight feet and 16 feet loops are not installed yet in this picture. RF flow is right to left from banana socket set to banana socket set. When installed in the hamshack window, the switches are on the inside and the loops of ladder-line are on the outside.



Here's a close up view of the one foot section. The RF flow is right to left into the banana sockets. The switches are shown in the shorted position, i.e. the one foot loop is floating completely out of the circuit to avoid capacitive effects. The bare copper wires in the center are the short. When the switches are thrown into the other position, the one foot loop is inserted into the circuit and the short is completely out of the circuit. This is the cleanest mechanical configuration W5DXP could think of but there might be a better way.

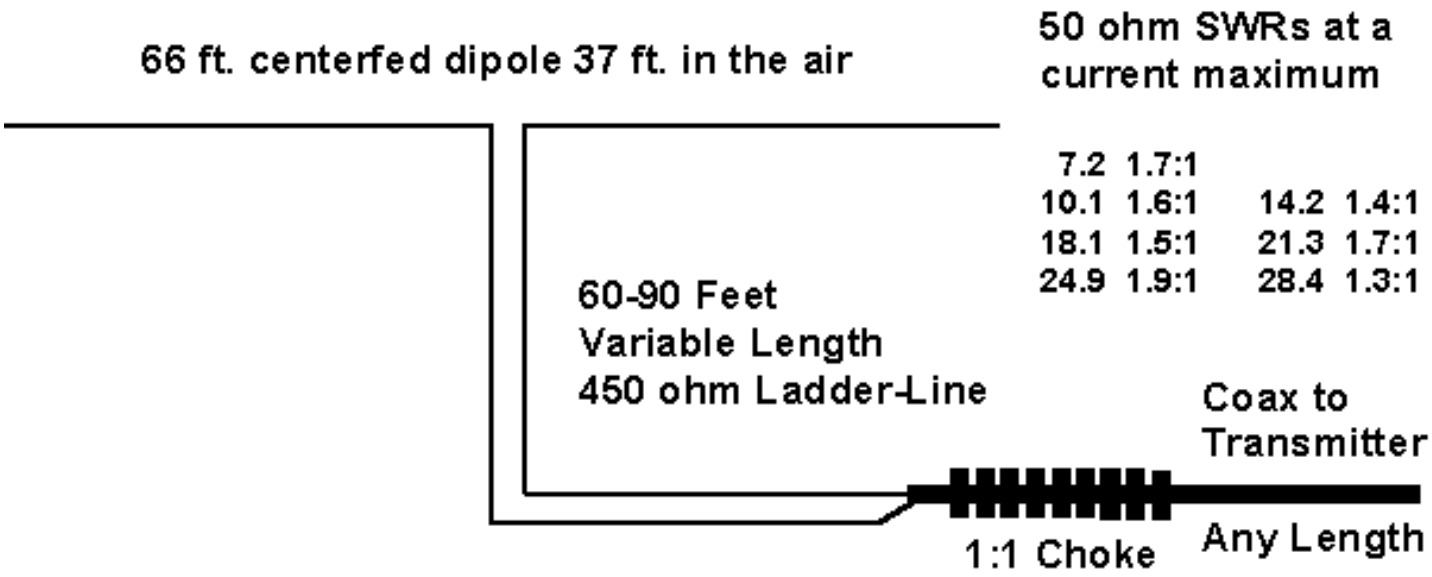


This is a plot of all the current maximum points between the antenna and W5DXP's shack. The transmission line is 90 feet long and the Ladder-Line Length Selector can add in an additional zero to 31 feet for a total of 90 feet to 121 feet. 90 feet matches the antenna on about 7.3 MHz and 121 feet matches the antenna on about 3.6 MHz. The matching points for all the other HF bands lie between these two extremes. Note that if a fixed length of ladder-line needs to be chosen for best results with this antenna, that length should be around 100 ft. which should work with internal autotuners. Caution: Do not expect a similar antenna erected in a different location to exactly match W5DXP's results. The antenna environment has a large effect on the antenna characteristics so W5DXP's results are only approximations when applied to other antenna locations and environments. Mounting this antenna in an inverted-V configuration, for instance, is likely to change the characteristics by an unexpected amount. "450" ohm ladder-line characteristic impedance varies all the way down to 375 ohms for the #14 stranded configuration and velocity factor varies among the different manufacturers and batches of ladder-line.



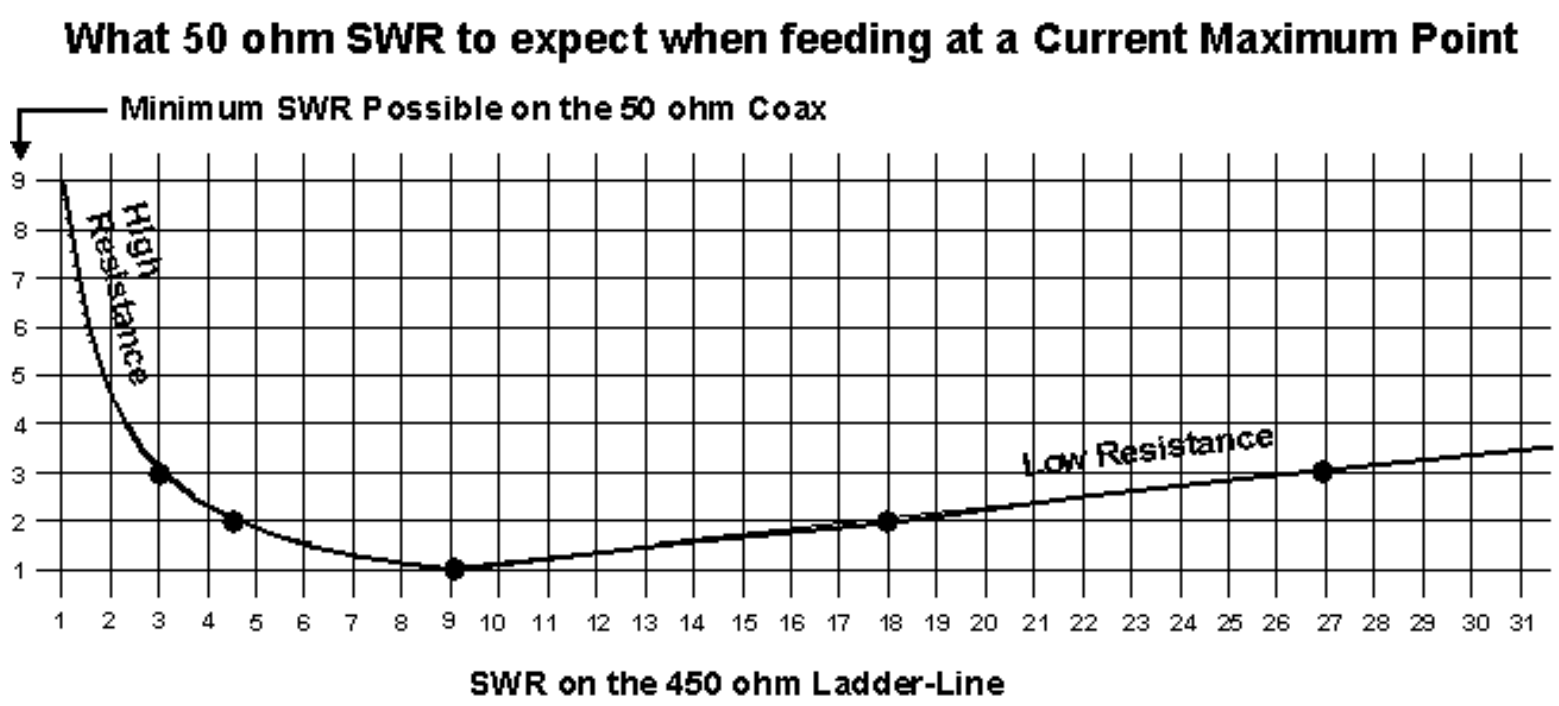
Who says a full-wave dipole is hard to match? **Here's what EZNEC predicts will be the 50 ohm SWR across the 40 meter band for W5DXP's No-Tuner All-HF-Band Antenna given the chart lengths of ladder-line. Similar SWRs occur in similar patterns on the other HF bands.**

No-Tuner "Shorty" HF-Band Antenna



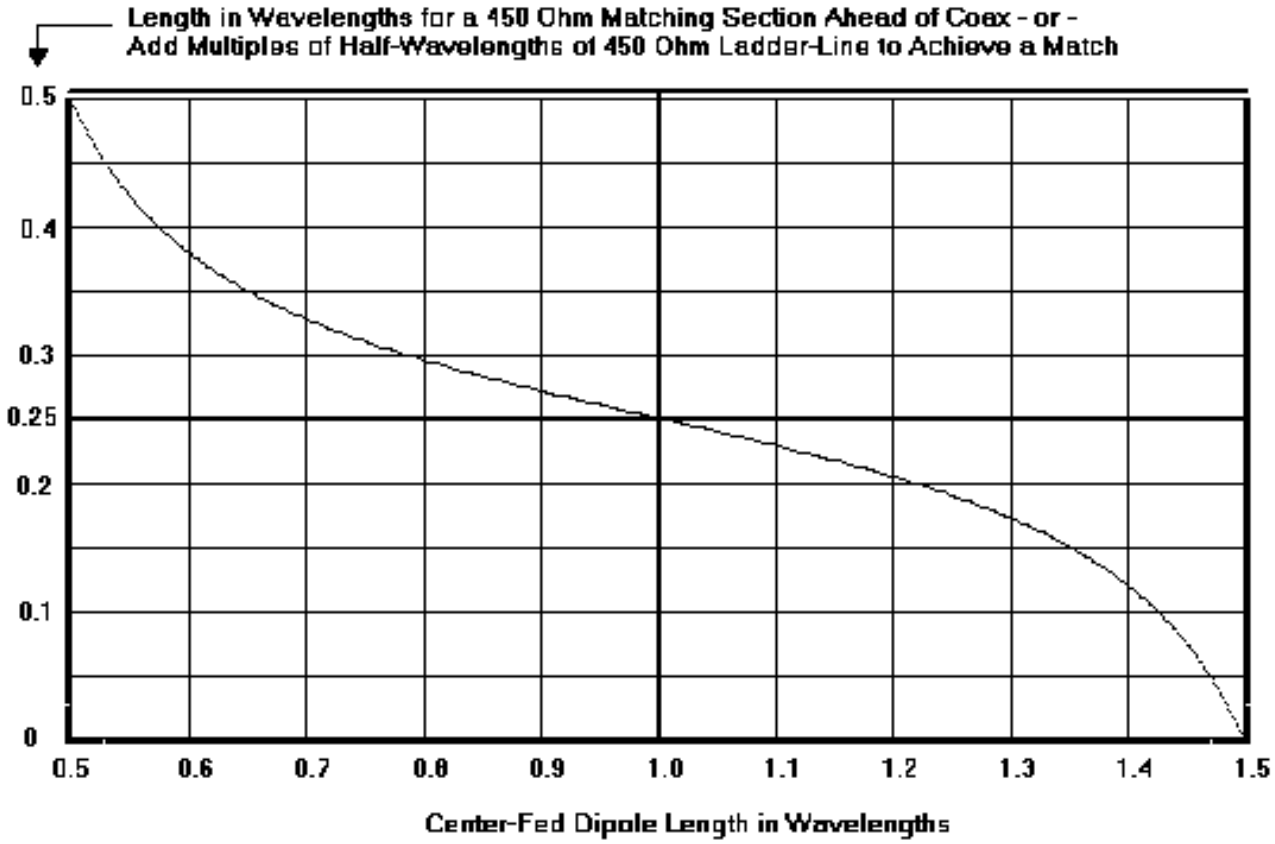
Ferrite beads for the 1:1 choke are available from Amidon Associates
Ten of the FB-77-5621 beads will work for RG-58
Fourteen of the FB-77-1024 beads will work for RG-213
Thirty of the FB-77-6301 beads will work for RG-174 or RG-316 (Teflon)

For those who don't have the space for a 130 foot antenna, here's a "Shorty" version designed to work on all HF ham frequencies above 7 MHz. Like the bigger version, the 50 ohm SWRs predicted by EZNEC are below 2:1 for the bands of interest. This antenna will work on 75 meters at reduced efficiency with a matching network or tuner.



Here is the physics that makes it all possible. Any 450 ohm SWR between 4.5:1 and 18:1 will result in a 50 ohm SWR of less than 2:1 IF the antenna system is fed at a current maximum point. ***Moral: Make your center-fed HF antenna system at least a half- wavelength long at your lowest operating frequency and feed it at a current maximum point on the ladder-line.***

Optimum Length For A Matching Section



This graph shows the optimum length for a matching section when feeding a center-fed horizontal dipole. The bottom of the chart is normalized to wavelengths so it works for most HF frequencies and most popular lengths of center-fed wire dipoles. The left side of the chart indicates the optimum wavelength for a 450 ohm ladder-line matching section for connection to coax or connection to a multiple of half-wavelengths of 450 ohm ladder-line.

Example: Assume a 102 ft dipole on 7.2 MHz. 102/(936/7.2) equals 0.785 wavelengths on 7.2 MHz. Reading the matching section length from the graph yields 0.3 wavelength. A wavelength of 450 ohm ladder-line on 7.2 MHz is 886/7.2= 123 ft. 0.3 times 123 equals 36.9 ft for the 7.2 MHz matching section. Add 123/2 = 61.5 ft if 36.9 ft is too short for a total of 98.4 ft.

The following BASIC program approximates the optimum feedline lengths given the length of a horizontal dipole and the frequency. It works for both 300 ohm and 450 ohm ladder-line by assuming a velocity factor of 0.8 for the 300 ohm and 0.9 for the 450 ohm. The results are only approximations based on EZNEC and must be fine-tuned to perfection in reality. Cut and paste this program to Notepad and store it in the BASIC directory as Imax.bas

Note: This BASIC program only works for *horizontal* dipoles, not for inverted-V's or any other folded antenna.

The Gain of the Axial-Mode Helix Antenna

by Dr. D.T. Emerson, National Radio Astronomy Observatory (NRAO++).
Antenna Compendium Volume 4, pp 64-68, 1995, published by the ARRL.

(Copyright on original article is held by the ARRL)

Summary

The axial-mode helix antenna, first described by Kraus in 1947, is probably the most widely used circularly-polarized antenna, either in space or on the ground. There are conflicting claims for the gain of the antenna; most amateur literature, and even many standard textbooks, quote gains which are far too optimistic. More realistic gain relationships are available now in the professional antenna journals, but are not well known in amateur circles.

This article summarizes probably the most extensive numerical modelling calculations on the helical antenna ever performed. NEC-2 was used to model some 10,000 different helical antennas, systematically changing the physical parameters of the antenna and investigating the effect on gain and feed match. For each calculation, between 600 and 1400 segments were used to model an antenna; with frequent checks on the validity of the calculations. Some 3000 hours of networked Sparc workstation compute cycles were used for the study.

The modelling data were compared with results from the professional antenna literature. Reassuringly, the modelling gives results which are intermediate between published experimental and theoretical work. The maximum possible gains are up to 4 or 5 dB lower than those derived from the original Kraus formula for gain. The maximum gain increases much more slowly with increasing antenna length than the simple Kraus formula would predict.

An empirical expression for the maximum possible gain Gmax of the helical antenna as a function of its length L in wavelengths is:

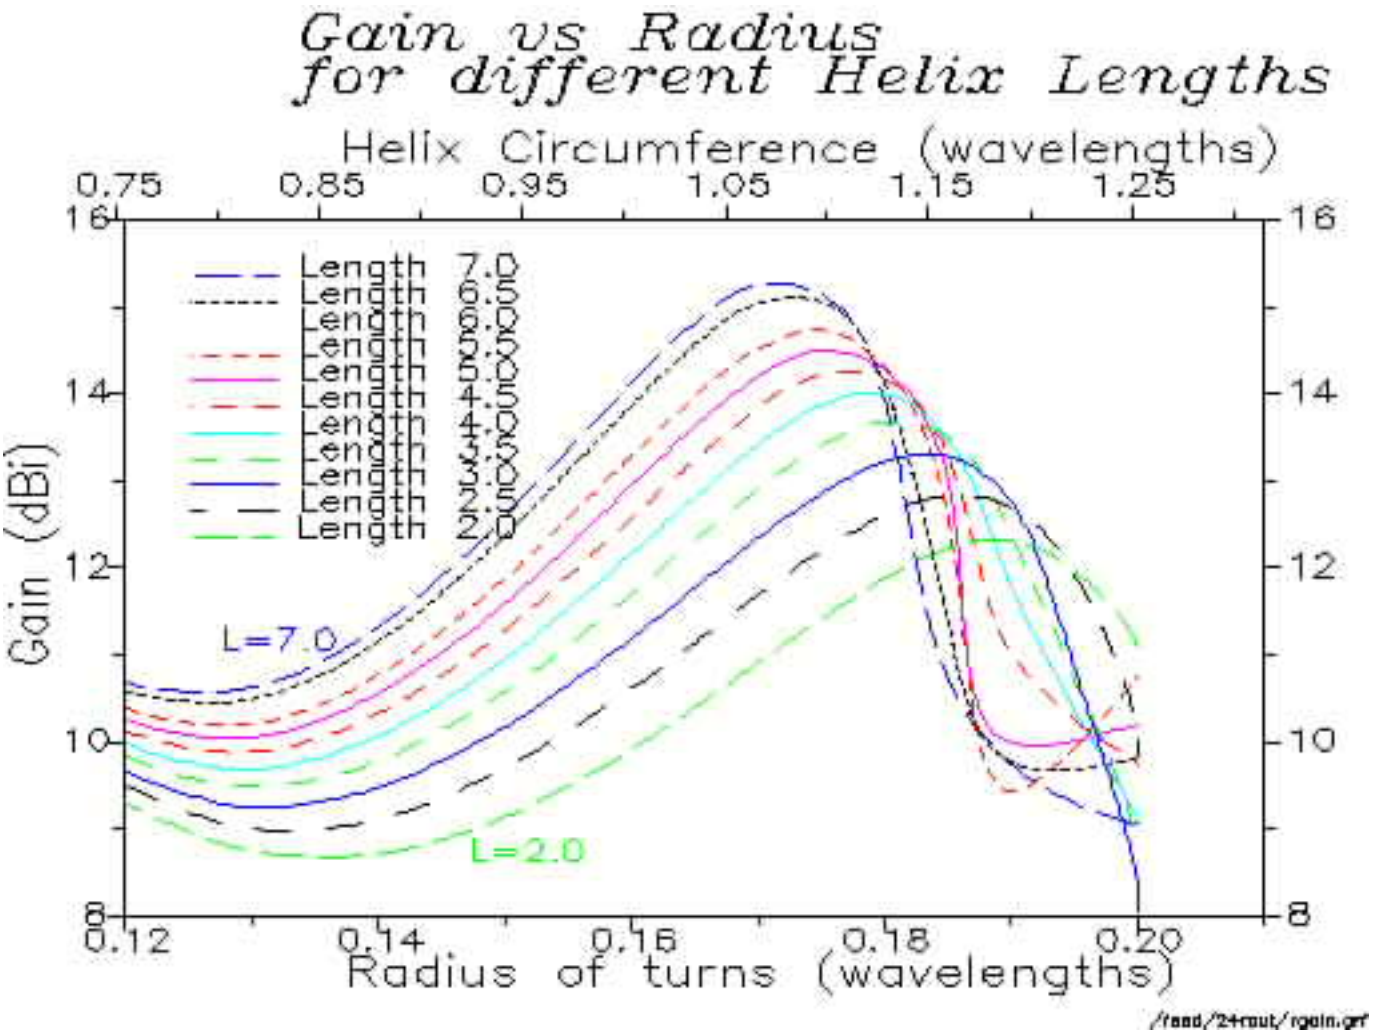
```
Gmax(dB) = 10.25 + 1.22 L - 0.0726 L^2
```

This expression is only valid for lengths L between 2 and 7 wavelengths.

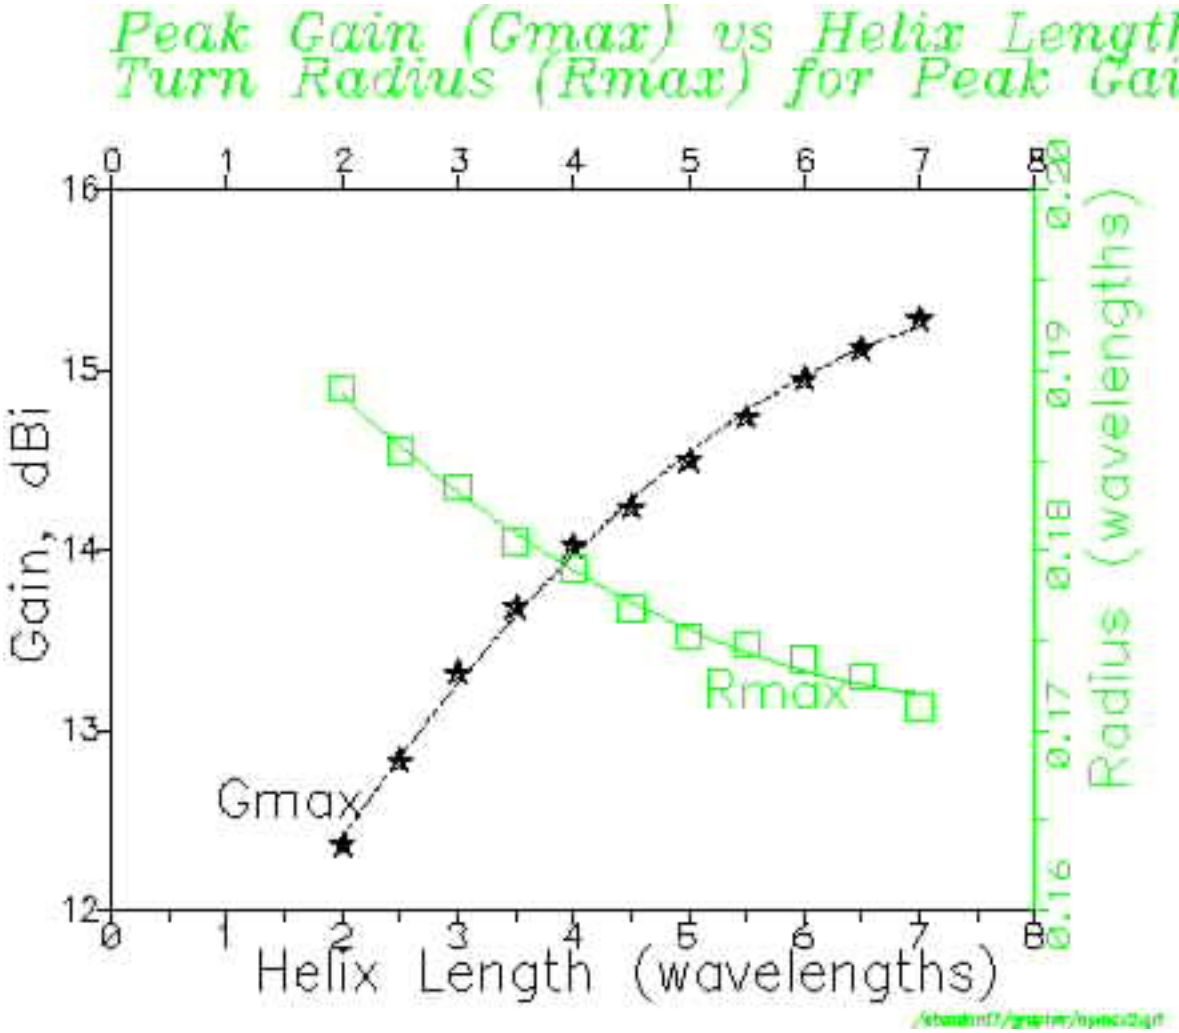
An empirical expression for the turn radius Rmax at which peak gain occurs as a function of length L in wavelengths is:

```
Rmax = 0.2025 - 0.0079 L + 0.000515 L^2
```

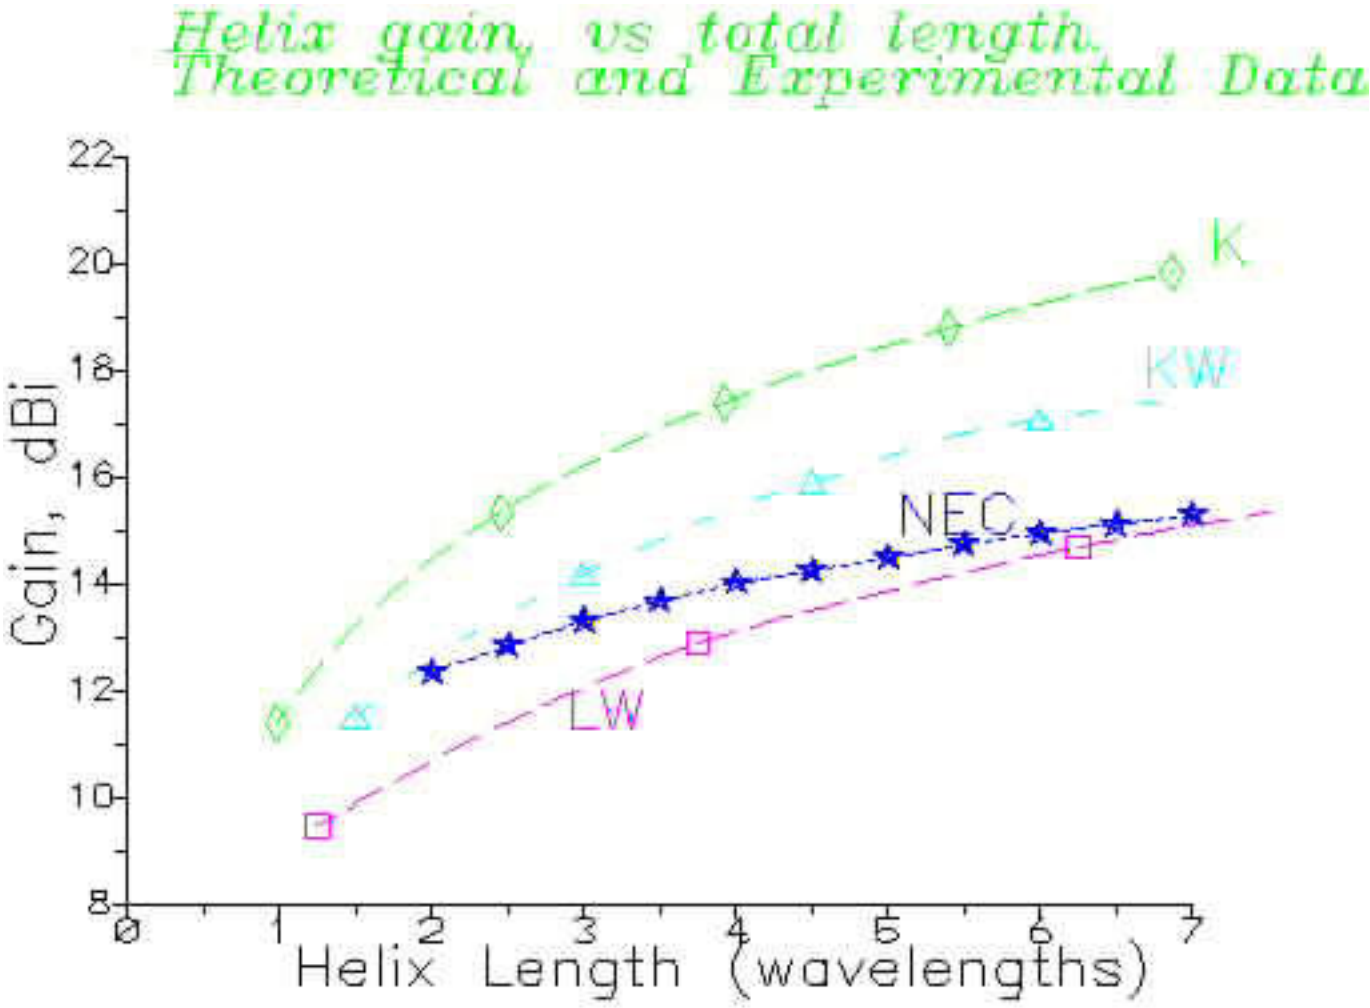
Again, this is only valid for lengths between 2 and 7 wavelengths.



Gain vs length and turn radius, with turn spacing 0.24 lambda. Note that the radius at which peak gain occurs decreases with antenna length.



The maximum realizable gain (stars, left axis) as a function of helix length, and the turn radius (squares, right axis) at which peak gain occurs.



The peak gain of a helix as a function of length, comparing NEC modelling, experiment and theory. K is the gain from the Kraus formula. KW (long dashes) are the measurements of King and Wong. NEC (short dashes) is from the numerical modelling in this article, and LW is from the theory of Lee and Wong. The modelling results are intermediate between theory and measurement.

In summary, this extensive modelling study is in good agreement with theory and measurement from the professional literature, all of which show that the simple Kraus formula for gain of a helix is far too optimistic - by up to 4 or 5 dB.

The modelling shows that, at a given value of turn spacing, the optimum turn radius for peak gain decreases slightly as the helix is made longer. The gain is almost independent of wire diameter, or of the presence of a short feed stub between the ground plane and the start of the helix. The resistance of wire used to construct the helix, even if several times worse than aluminium, has little effect on efficiency. A half-lambda square groundplane is nearly as good as an infinite groundplane. The use of radials, rather than a continuous groundplane, gives a gain penalty of some 3.5 dB.

Please consult the original article for more results, and for literature references. A preprint of a more

detailed article on the gain of the helix antenna, prepared for the professional literature, is available from the author. (Please send e-mail to demerson@nrao.edu.)

Horizontal Half-wave Dipole above a Counterpoise

** Copyright (c) Ralph Holland 1996, Copyright (c)Amateur Radio 1996.*

Introduction

All antennas that are situated close to the ground are affected by that ground to some extent.

The most obvious effect is that the ground forces the antenna's radiation pattern to appear in the half-space above the ground. This is illustrated by comparing the radiation around a monopole fed against ground to that of a dipole in free-space. The monopole has twice the power in the hemisphere above the ground compared with the power in either hemisphere of symmetry for the dipole in free-space. The nature of this reflection of energy above the ground is governed by the polarisation of the antenna and the ground effectiveness. The dielectric constant and conductivity of the ground determines how well the ground acts as a conductor and hence a reflector.

A less obvious effect is that the ground absorbs energy from the antenna; this energy is wasted in the ground's intrinsic resistance (Ref 3).

The placement of an artificial ground, or counterpoise, can decrease the ground losses and enhance the performance of a horizontal antenna. The enhancement can be investigated by performing comparative measurements of the feedpoint resistance or by performing computer simulations.

This article is based on computer simulations using NEC-2 (Ref 1) for antenna systems at 1.825 MHz over average ground with a relative dielectric constant of 13 and conductivity of 5 milli-Seimens per metre [13,5]. The simulations were performed for ideal (lossless) antenna elements with a diameter of 1.22 milli-metres.

Terminology

Displacement is the term used for the distance between the counterpoise (which is the antenna system's lowest element) and the ground. Separation is the term used for the distance between the driven-element and the counterpoise. Displacement, in the regular dipole case, is the distance between the dipole and the ground.

Results

Figure 1 illustrates the efficiency of the horizontal half-wave dipole at various displacements. In general, the efficiency improves as the dipole is raised higher. Note that 100 percent efficiency is not achieved at a quarter wavelength displacement because, even at this height, the ground has introduced some losses into the antenna system.

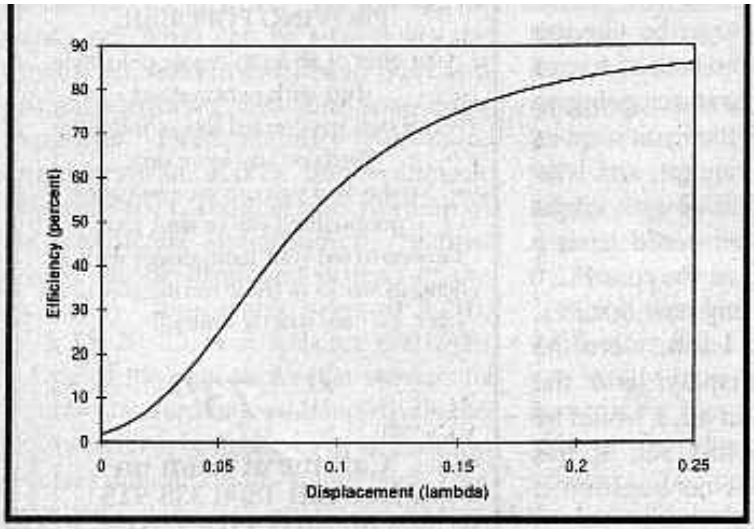

Figure 1 – Efficiency of a half-wave dipole above ground [13,5].

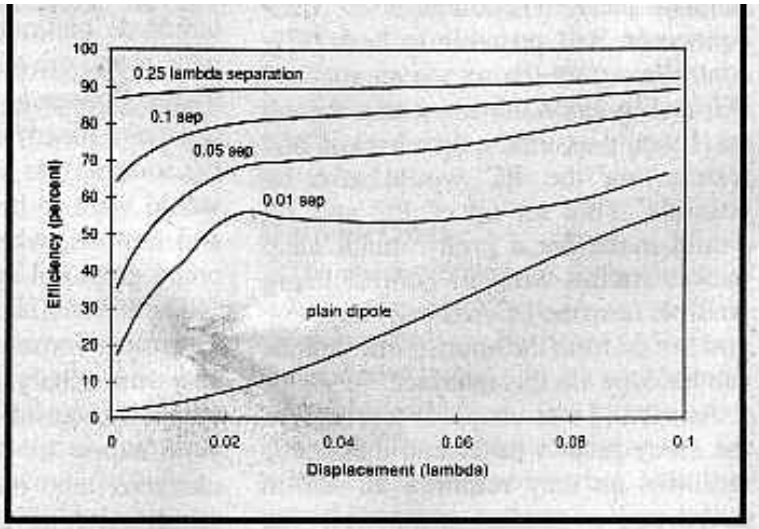

Figure 2 – Efficiency of a half-wave dipole separated from a counterpoise with various displacements above real ground.

Figure 2.0 illustrates the efficiency for various counterpoise systems and a dipole above ground. Notice that there is a knee in the counterpoise curves, which indicates that there is an optimum displacement. Be careful when interpreting the graphs, increasing the separation suffers from the law of diminishing returns; the efficiency of a counterpoise system must be compared with that of a dipole at the same equivalent height, ie. the counterpoise displacement plus the driven element separation. Observe how a counterpoise improves the efficiency of a horizontal antenna system.

Figure 3 shows the radiation pattern of a horizontal dipole displaced 0.07 wavelengths above ground.

Figure 4 shows the radiation pattern of a dipole offset by 0.05 wavelengths above a counterpoise that is displaced 0.02 wavelengths above the ground (same equivalent height as the dipole only system).

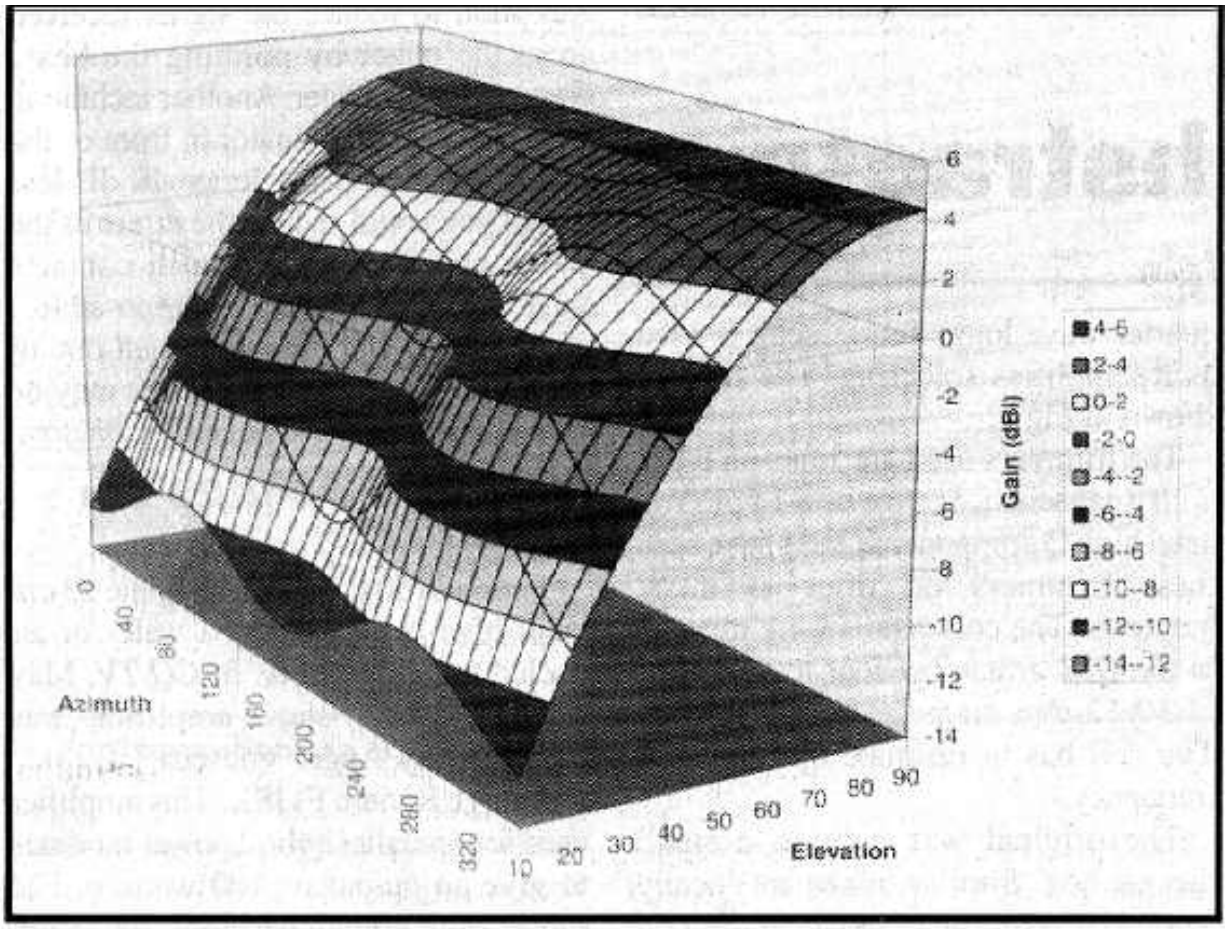

Figure 3 – Radiation pattern from a half-wave horizontal dipole 0.07 wavelengths above ground [13,5].

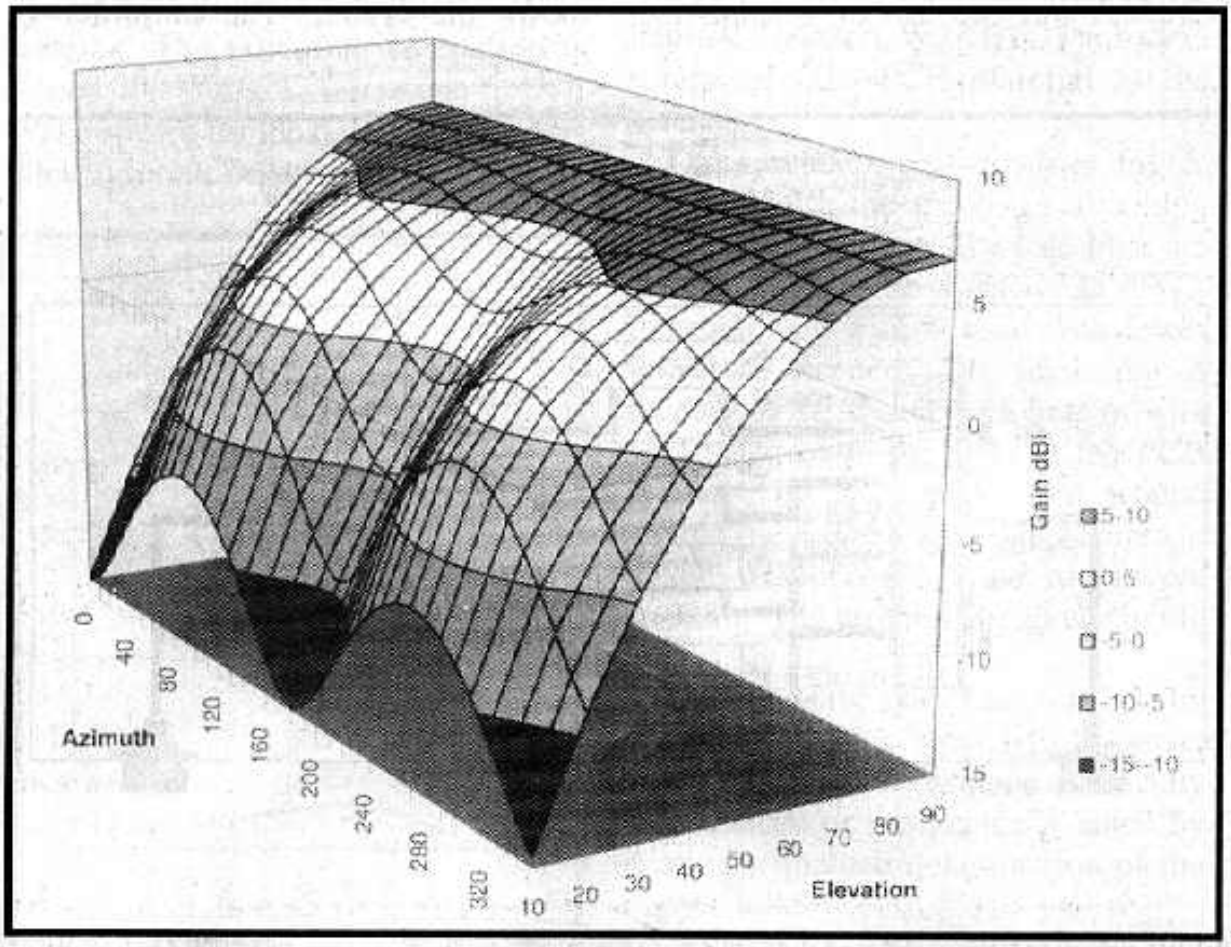

Figure 4 – Radiation pattern from horizontal half-wave dipole above a half-wave counterpoise 0.02 wavelengths above ground [13,5].

The horizontal dipole system has a minimum gain of 0 dBi at 51 degrees elevation, while the counterpoise system has a minimum gain of 0 dBi at about 42 degrees of elevation. Alternatively, antenna gain comparisons at all elevation angles show that the counterpoise gain is greater than the dipole system by 2.53 (0.05 dB. This demonstrates that the counterpoise is a more effective ground system; the counterpoise reflects more energy into the half-space so less is wasted in the intrinsic ground resistance and more is radiated.

Conclusions

The placement of a counterpoise below a horizontal antenna can improve the antenna efficiency by a reasonable amount. The effect under a horizontal antenna is similar to the effect of elevated ground-planes for vertical antennas (Ref 2). You can measure this effect by observing an increase in field strength or by observing the lowering of your feedpoint resistance when adding the counterpoise (Ref 3).

At 160m, with ground parameters [13,5], the effect peaks with counterpoise displacements of about 0.02 wavelengths above the ground.

Increasing the antenna system efficiency with a counterpoise increases the gain at all angles, effectively lowering the effective radiation angles.

Horizontal Antennas above Real Ground

* Copyright (c) Ralph Holland 1996, Copyright (c) Amateur Radio 1996.

Introduction

Antennas are influenced by the effect of the ground and by the type of conductors from which they are constructed. The feedpoint impedance is the summation of the radiator's self impedance, the mutual impedance of its image in the ground, and the loss resistance.

The loss resistance is the summation of the R.F. resistance in the conductor, and the resistance introduced by consumption of power in ground losses and other media close to the antenna. The conductor's resistance is modified by the skin-effect which causes the current to only flow in the outer parts, or skin, of the conductor. The effect causes the resulting resistance to increases in proportion to the square root of the frequency (see Table 1 and Table 2).

Horizontal antennas are subjected to the influence of a broadsize image in the ground. The antenna and its image are in anti-phase, so radiation tends to be cancelled at low angles and the radiation resistance is lowered because the mutual impedance of the image is subtracted from the self-impedance of the driven element.

Modelling

To quantify the effects of locating antennas above real ground, I have once again resorted to computer modelling using NEC-2 (Ref 1). All simulation results have been performed with 1.22mm diameter wire (SWG #18) and assume lossless conductors.

The simulation results are displayed graphically so you can determine the trends and evaluate your own antennas. The soil parameters for each simulation are enclosed in square brackets. For example, [13,5] represents ground with a relative dielectric constant of 13 and conductivity of 5 milli-Siemens / m (2S = 1/2ohm, while 4S = 1/4 ohm). The selected values are: [5,1] for poor soil, [13,5] for average clay soil, [20,30.3] for good soil and [80,5000] for sea water, which is very close to perfect.

Table 1 and Table 2 are included so you can evaluate conductor resistance losses due to the skin effect (Ref 2).

Results

Figure 1 shows the effects of various types of grounds on a 1.825 MHz horizontal 0.5 wave dipole between 0.01 and 0.25 wavelengths above the ground. Note how over poorer soils the feedpoint impedance is dramatically higher than the resistance for perfect ground. Notice how the feedpoint resistance for a horizontal antenna becomes very low as the antenna approaches a perfect earth. (The feedpoint resistance of a perfect conductor over a perfectly conducting ground is the radiation resistance of the antenna.)

Figure 2 illustrates the overall antenna efficiency; a measure of how much power is radiated over the hemisphere, compared to power fed into the antenna (the missing power is absorbed by the ground).

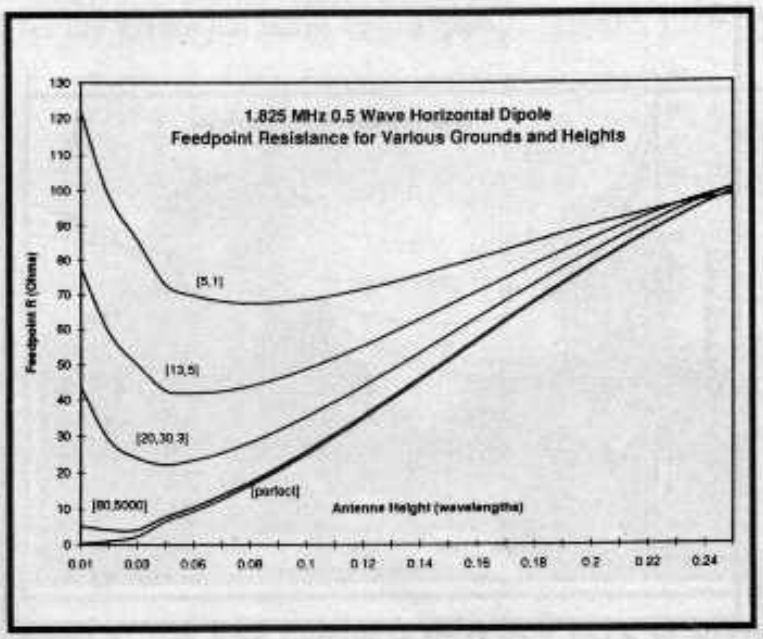

Figure 1

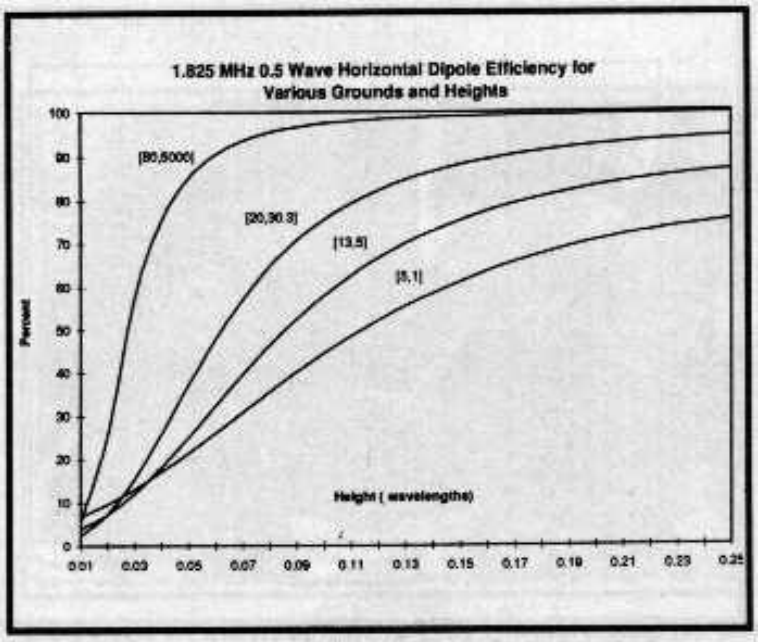

Figure 2

Figure 3 illustrates the effect upon the maximum gain. (However, at 160m, poor ground means the maximum gain is at an elevation of 90 degrees - ie straight up!)

Figures 4, 5, and 6 show the effect upon feedpoint resistance at 3.5 MHz, 7.0 MHz and 14.0 MHz respectively.

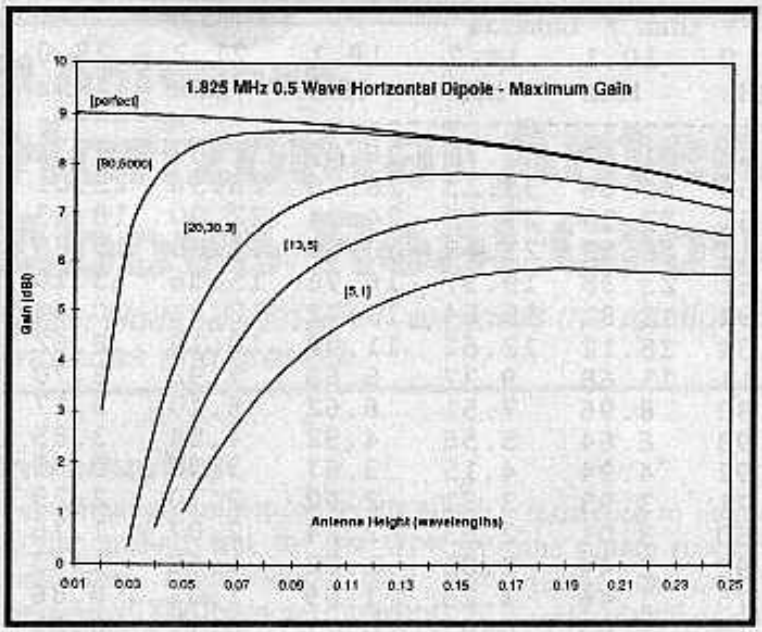

Figure 3

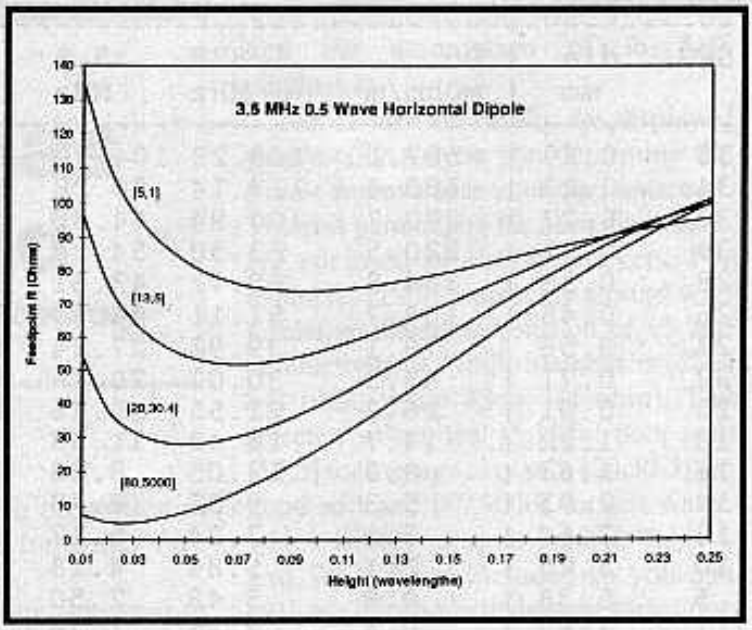

Figure 4

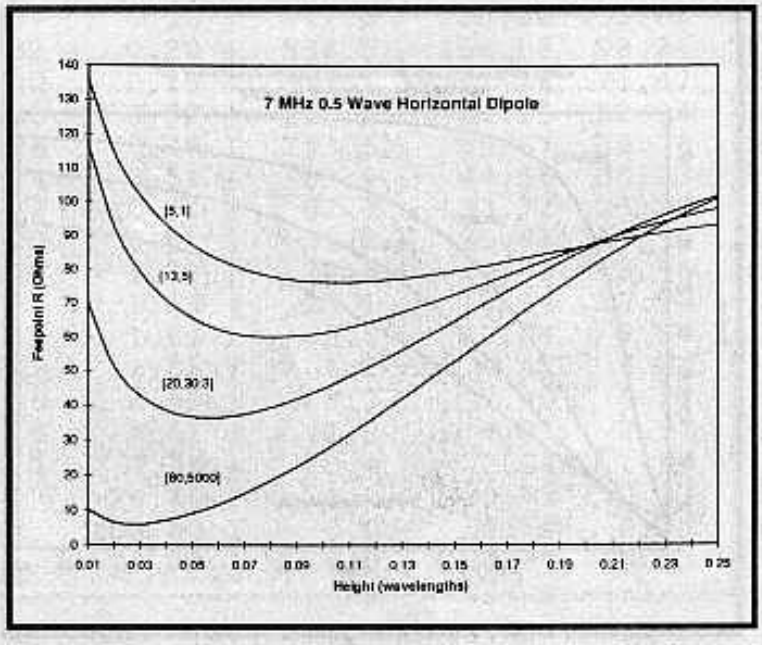

Figure 5

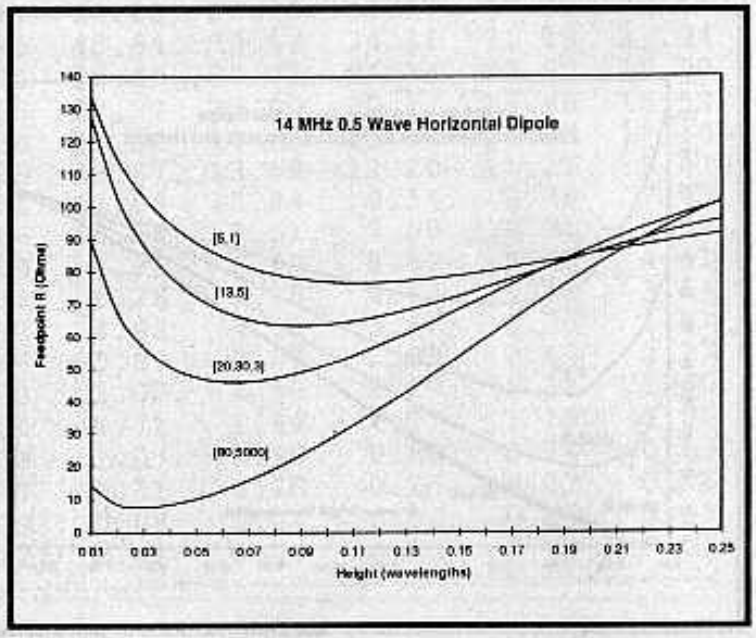

Figure 6

Table 1 and Table 2 give the R.F. resistance of round copper wire at various frequencies. The values are listed in ohms per wavelength. You must halve these values for wires carrying cosinusoidal currents. The resulting value when added to the graphical results accounts for losses in a non-ideal conductor.

Conclusions

The radiation resistance of a horizontal antenna is lowered as the antenna is brought closer to the ground because self and mutual impedances subtract.

As a horizontal antenna approaches lossy media the feedpoint resistance rises due to increasing power losses in the media. You must be wary of this tendency for low antennas to apparently present a good feedpoint resistance.

Poor conductors, or inappropriate conductor sizes, will also introduce loss resistance. This effect is particularly noticeable in cases such as loading coils.

By comparison though, a horizontal radiator has less ground loss than a vertical antenna mounted at the same average height (compare the graphs for horizontals against those for verticals from Ref 3.0).

7-HAM RADIO "UNIQUE HEALTH HAZARDS"

"IK-STIC" by W2IK

(NOT TO BE CONFUSED WITH MY "IK-STIC 2" WHICH IS A MUCH BETTER DESIGN: CLICK HERE TO BE RE-DIRECTED)

The "IK-STIC" is essentially a multi-band vertical dipole antenna which is used in the field for quick set-up and quick band change. Since operation on each band requires antennas of different lengths, I devised a quick method of modifying the length to suit the band you choose to operate. There are no coils or traps. Each dipole band gives 100% radiation, thereby allowing maximum signal at maximum height.

==========

TO BUILD THIS ANTENNA YOU NEED:

1 - MFJ 1910 33 ft fiberglass mast (fig.1) the best choice

click above for link (telescopes down to 3.8 feet !)

OR

1 - WorldRadio SD-20 TELESCOPING MAST AND 1 PIECE of 12ft. 1 1/2 inch PVC pipe. (Cheaper than the MFJ purchase, just as good)

(insert SD-20 one foot into PVC and put a stop bolt in the PVC so the pole won't slide down further)

++++++++++++++++++++++++

You might wish to make an additional support (from PVC pipe) to hold the mast upright (or you may skip this and lash the mast to a tree or any NON-CONDUCTOR)

1 - either "CB" or 10 meter dipole antenna

(I bought a "CB" dipole, with center connector.. Workman Model BS-1)

(or you can build one using insulated wire) (see fig. 2)

1 - roll of STRANDED, insulated connection wire

(Radio Shack size #18-22 100')

Several Spade Connectors (Home Depot)

(both male and female with insulated covering)

BUILDING THE ANTENNA

Take the "cb" or ten meter dipole antenna, which already has a center UHF conector to accept a coax cable, and measure each side from the center. Trim EACH SIDE so that you have 8' 3 1/2" measured from the center. This makes a dipole of 16' 7" ..or a 10 meter dipole. At the ends of each leg, strip

Fig.2 Dipole with spade terminals

off about 1/4" of the insulation and attach a spade connector and crimp it AND solder it in place. see Figure 2.

FIG. 3

MAKING "BAND ADDERS"

Next, for each band other than 10 meters you wish to operate on, you will need to build "adders" for EACH leg of your ten meter dipole. For example: If you choose to make the dipole operate on 15 meters, the length of a 15 meter dipole is about 22' 2" or 11' 1" on each leg. Since you already have a dipole length of 16' 7", or 8' 3 1/2" on each side, you just need to make two "adders" of 2' 9 1/2". Cut two EQUAL lengths of stranded wire (each 2' 9 1/2") and add the opposite-type spade connector, so it mates with the ones you placed on the 10 meter dipole (see fig 3) crimp AND solder. You need only add it to ONE end of each "adder". When these wires are added to the 10 meter dipole, you now have a 15 meter dipole. Make other "band adders" using the same method. You see how easy it is to make "adders" for every band you choose to operate. I made them for 5 bands all the way to 40 meters.(see fig.4) DON'T try to skimp by trying to make "adders" on "adders" as it will make your set-up very complicated.

Adder sizes: Make TWO (one for each side) 15 meters: 2' 9 1/2" 20 meters: 8' 2" 40 meters: 24' 6" 17 meters: 4' 7 1/2" note: all approximate lengths.....mid bands

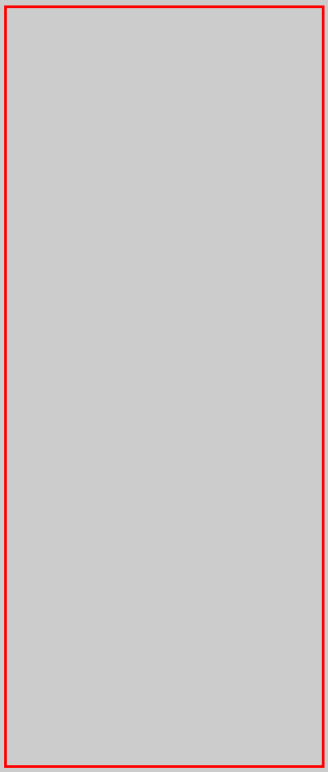
FIG. 4

SET UP AND OPERATION

Before you set your antenna up, mark which side of your 10 meter dipole antenna is connected to the CENTER of your coax connector. This side needs to be the highest in the air for best results. Decide which band you wish to operate on and connect your "adders" as needed (one on each side of the dipole). Take a rubber band and use it to hold the end of your "adder" to the TOP of the fully extended mast. Make it a very snug fit as this will hold the antenna as it runs down the mast.

You may wish to use a small amount of tape to hold the antenna to the mast just above the connector point to reduce any additional stress should you tug on the cable. Now add your coax to your antenna allowing it to flow down freely. The lowest end of your antenna wire should now be taped or rubber-banded to the low point on the mast. The antenna will not run to the ground unless you made a 30 or 40 meter antenna or used the Worldradio mast w/pvc. If you did, just tape where it meets the lowest point of the mast and let the additional wire rest on the ground in a straight line. (Be sure NO ONE comes in contact with the wire during operation.) Note: This is a vertical antenna. It can be used in tight spaces where an inverted "V" , etc cannot fit. (such as a limited area campsite) It needs no guys !

Any time you wish to change bands, just exchange the "adders" for the pair that matches your new band...I find this takes less than 2 minutes. So there you have the "IK-STIC" , all band antenna that weighs less than 5 pounds, needs NO tuner, and you can take it ANYWHERE ! I have worked hundreds of hams in dozens of countries while camping and at special events.



I hope you enjoy it too! Remember: It's called the "IK-STIC" by W2IK !

(the ideas described may not be reproduced without author credit)

W2IK's "IK-STIC 2"

DESIGNED BY BOB HEJL - W2IK

(PUBLISHED IN AUGUST 2004 "WORLDRADIO")

The "IK-STIC 2" is a vertical, all band, antenna that is over 25 feet tall yet weighs under 5 pounds ! Using a tuner it can easily cover the amateur radio HF bands from 40 - 10 Meters. No unsightly wires as the radiating wire is inside the telescoping mast!

5992
HITOMETER

TO CONSTRUCT THIS ANTENNA YOU NEED:

ONE SD-20 Telescoping mast (WorldRadio sells these)
ONE 6 foot section of 1 1/2 inch PVC Pipe
50 feet of 20 or 22 gauge STRANDED, INSULATED Wire
ONE SO-239 Barrel Connector with washers and Nuts
ONE male and female push on connectors (see photos)
TWO Large (6 inch) Hose clamps (see photos)
Electrical Tape, Epoxy, Duct tape and asst. hardware.

ANTENNA CONSTRUCTION

FITTING THE INTERNAL ANTENNA WIRE INSIDE THE TELESCOPING MAST:

Take the SD-20 telescoping mast and remove the bottom cap by unscrewing it. Looking in you will see the sections nestled in place. Remove the rubber plug from the next to thinnest section so now all the sections are "open". Carefully take a 21 foot piece of 20 gauge, stranded, insulated wire and tie a very small knot at the end. Take the knotted end and insert it into the smallest section of the telescoping mast and using a straight wire made from a coat hanger, shove the stranded wire into the section as far as it can go. Then take a small amount of epoxy and glue the wire into place so it can't be removed from the top section. SLOWLY telescope out the entire mast, making sure that the wire slides inside easily. When the mast is fully extended you will have almost 20 feet of wire inside. Leave about 5 inches after the mast is fully extended and cut the wire. This will leave a 5 inch "play" to connect the wire at the bottom. Now CAREFULLY drill a small hole in the rubber base of the mast pointing out SIDEWAYS. Epoxy a push on connector into the hole. Solder another 4 inch piece of that same stranded wire onto the connector on the INSIDE. On the bottom cap of the mast, drill a hole that will allow you to half way insert, and tightly secure, that SO-239 barrel connector. Carefully epoxy it on the inside of the cap so it won't loosen. Next, solder the long wire that is in the mast onto the inner part of the SO-239 connector. Solder the wire from the push on terminal to the outer section of the SO-239 connector. Take the cap and give it about 7 COUNTER CLOCK WISE turns so the two wires are twisted. This way, when you screw the cap on, the wires will untwist in the mast. Tighten the end cap, but do not glue it.

WINDING THE PVC COIL SECTION:

Next take 25 feet of that same stranded wire and start to wrap it around the 1 1/2" PVC pipe at a point 14 inches from one end. (This becomes the top end.) MAKE SURE YOU LEAVE 8 inches of "free wire" before you start the coil wrap. Slowly wind the wire around the PVC pipe creating a coil, leaving a spacing of 1 1/2 - 2 inches from each turn. As you wind it down the pipe, you may wish to secure it every so often with electrical tape. The winding does not have to be exact, but keep it as evenly spaced as you can. One foot before the bottom, create a tight wrap of the wire, leaving no gaps on the turns. At the end, tape the wire to the PVC pipe. When you are done, wrap the entire coil in electrical tape so the coil stays in place. On the top end, solder a mating end of a push on connector so it can plug into the mast's side connector.

Wrap several turns of Duct Tape to the very top of the PVC mast. This will serve to offset the taper in the telescoping mast when it gets mounted to the PVC pipe. Using two adjustable hose clamps, carefully mount the very bottom of the telescoping mast to the top one foot of the PVC pipe. DO NOT OVER TIGHTEN. It takes very little compression to keep the mast in place. When you have done this, you can extend the mast out it's entire 20 foot length. To keep the entire antenna up-right, slip it over a 4 foot section of appropriate thin wall steel tubing that has been pounded in the ground about one foot. The lower coiled section of the antenna on the PVC pipe will then be slightly "ground coupled". This helps with the antenna's operation on 30 and 40 meters. Plug in the lower coil (The PVC pipe) into the male connector on the side of the telescoping mast. The SO-239 connector is where you screw in your coax cable to your radio. Make a few windings of whatever coax you are using at the connector point and tape them tightly together to prevent RF from returning on the coax shield. Connect the other end of the cable to your tuner and you are all set to go !!.

To dis-assemble the antenna, just remove the coax, loosen the hose clamps and take down the mast after unplugging the PVC coil plug. CAREFULLY retract the mast and the internal wire should slowly coil down into the masting. DO NOT FORCE THE SECTIONS. A few gentle jiggles and a twist or two will do the trick. After several uses it will be easier to retract the sections as the internal wire will have "memorized" how to coil up. You can even store the telescoping mast in the PVC pipe by making a small slot at the bottom of the PVC tube to accommodate the connector that is on the side of the telescoping mast . The antenna is very simple, light and works well when tuned properly. My first contact was on 15 meters when I spoke to Siberia. I have used it on all the bands it covers and have also made an adapter so it mounts on the ball hitch of my truck. This is great when you are parked and can't make a hole in the ground. (NOTE: If you wish to make an "IK-STIC 2" that covers 160-10 meters with a tuner, use a 7 FOOT PVC PIPE instead of the 6 ft. pvc and coil 35 feet of wire around it using 1 inch spacing between wraps and two feet near the end increase the spacing until you run out of the wire and the end of the coil wrap is four - six inches from the bottom of the PVC pipe. Any longer coil winding that this will make it difficult to tune the antenna on 10 meters.) (Use the rest of the antenna building dimensions as outlined above.)

REMEMBER.... it's called the "IK-STIC 2"

Designed by Bob Hejl - W2IK

This antenna has been used at Field Day operations, Special Events Stations, JOTA Events and County Activations with great results.

RADIO HABANA CUBA

THE EVER-POPULAR INVERTED "L" ANTENNA

BY ARNIE CORO (CO2KK)
Host of "Dxers Unlimited"

SEND YOUR COMMENTS, QUESTIONS AND IDEAS DIRECTLY TO ME AT:
arnie@radiohc.org

Ever wanted to install a shortwave receiving antenna FAST?!!! Then I am almost sure that you will want to learn more about the "Inverted L" antenna... About the easiest effective skywire to build ...

Just two supports... may be two masts, a mast and a tree, a mast and a nearby building... it need not be perfectly horizontal above ground... as a matter of fact if the inverted "L" is installed in a slightly tilted angle it seems to work better.

Although strictly speaking a true inverted L has the downlead connected to one end of the horizontal section... my version calls for connecting the downlead (a single wire) to a point about 20 percent from one end.

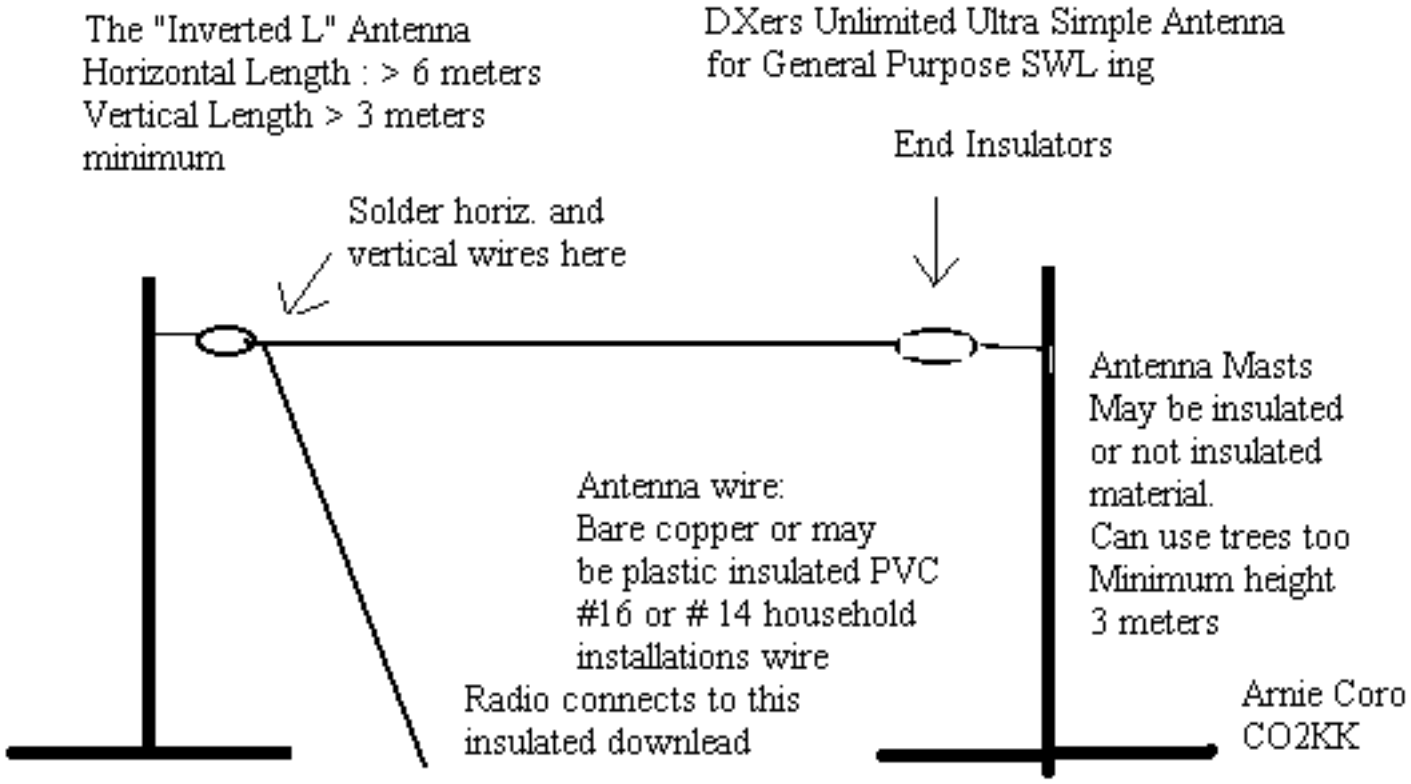
The antenna should be connected to your receiver via an antenna tuner with a real wide matching margin. For a 10 to 15 meter horizontal section, strung between two masts of about 5 to 7 meters each, you may expect very nice performance on frequencies extending from about 3 to 30 megahertz.

Using the inverted "L" for transmitting, does require the installation of a good ground system or a "floating counterpoise", a device coming from the early days of radio that provides an amazing improvement in performance of many antennas... More about the "floating counterpoise" soon right here at this WWW site...

You may want to build your inverted "L" with copper wire of no less than no. 16 gauge.. I prefer to use PVC covered copper wire of no 16 or no 14, same type as used by electricians for home installations.

Overall antenna length is not really critical, but the inverted "L" does need have a

horizontal section of no less than 5 to 7 meters and a vertical section of no less than 3 to 5 meters to work effectively. The most tested version here has a spacing between masts of 20 meters, a height above average terrain of no less than 5 meters and I used a single wire floating counterpoise, installed below the horizontal section of the antenna.



Do remember than in order to obtain optimum performance from this very simple, yet effective, short wave antenna, you do need to install it properly, solder the antenna downlead to the horizontal section, and use an ANTENNA TUNER...

Wish you success with this rather simple antenna project...

Doubts??? Then send a message to arnie@radiohc.org

The KGØZP Super Linear-Loaded Inverted V

How do you fit a full length 160 meter antenna into a 40 foot deep yard?
Install the KGØZP Super Linear-Loaded Inverted V, of course!

The Super Linear-Loaded Inverted V allows you to select your two favorite and most used frequencies as band centers, and offers excellent bandwidth as well.

The designers installation centerpoints are set at 1.840 the center of the DX window or calling frequency and 1.875 at an SWR of 1.1-1
The bandspread at 1.5-1 is 20 kc at each center or
40 kc to an SWR of 2-1

The linear-loading section is mounted near enough to the ground that you can easily install or remove precut pigtails using an alligator clip to move the center point temporarily to make that sked, or you can tune the whole 160 meter band with a simple antenna tuner.

The formula for construction is the same as for any dipole 468/fMhz and the design will work equally well on 80 or 40 meters.

Reader Please Note: The photos on this page are greatly compressed to insure quick downloading.
The link accompaning each photo will cause the uncompressed full size photo to download.

It would be impossible to show an overall view of the whole antenna system in such a way that you could see the wires.

With that in mind, I have taken a couple of daylight pictures as well as flash night pictures which allowed me to highlight the wires against a black sky.

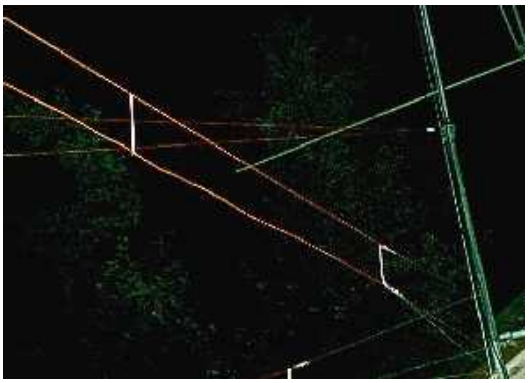
Lets take a thumbnail look at a daylight view of the Rohn 50 foot push-up pole utilized for this installation.

This is quite a busy photograph, so I will name the items in descending order to help pinpoint the areas relavent to the Super Linear-Loaded Inverted V. Link to view photo in hi-res!

The white stick at the top extending off the upper edge of the photo is a Diamond Tri-bander, model X3200A, fed with 9913 coax.
Directly below the tribander is the first guying ring. This is a dummy ring is used to ground and hold the upper wire of a Wermager type Broadband Sloper. In the full sized photo you can just barely see this wire extending left forward.
The highest of the three actual guying rings (second one down from the top) is at the 40 foot high point on the tower, a pulley is connected to this guying ring and through it is threaded a high quality flagpole rope. This rope can be used to raise and lower the balun for experimenting with different antenna designs, without changing the position of the push-pole.
The Super Linear-Loaded Inverted V, the topic of discussion is connected to this balun. The tension on the wires is so great that it holds the balun outward, the line descending from the bottom of the balun is Super Mini-8 coax. The pull of the Inverted V's two antenna wires is offset by two guywires on the other side of the guying ring. I have a wide yard and could keep the apex slightly wider than 90 degrees.
The next guy ring down is at the 30 foot height point and has nothing more three guy wires.
The lowest guy ring visible in the photograph is at the 20 foot level, and is the feedpoint for the Fan portion of a Wermager type Broadband Sloper originally used on 160 but now cut for 80 meters. I would like to mention again that the upper wire of the Wermager type Broadband Sloper is the wire grounded to the push-pole at the dummy guy ring at the very top. The other end of this wire is tied to the same location as the guy wire coming from the 30 foot guy ring, which places the metal guy wire directly between the driven Fan and the grounded sloper element of the Wermager type Broadband Dipole.

This photo is a view showing the East outbound leg of the Super Linear-Loaded Inverted V. In the upper left of the photo, you can see the single sloping wire descending from the balun. The two horizontal wires below comprise part of the Linear-Loading section. Link to view photo in hi-res!

The remaining photo's were taken at night using a flash, then enhanced to make the wires more prominent.



In this first photo, you can easily see that the Linear-Loading section is a good distance away from the push-pole. I used a distance of 5 feet in this installation, but you can reduce this distance to 3 feet if necessary. The vertical spacers are drinking straws, one nested inside the other for greater strength, a nylon tie line is fed through the center of the straws. Link to view photo in hi-res!
The upper tie off lines are located 1 foot above the standoff mounted to the eave. The lower tie off lines should also be located at or just above the standoff. Original twine used during initial setup is still visible and should have been removed before taking the photo.

The white insulator some 5 feet above the linear loading section is the feedpoint for the Fan portion of the Wermager type Broadband Sloper.

SPECIAL NOTATION: The upper wire and the lower wire of the linear-loading section are connected at this end only. This will be described in greater detail in the construction notes section. Link to view photo in hi-res!

These last two photos show the East and West outbound ends of the Super Linear-Loaded Inverted V.

If you look closely, you can see the pigtails wrapped around the lower nylon guys.

In the photo on the left of the East outbound end, the wire from the balun down to the insulator is not visible. The upper guy wire from the insulator is metal, the lower is nylon. An additional twisted wire above the insulator is used to lift the linear loading section slightly higher than the existing guy mount allows, I did this only because I had something above each outbound end to tie to. Link to view left photo in hi-res!

The right photo shows slightly greater detail and the antenna wire from the balun is clearly visible. There are no electrical connections at the outbound end of the linear-loading section. Link to view right photo in hi-res!
Again, if you look closely, you can see the pigtail extension wrapped around the lower nylon guy.

Construction Notes:

The construction of the Super Linear-Loaded Inverted V is quite simple and follows the same formula as for a standard dipole. 468/fMhz (FourHundredSixtyEight divided by the Frequency in Megahertz give you the total length in feet for a 1/2 wave dipole). In practice you will use two wires, each being 130 feet long. The antenna shown in the photos is made from 14 guage insulated copper wire. I ran out of insulators and am temporarily using loops made from 1/4 inch nylon cord at the push-pole end of the linear-loading section. If you start with two 130 foot long wires, you do not have to measure the turning or ending points, they will fall in place depending upon the height you install the horizontal portion of the antenna.

The height of the feedpoint can vary considerably, however, the higher the better. If you can only go up 30 or 35 feet, the antenna will still perform almost as well, but you will require a further horizontal distance to work in. With the feedpoint at 40 feet, the sloping elements are roughly 60 feet long at 40 feet away from the push-up pole. Any distance from 40 feet to 80 feet in length seems to make little difference in the performance of this antenna.

A balun is not an absolute necessity, however, if space constraints keep you from obtaining a spread between the sloping wires greater than 90 degrees, then a balun is strongly suggested.

For all practical purposes, installation is the same as for an inverted V, a feed type insulator or balun is assembled with the coax and both of the 130 foot long wires. Connection of the coax is the same as for a standard dipole. The center conductor goes to one wire and the shield to the other wire. The feed insulator or balun is now hoisted to it's permanent position on your push-pole, tower, gable or wherever you are mounting your antenna.

I will describe the finished setup first, then give some quick install tips immediately following.

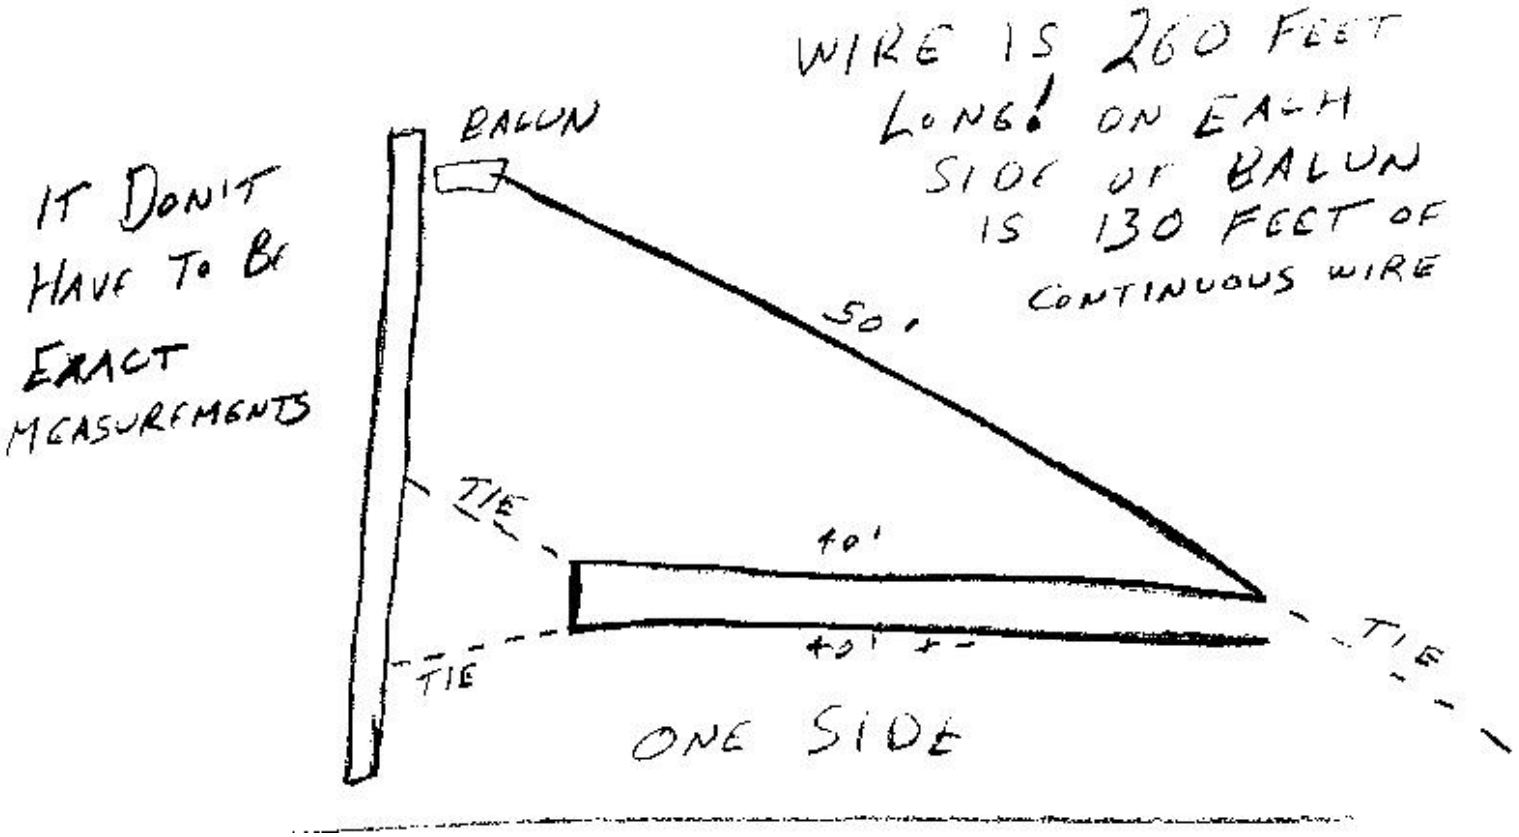
One side of the antenna is assembled first and will require a minimum of three insulators or you can use nylon mounts by giving the wire a twist to form a loop to connect the nylon rope to.
The antenna wire is brought out across the yard and the end of the wire is passed through an insulator at the outbound end of the antenna. The antenna wire is then brought back toward the push-pole and passed through the second insulator. The second insulator should be installed about 6 feet away from the push-pole temporarily. The wire then passes through a third insulator 6 to 8 inches below the second insulator, and then proceeds back out to the outbound end.

The ideal installation would have the feedpoint 50 feet above ground level and the linear-loading section 20 feet above ground level. In practice, the feedpoint can be as low as 30 feet above ground level and the linear-loading section as low as 10 feet from the ground without affecting performance to drastically. In any case, the linear-loading section should be maintained as close to horizontal as possible.

The idea is to determine at what height you wish to install the horizontal linear-loading section, and then adjust the insulators and distance between the push-pole and inside end of the linear-loading section so that the first insulator and end of the wire are on the same plane. And you'll really love this, give or take 2 or 3 feet on that tail, preferably give a few feet extra for trimming to resonance.

Any non-metal spacer can be used to maintain distance between the elements of the linear-loading section! No need to go overboard here, it's close enough to the ground you can replace the simple item I use in Quick Tips below.

Simple Sketch showing path of antenna wire on one side of balun.



Quick Tips:

Here is how to install this antenna system and have it up and running in well under an hour, exluding push-pole installation of course.

1. Install the wires to your balun and connect the coax, hoist it into position and secure firmly.
2. Pull one wire out taught to your guy mount and secure temporarily.
3. Take the loose end of this same wire and secure it to the push-pole temporarily at the desired final installation height. Note: This end of the wire will be at the other end of the yard when finished.
4. Go back to the outbound end of the antenna, using a stepladder if necessary, pull the wire so that it is taught from the push-pole and lift the wire until it is perfectly horizontal.
5. With a magic marker or piece of tape, mark the sloping wire at the point where the wire from the push-pole crosses the sloping wire. This is where the outbound insulator is to be installed.
6. Install the outbound insulator and tie off (guy) this portion of the antenna to permanent tension.
7. Disconnect the loose end of the wire from the push-pole, pass it through an insulator and bring the loose end out to the outbound end and temporarily connect it to the now secure insulator outbound insulator, leaving 2 to 3 feet of loose pigtail extending through this insulator.
8. Pull the wires from the insulator toward the push-pole until they are in balance at equal lengths from the outbound end, at this bend take the insulator and give it a twist, release the loose pigtail at the outbound end, then secure the push-pole end of the top linear-loading wire and it's insulator to the push-pole at it's permanent position.
9. Install your first spacer (see spacers below) by passing the loose end of the wire through it, bring it up snug to the insulator, install the second insulator and give it a twist to hold it secure. Tie this insulator off to the push-pole as well, trying to keep the spacer vertical.
10. Install additional spacers, one about every five feet, to maintain separation of the upper and lower linear-loading sections.
11. When you reach the outbound end, install your last spacer at the insulator, form a loop in the lower wire for attaching a nylon tie off rope. Pull the rope to tighten the lower linear-loading wire and tie off to the guy mount. Wrap the remaining 2 or 3 feet of pigtail around the nylon rope.
12. Duplicate the above instructions for the other leg of the antenna!

SPACERS:
I take simple drinking straws to use for spacers. But reinforce them to two thicknesses for all the spacers except the inbound spacer near the push pole, this one is three or four thicknesses.
To strengthen a soda straw, you merely slit another soda straw end to end and insert it inside of the whole unslit soda straw.
You only need to pass the unslit whole soda straw over the wire for the inbound spacer, the other two or three slit straws can be added right over the wire and then slid into the whole unslit straw.

Joining the straws to the wires:
I take 24 inch long pieces of braided nylon, like mini-blind sash cord, fold it in half, hold it on one side of the top wire with the loop up and open, then I pass the loose ends of the rope over the wire and through the loop, pull it snug and let the ropes hang until I get all the ties (ropes) installed. By taking a 12 inch long piece of 18 or 20 guage wire and bending a sharp turn at one end, you can use that to slip the ends of the ropes into and slide the soda straw over the wire pulling the rope down through the straw. Place the loose ends of the rope one on each side of the lower wire and tie a square knot, drawing the wire up tight against the soda straws. Don't worry if they are atilt right now, you can true them up later.
After the antenna is assembled, tied down nice and snug, and tuned. I will adjust the soda straws to vertical and place a dab of something like plasti-dip-your-grip or dumb gum over the tops of the straws to hid the nylon braid from UV and weather. I usually don't worry about the knot end or lower end of the straw.

Tune-Up:
If I have obstructions in the yard that interfere more with one leg than the other, I will make the shield side of the coax go to that side and the center conductor to the clearer of the legs. Now I tell you!
I normally tune both legs of the antenna first to 1.840 MHz, then I will continue to cut the clearer leg of the antenna all the way down to 1.950 MHz. I will then make a pigtail with an alligator clip on it and retune that leg of the antenna to 1.875 MHz. You can wrap the pigtail around the nylon guy and slide it down at least 6 inches away from the tuned pigtail end and it won't interfere with your upper band setting. In my case, I leave the pigtail connected as 1.875 MHz is one of my popular areas of the band for ragchewing. I may be over 50, but to really fit in up at 1.950, I need another 40 years under my belt, Hi Hi..... You may make other pigtails to center in other areas of the band also. It works on either leg of the antenna!

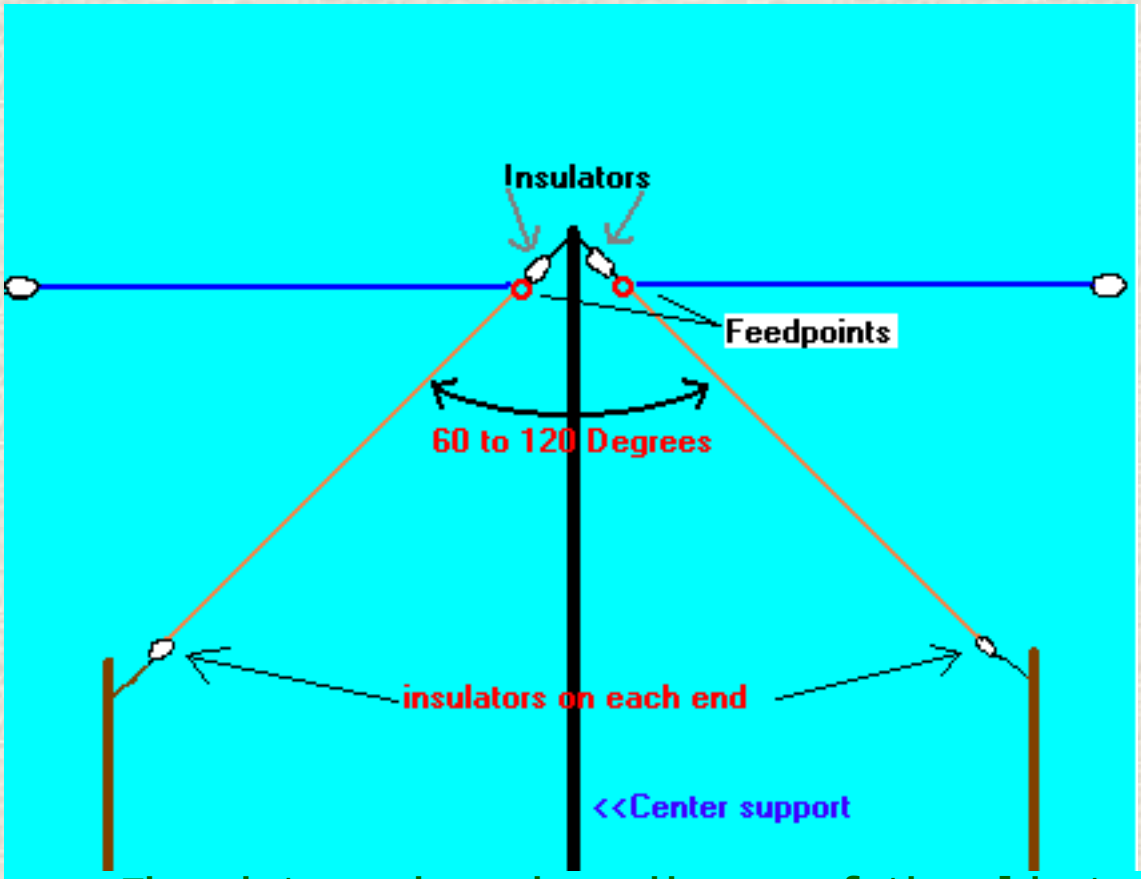
THE DIPOLE AND INVERTED VEE CALCULATOR WITH DRAWING
TWO CLASSIC ANTENNAS

BACK TO ANTENNA LAB



The picture above is a diagram of the old standby CLASSIC antennas....
the Dipole and the Inverted Vee.
They are shown superimposed on each other in the drawing.
The Blue line is the example of a dipole.
The copper colored line is the inverted vee configuration.
The inverted vee is is just a lazy dipole that can't hold it's arms up and is about 4 to 5% shorter on each half!
Both antennas can be constructed just about anywhere using any type of wire you may have and can be used with 50-75 ohm coax or open wire ladder line and a tuner. The use of an rf choke balun is recommended!
You could use the calculator to build a 75 meter dipole and then calculate an inverted vee for other bands suspended under it from the same support and feed both with the same line to xmtr. A little experimentation may be required for adjustment of the SRW, tuning the 75 meter dipole first for lowest SWR and then the inverted Vee.
EXPERIMENT! EXPERIMENT! EXPERIMENT!

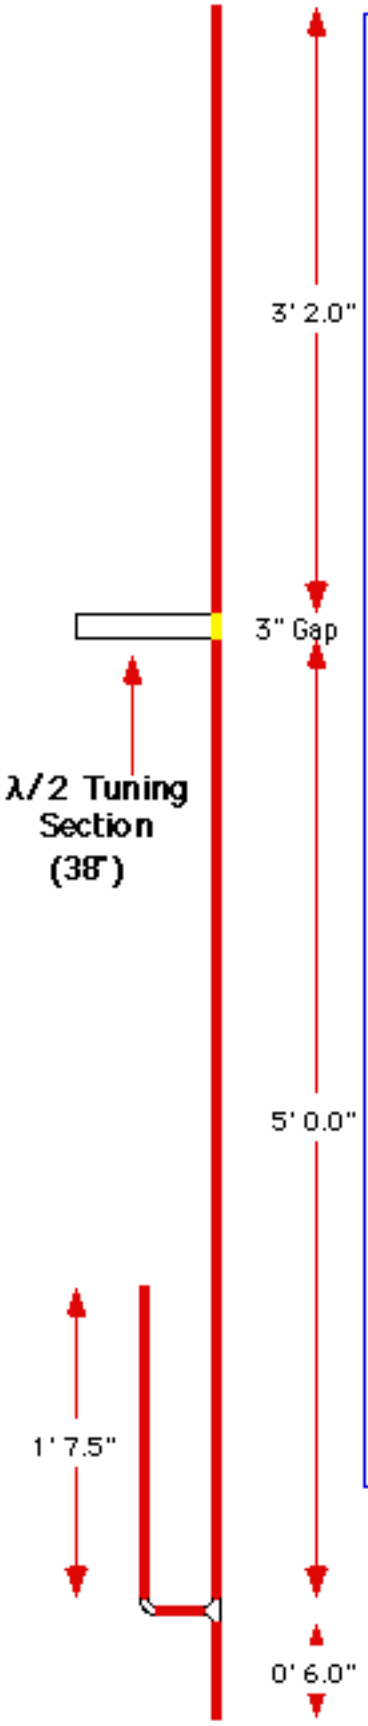
The Super J-Pole Antenna(Collinear Design)

Below is a Javascript for calculating the lengths of tubing to be used for the construction of a Super J-Pole. The antenna I constructed was made of 1/2" tubing.

Frequency

Bottom Section	inches
Top Section	inches
Matching section	inches



Super 2 Meter J Pole Antenna (a.k.a. Collinear Antenna) with helpful modifications by Aaron Schmitz, KB0YKI

Construction Details:

1. Cut copper to proper lengths.
2. Flux and solder bottom J Pole section.
3. Cut a 38" piece of 12 gauge wire.
4. Solder a 1/2" coupler on the top J pole section and bottom of the top λ/2 length of pipe.
5. Drill a 1/8" hole into each coupler through the pipe.
6. Strip back 3/8" of insulation on wire.
7. Insert wire ends into holes and solder.
8. Bend wire into a 3/4 circle around pipe with a 6" radius.
9. Insert 1/2" X 4" dowel rod into coupler.
10. Completely seal all areas from moisture. Paint it if you would like.
11. Attach coax and have fun!!

The End-Fed Halfwave Antenna

According to AA5TB

The End-Fed Halfwave Antenna is nothing more then a resonant dipole antenna that is fed at the high voltage point (high impedance end) instead of in the center, which would be high current point (low impedance). This antenna is as old as radio and is probably best known as the Zepp Antenna named after the airship is was commonly used on, Zeppelin. Since in the early days of radio the wavelengths used were very long the antennas were also long. An end-fed antenna that could be trailed behind the airship was much easier to implement then a center-fed dipole or a 1/4 wavelength antenna that required and extensive ground plane to function properly. Amateur radio operators had found that when an antenna was cut 1/2 wavelength on the lowest frequency of operation it could still be end fed at a voltage loop at all harmonic related frequencies. And since all of the amateur radio frequencies at one time were all harmonically related this made an ideal all-band antenna.

The main reason I like the End-Fed Halfwave Antenna is that it makes an excellent portable antenna for the field. I often take my my QRP gear out to the field during camping trips and the less antenna gear I need to bring the better. With the End-Fed Halfwave Antenna all I need is a short (or no) feed line to my coupler, a half wavelength of wire, and a bit of rope and I'm all set. The feedpoint usually ends up near the ground and if I can I prefer to run the wire vertically although I've had very good success with it run out horizontally only about 10' up.

When used as a vertical the End-Fed Halfwave Antenna is ideal because like the dipole antenna, it is self-completing (because it IS a dipole!). That is, it doesn't require a return path or "counterpoise" to properly radiate. This makes it an ideal portable antenna. There are many portable antenna designs in use that really require an extensive ground plane to be efficient, such as the 1/4 monopole or loaded versions of such. Yes, even though the 1/4 monopoles with a few radials will work and often work good, there is no escaping the fact that power is being wasted in the ground and I don't that feel carrying around a bunch of radials is all that much fun.

Now the last statement about this antenna requiring no radials has been debated extensively. In ON4UN's book, "ON4UN's Low-Band DXing" he has modeled the vertical End-Fed Halfwave Antenna and has shown that a radial system with numerous, very long radials will increase the performance of the antenna. He indicates how currents are indeed setup within the ground and losses will occur if radials aren't used. Therefore, he concludes that radials must still be used. I agree with his data but I disagree with his

conclusion. I disagree because the currents that are setup in the ground are maximum at about 1/4 to 1/3 wavelength from the base of the antenna, unlike the 1/4 monopole that has a maximum ground current density right at the base. The other fact is that with the 1/4 wave antenna, this return current in the ground is required for the antenna to function. For the 1/2 wave antenna, the ground current is there simply due to the ground being in the near field of the antenna. The higher you raise the antenna, the less current there will be in the ground. In practice I have found that the vertical End-Fed Halfwave Antenna with no radials outperforms a horizontal dipole at 20' on 20m on short and long paths. Sure, many radials one wavelength long may improve the performance a extra fraction of a dB but if it already works great why go through the trouble during portable operation? Now if you were creating a contest station on your ranch you may want to provide this elaborate ground system.

Others have suggested that one 1/4 wavelength radial should be used to keep the coupler at a low impedance. This might make you feel better about keeping RF at bay near the coupler but in practice I haven't needed it. In fact, if this does make a difference then current must be flowing in this 1/4 wavelength of wire and since there is only one wire it will radiate. I have found that this is usually caused by the antenna not really being an electrical halfwave in length. Having a radiating part of your antenna laying on the lossy ground can't be all that great.

Now there are several ways to feed a End-Fed Halfwave Antenna. These methods can be put into two categories:

1. Tuned circuits using lumped components.
2. Transmission line transformers.

The idea is to convert the very high impedance of the antenna (usually around 5k ohms in real life) down to the relatively low impedance (50 ohms) of the transmission line. Now it should be known that if the antenna was infinitely thin, in outer space, and was exactly resonant no energy could be coupled into this antenna using this method (this is what the physicists will tell you). If things were perfect you would have to couple into the antenna just slightly in from the very end of the antenna. In other words, move the feed point from the very end to a foot or two from the end. This would mean that the antenna would be on one side and a very short return wire would be on the other side. This would present a small amount of capacitive coupling from one side of the circuit to the other and RF current would flow. "Luckily", things are never perfect and this situation almost always exists anyway. Therefore, a small return wire may be necessary although there is usually enough stray capacitance from one side of the circuit to the other to satisfy this requirement without any additional return wires.

When using lumped components a parallel circuit is connected to the end of the antenna and tuned to resonance at the operating frequency. This parallel tuned (tank) circuit also

presents a high impedance and easily couples to the antenna. To step the impedance down to 50 ohms you can use either a small winding around the "cold" end of the main coil in the parallel circuit to use as a primary winding or simply use a tap on the main winding just up from the "cold" end of the main coil. The latter approach is essentially an autotransformer and the tap that presents the lowest VSWR at the resonant frequency is the correct one. A Cushcraft Ringo is another example of this type of antenna. It is essentially using the autotransformer parallel tuned circuit approach but since the frequency is so high the main coil is just one turn of aluminum.

When using a transmission line as a transformer a length of line that is roughly 1/4 electrical wave in length is used. The velocity factor of the line must be taken into account and can vary from one brand or type of transmission line to another. Essentially what we do is use a section of transmission line to transform the high impedance of the antenna (~5000 ohms) down to vicinity of 50 ohms. Then, across the feedpoint we place a short section of shorted transmission (stub) line to finish the transformation. We now have what is best known as a J-Pole antenna. It is often described as a shorted section of a 1/4 wavelength transmission line that is tapped at the 50 ohm point but Gary E. O'Neil, N3GO has done extensive studies regarding this type of feed and his text on the subject is recommended reading. We usually would want some way to ensure the external currents are not coupled onto the coax with some form of a balun although most designs do not incorporate one. J-Pole antennas are very common for VHF/UHF operation although most users don't realize that they are using an End-Fed Halfwave Antenna. I have used J-Pole antennas extensively but I believe Gary can describe them much better then I can.

Here are various methods of feeding an End-Fed Halfwave Antenna

(The return connection can be ground or just enough conductor to present a bit of stray capacitance)

EMPIRICAL RESULTS

During the Lockheed Martin Recreational Association Amateur Radio Club's (whew!) year 2000 Field Day we operated 2A-Battery QRP. We had several wire antennas at our disposal but I would like to give you the EMPIRICAL results of an antenna test that I squeezed in.

On 20m I put up the following two resonant antennas with the following conditions:

1. End-fed vertical halfwave dipole with the bottom up 3' from the ground. A link coupled parallel coil/capacitor circuit for impedance matching to coax. NO RADIALS or GROUND SCREEN.

2. Center-fed (via choke balun) horizontal halfwave dipole up 20' broadside north/south.

3. Same length of RG-58 feedline with losses measured at 1.1dB each.

4. The horizontal dipole was clear of support branches and foliage by several feet.

5. The vertical dipole was clear except that the top couple of feet were thread into the foliage.

6. The antennas were CROSS polarized and separated by at least one halfwave length so mutual coupling should have been minimal.

7. Soil was probably average-good. The ground is normally solid limestone just below the surface but this area probably has top soil sediment from the West Fork of the Trinity River judging by the giant pecan and cedar elm trees.

Now, I have used a horizontal dipole at similiar heights for many years at home and it has always been my a very sure performer, stateside and DX. I didn't expect any better performance without going to a more directional gain antenna or an increase in height. I have used the end-fed halfwave style of antenna for years during my portable excursions and it has always performed well and I have never used radials with it. My expectations were that the vertical dipole would perform better on stations greater then about 2000 miles and that the dipole would perform better on the shorter paths, especially since the peak of its major lobe would be straight up at that height. I was incorrect.

The end-fed halfwave (vertical dipole) routinely outperformed the horizontal dipole on <2000 miles paths by AT LEAST an estimated 6dB except during very short periods of time when the signal would be predominately horizontally polarized. Mysteriously, there

was not as dramatic of a difference on DX signals although the vertical was almost always better.

The dB delta was estimated by S-meter readings on a rig that I had measured to deflect about 1 S-unit every 4dB. The vertical dipole was often better by about 2 S-units so 6dB is probably a conservative figure.

Sprodaic-E propagation was very prevailent during that Field Day and on 20m I was working stations at times only 150-200 miles away on skywave yet the end-fed halfwave was still outperforming the horizontal dipole.

I kept looking for something wrong with the horizontal dipole but could find nothing. What could go wrong with a dipole anyway :-) ?

I admit this wasn't a purely scientific test but I believe it was a reasonable A/B test.

Bottom line...

1. A vertical end-fed halfwave dipole outperformed the tried-and-true horizontal dipole at my Field Day site even though I would not have originally suspected that this would be the case.

2. Radials and a ground screen are NOT required but you may use them to gain that extra fraction of a dB (L.B. Cebik, W4RNL) (QST, July 2000, pg38) if it makes you feel better. There is little current in a ground screen for this antenna until about 1/4 wavelength from the antenna axis, so make your ground screen BIG and carry LOTS of wire. A ground screen may significantly detune a halfwave antenna from resonance since you will be placing a large conductive mass near the high impedance end of the antenna. You may create your own problems. If the antenna is not near a halfwave length, more current will flow near the base of the antenna requiring a better ground screen.

3. I wish I could put one up at my house vertically.

I would like to hear from others who can perform this type of A/B test using skywave signals for the vertical end-fed halfwave dipole versus other field ready antennas. I really did not expect this kind of difference between the horizontal dipole and the vertical end-fed halfwave dipole antenna during portable use and I still would like to have more measurement data.

By the way, we only made about 330 Q's on CW (15/20/40) and 240 Q's on SSB (10/15/20/40) with our solar charged battery operated QRP gear. We could have made more but I spent a lot of CW operating time Elmering some new and potentially new hams about ham radio and this was worth more "points" then the QSO's. I did have one short

rag chew with a station in Tokyo, Japan using the end-fed vertical halfwave.

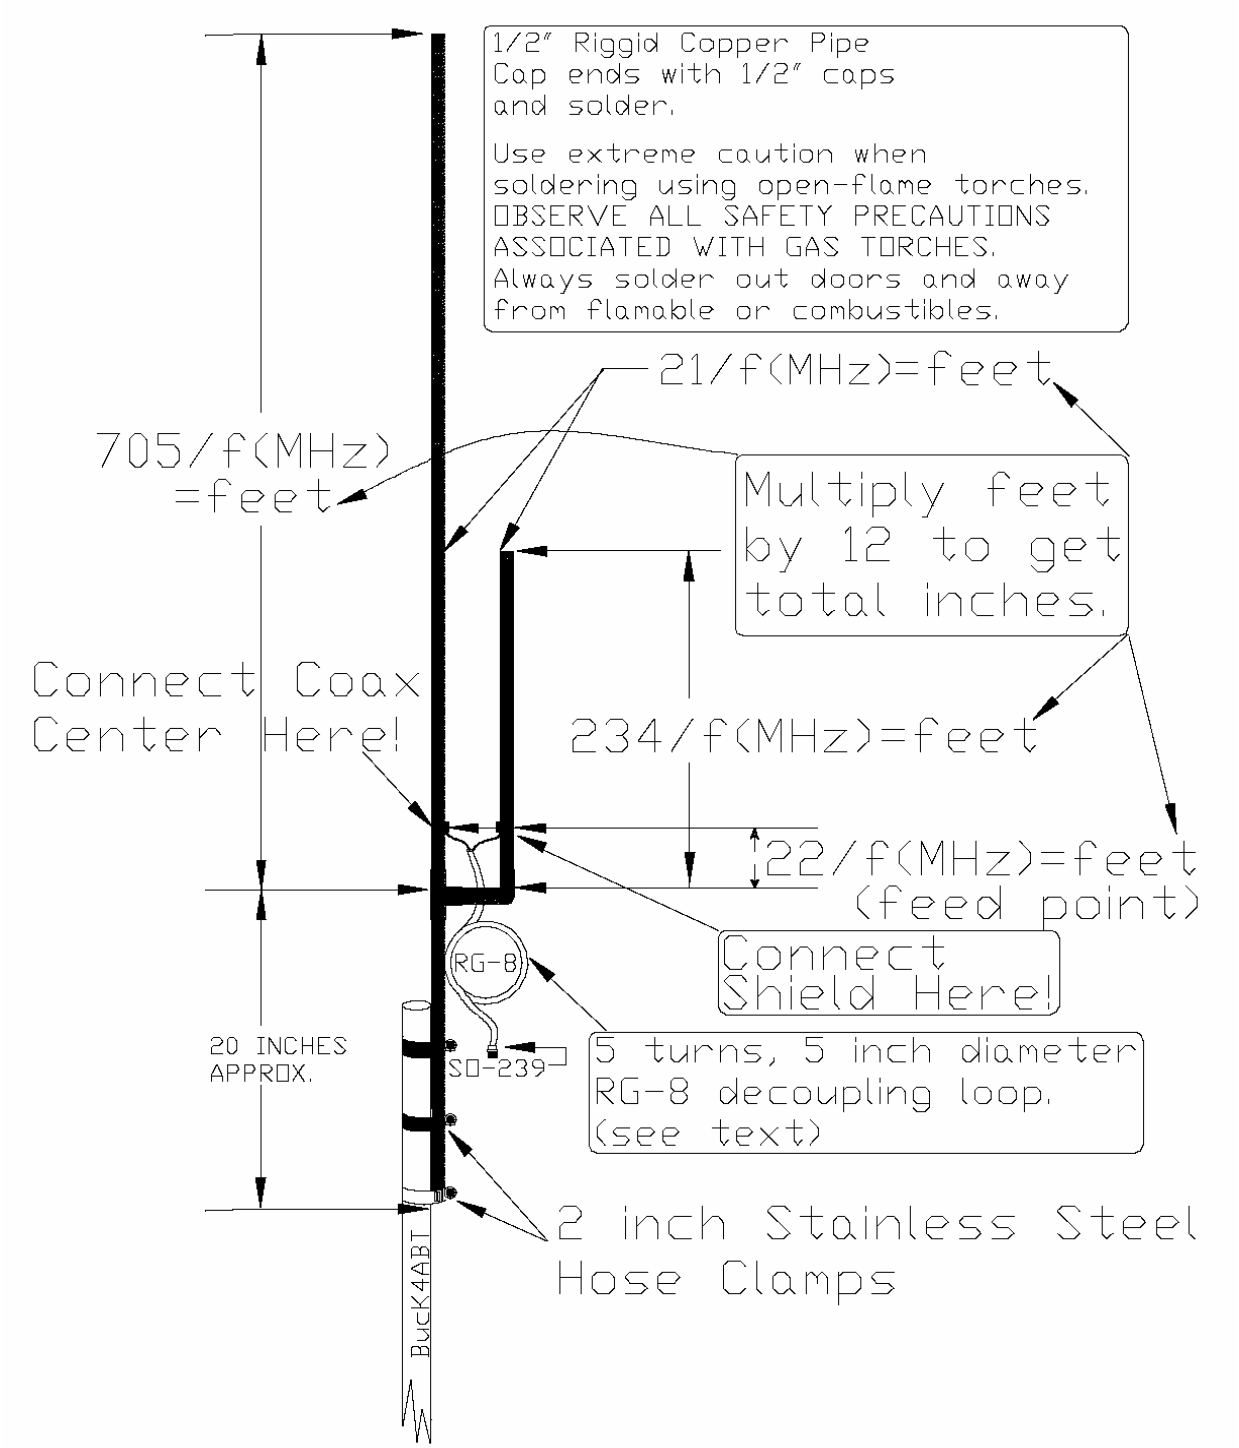
Last updated on May 21, 2004.

On line since July, 1998



Notice how the decoupling loop is formed from a length of the coax coiled into a 5 turn, 5 inch diameter loop. The coil is then attached it to the mast as shown above. For the final touch, attach an SO-239 (female) coax connector; see text.

A more efficient decoupling transformer is available from:

BUX CommCo, at: www.BUXcommCo.com

AN OUNCE OF LIGHTNING PROTECTION:

The shorted matching stub of the J-pole also appears as if it is a short circuit across the antenna terminals of the connected radio or transceiver. There is also and ounce of protection from static discharges via the antenna port even if you don't make a practice of disconnecting your antenna before a storm. To make life easier and, should you ever need to exchange or replace the antenna, you may wish to do as I have. I made up a section of RG-8 coax. I then dressed and tinned one end and inserted it/them under the feed-point hose clamps. I then coiled a length of the coax into a 5 turn, 5 inch diameter coil (the decoupling loop). I attached it to the (metal) mast as shown in **figure 2**. For the final touch, I fitted the (lower) end with an SO-239 (female) coax connector.

To adjust the Vswr to frequency (145.770 MHz for 2 meters or 51.12 MHz for 6 meters) slide the feed point (hose clamps) up or down as required. You should be able to set the VSWR very close to 1:1 (It is best to make the VSWR setting using at least 25 feet of coax between the SWR meter and the J-pole connector). I have a ten foot section of 1 & 1/4 inch pipe standing in my backyard with three feet of it in the ground. I attach the antenna to the pipe using 2 inch hose clamps. A long length of (not coiled) coax allows me to move away from the antenna at least a wavelength while making the VSWR tests. In short; Do not stand near the antenna while testing VSWR.

Having Fun while saving lives with PacketRadio is what we're all about. For more information and illustrations for the J-pole, visit the PacketRadio Networking home pages on the internet at; http://www.PacketRadio.com/jpole.htm

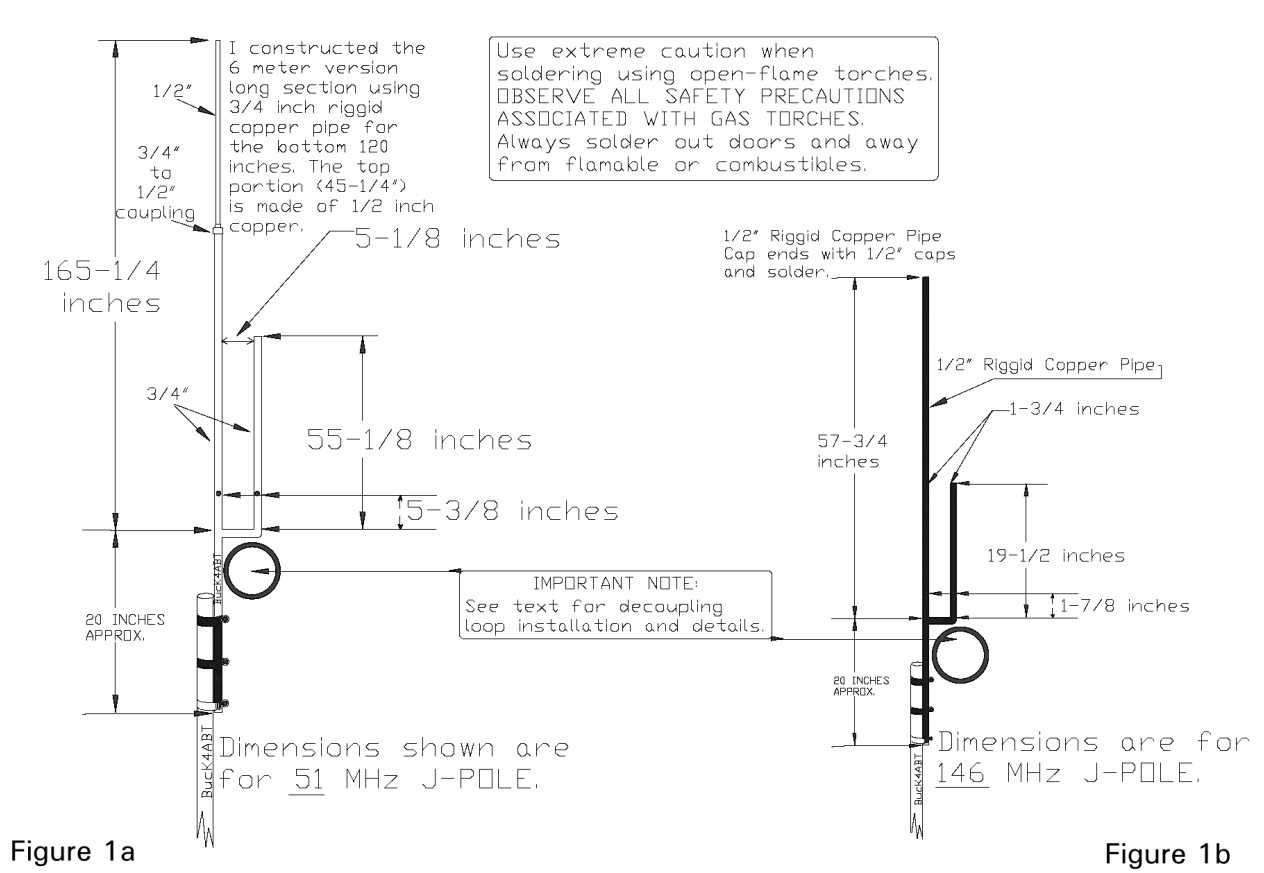

Figure 1a

Figure 1b

Rigid copper water pipe is not as heavy as some might think. Especially when it is only 58 inches long at 2 meters (1a), and when used at 6 meters (1b), a J-pole is about 166 inches long (see text).

To get the correct amount of heat to braze the EMT together, I must use a combination torch/flame that uses oxygen and acetylene gas or a less expensive Benz-O-Matic™ oxygen and MAPP gas.

The latter is available at most Lowe's Building materials for less than 40 dollars ($39.95). The kit comes with enough welding rods to build one antenna. It also comes with two disposable tanks; one of oxygen and one MAPP. The catch is… one canister of oxygen is not enough to finish the job (one 6 meter J-pole). If you ever consider such a project, make sure that you have at least two canisters of oxygen ($7.95 each).
In any case, make sure you are out of doors and away from combustible materials while using this type welding system. ***PLEASE use extreme caution when working with open flame torches of any kind.***

SOME NOTES ABOUT J-POLES:

There are very good reasons why the J-Pole antenna has become so popular in the past few years. They are economical and easy to build. Now that we have the support data, we are finding they are also rugged enough for the more hostile environments that we have at our node and repeater sites, even below 145 MHz... on our 9600 baud backbone at 51 MHz.

The 6 meter J-poles that I've installed on my nodes are exhibiting over 4 db increase in signal strength above the dipoles that were in use on my 9600 baud (6 meter) nodes.

The most recent antenna I replaced with a J-pole was a 2 meter (see figure 1b), aluminum, base station, commercially built, amateur antenna purported to have more than 3 db gain over a dipole. The J-pole I replaced at node K4ABT-7, alias 007 has increased the average signal at fifteen (15) miles by more than 5 db; ENOUGH SAID!

Our J-pole does not have radials! SO WHAT.. well this is what. Without radials, there are antenna (RF) currents that flow along the outer surface of the coax cable shield that introduce VSWR along its length. This kind of RF action tends to corrupt performance of an antenna that has no radials. Two things can happen; RF may be absorbed and hot-spots along the coax shield will raise the VSWR to an unusable level. To prevent this from happening we add a form of decoupling loop just below the feedpoint of the J-pole (see figure 2).

Our decoupling loop is sometimes mistaken for a matching balun. This is OK as it does perform some of the properties of a balun while altering the flow of RF back onto the coax cable shield. In short, this decoupling loop performs by canceling these effects, and creating a balanced to unbalanced matching transformer. Oh, didn't I say that before… the J-pole is a "balanced" fed antenna… the 50 ohm coax that we use to feed it with is "unbalanced," thus we have another reason for adding the decoupling loop… .. OK Lew, … it's a balun.

To make our decoupling loop, for the 6 meter J-pole, let's use a length of the same type coax that we use as the feedline. Make a five (5) turn coil (**4 turns for 2 meters**), five (5) inches in diameter and tape it to J-pole mast, below the feed point(s).

We do this near the point where it connects to the antenna (***see figure 2***). In either case, this five turn, five inch diameter coil serves to isolate the feed line's outer conductor from reflected energy (RF) of the antenna radiating element(s).

To set some of you at ease with the feed point question: I did run some tests on the two ways to feed the antenna…e.g. whether it made a difference if the center conductor were connected to the short tuning stub or longer (radiator) section of the J-pole?

Zig or Zag:

Although there is not a big change in VSWR, let it be known! There is a *pronounced* (***worse***) difference in field intensity when the coax center conducted is attached the short stub of the J-pole; NOT GOOD! Without a lot of fanfare, ... **A RULE**; ***Be sure the coax CENTER conductor is attached to the LONGER SECTION of the J-pole*** and the coax shield attaches to the short section.

SOMETHING TO THINK ABOUT:

All the SNO's who support the Packet habit by supporting a Packet node at a high location knows or has experienced what I'm saying. So while I was atop one my Packet node sites an idea hit me… as Steve N4JTH says… I had a brain.. uh.. "wind-breaker."

Most of the antennas that I have been installing at the new node sites are the copper version of the J-POLE. I've removed most of the fiber-glass antennas and ALL the aluminum composition types and models.

I've learned that aluminum was not intended for use at high elevations, especially where ice and wind wreak havoc on them all winter… or until they succumb to the onslaught of this kind of environment.

I tried the next level of durability in the metallic family; copper. Rigid copper water pipe is not as heavy as some might think. Especially when it is only 58 inches long at 2 meters and when used at 6 meters, a J-pole is about 166 inches long. To make the 6 meter version a bit lighter, and still maintain the durability, I make the bottom 120 inches of 3/4 inch rigid copper, and the final (top section, 45 and 1/2 inches), I make of 1/2 inch rigid copper pipe(see figure 1a). We'll discuss this idea further, a bit later. For the record, I find that EMT makes a great J-pole and I find the same characteristics with 1/2" EMT as I find with 1/2" copper.

LET'S TALK ABOUT THE J-POLE:

The J-pole has, for the most part, been a 2 meter and 70 cm antenna. Matter of fact, the first ones were designed and constructed using 300 ohm, television twin lead (or 450 ohm ladder-line, See Lew McCoy W1ICP J-pole article, JULY 1994). Not many configurations are supportive of building J-poles for frequencies below 144 MHz or for environments that were demanding of a more rugged type antenna.

A few years ago, I replaced a 6 meter **di**pole at one of my Packet node sites (3000 feet) with a six meter **J**-pole (see figure 1a). The first thing I noticed was that instead of just hitting the local 9k6 backbone nodes (those within 50 miles), I am suddenly reaching nodes a hundred miles away.. atop Herndon Mountain in **WEST** Virginia. That is a bit farther than 100 miles. The path is there 95% of the time with the J-pole. The path was there 0% of the time with the old 6 meter dipole.

To help support this data and the use of the more "durable" J-pole, and at frequencies below 145 MHz I received some welcome help at gathering data from **AL (K4ZMC):**

Al Feldman K4ZMC is a long time friend who has been around Packet radio as long as Packet radio has been around. AL installed a 6 meter (copper) J-pole at his "very hostile environment site" above 4000 feet. The node site K4ZMC-7=**MARS** (NO, not on planet MARS.) is near ***Mars*** Hill, NC. Actually, the first antenna went to the 9600 baud backbone node on six meters, K4ZMC-9, alias 9600.

When AL installed the J-pole at node 9600, I had the support I needed to begin compiling data on the performance of the J-pole at six meters… and with Als location being such that it is, it gave support for the durability of the ruggedized version.

Since then, I've begun using three-quarter inch (3/4") electrical metal thin-wall conduit, or EMT as it is called, to construct my 6 meter J-poles. EMT, although a bit heavier, is yet stronger and sustains even stronger winds than the copper version does. I used the EMT version at K4ABT-4=9603 atop Poor mountain SW of Roanoke, VA. The reason I did so here is because I've lost several aluminum antennae at this location, and I felt that I needed to make this antenna a very "beefy" version to handle the high winds and heavy ice loads at this site.

The reason I've not said a lot about the EMT version is because the rigid copper water-pipe version can be built (joints soldered, sweated together) using a single canister, Benz-O-Matic™ propane torch.

This is **not** the case with the EMT version. It must be built using brass compound brazing rods. Thus we have a requirement for a hotter melting flame than a propane torch can produce.

Buck Rogers K4ABT

For association and the record, the ZEPP was one of the early antennas used as a "trailing" antenna behind the Zeppelin (Blimps) of the early forties. Later it was fashioned into an antenna for higher frequencies, and in the seventies, and early eighties the name was changed to the "J-pole" to favor its appearance when constructed as a VHF vertical.

In the late fifties or early sixties, I read an article written by Lew McCoy W1ICP. It was about an antenna called a "Zepp." In his reference the antenna resembled one I had raised called a, "windom." After building Lew's version, I liked its performance better.

Thus began a new era for me, experimenting and building the Zepp (J-pole) antennas. I've since built J-pole antennas that operate on ham bands from 14 MHz all the way to 912 MHz. I've build J-poles of everything from 300 ohm TV twin-lead, 450 ohm ladder line, copper rigid water-pipe and even electrical metallic thin-wall conduit.

As I add new nodes to mountaintops here in Virginia, I often come up with another idea for a future **PACKET USER'S NOTEBOOK** article. For me, finding material for a future PacketRadio column is always easy. There is so much to write about, it's as if there is a never ending supply of fodder just over the next ridge.

This time, I think I have come across something that will be of interest not only to the PacketRadio system node operators, but to the voice repeater operators as well. Especially where the Packet node or voice repeater is situated on a mountain top that is a weather hostile location during the winter months.

Adding a new PacketRadio node or voice repeater is only half the battle. When I talk about "hostile environments," I am referring to the torture that our node or repeater antenna is subjected to during the heavy ice loads, snows, winds, and rain. When we are warm and comfortable in our home, the node or repeater site high on that mountain top may be receiving gale-force winds and the antenna may be slowly loading up with a new layer of radial ice.
My friend Chuck and I were atop one of these mountain tops recently and the wind was coming at us like a cold … no, a frozen knife. The gusts were topping over 50 mph. Now to some, this is not too heavy a wind, but when the wind continues at this clip, hour after hour, the toll on the site usually begins to show signs of wear and tear early on.

The part of our site that takes the worse beating is the antenna. I've tried almost every kind, shape, and model at these sites. At 3000 and 4000 feet, we begin to see damage to the antenna soon enough.

I began thinking; If this is bad here on this lil 3000 foot knob, then ole Fred WB4QOC really has a problem with his node antennas. atop Grandfather mountain, NC (nodes WB4QOC-5 and WB4QOC-6) and Mount Mitchell, NC (nodes WB4QOC-2 and WB4QOC-3). Grandfather mountain is over 5400 feet and Mount Mitchell is the highest point in the USA east of the Mississippi river at 6684 feet.

We do know that winds in excess of 190 mph have been recorded atop Grandfather mountain, but we understand that the equipment used to measure the wind velocity at Mount Mitchell was blown away… pegged out, and burned out the bearings in the anemometer. The first winter that node 6684 was active, he replaced the ISO.. something-another with a stainless-steel whip. It lasted the rest of the season… until it was found in the parking lot of a nearby lodge. It was shot!. Our next try was with a very stubby, quarter inch diameter Wintenna dipole. Dern that thing lasted through the next winter. It must have been a good one… someone climbed up there and took it. We know it was not blown away… wind don't use cable cutters to remove antennas. I think Fred went with a insulated chunk of water-pipe. That is until now.

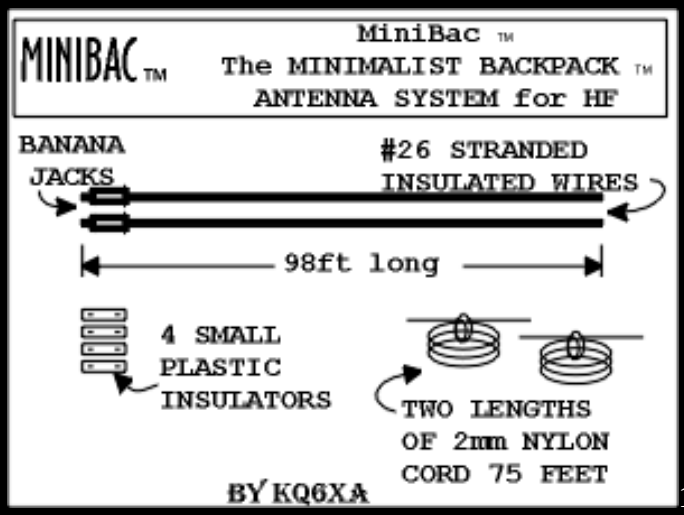
THE MINIMALIST BACKPACK ™ ANTENNA SYSTEM

(C)1999, 2000 BONNIE CRYSTAL KQ6XA

HF Antenna for the Micro-Light Backpacking Enthusiast

SIMPLE CONSTRUCTION DETAILS AND SUGGESTIONS ON VARIOUS FIELD CONFIGURATIONS



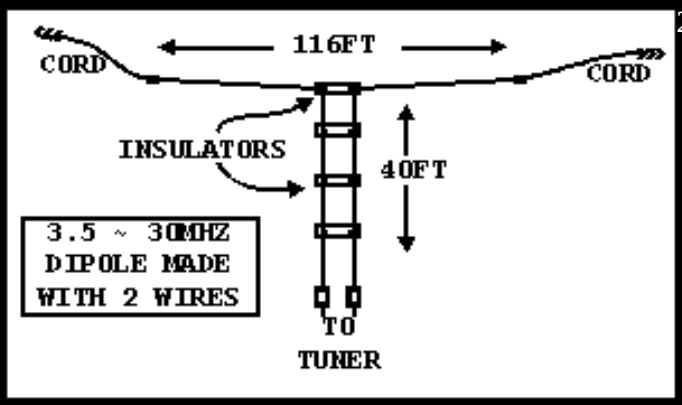
1

MiniBac.

The Minimalist Backpack Antenna System. Designed to be extremely efficient for both weight and radiation.

Components of the Minibac

QTY	ITEM
2	98 FEET, STRANDED COPPER INSULATED WIRE, #26 AWG
2	75 FEET, NYLON CORD, 2mm
4	INSULATORS, LIGHTWEIGHT
2	BANANA PLUGS

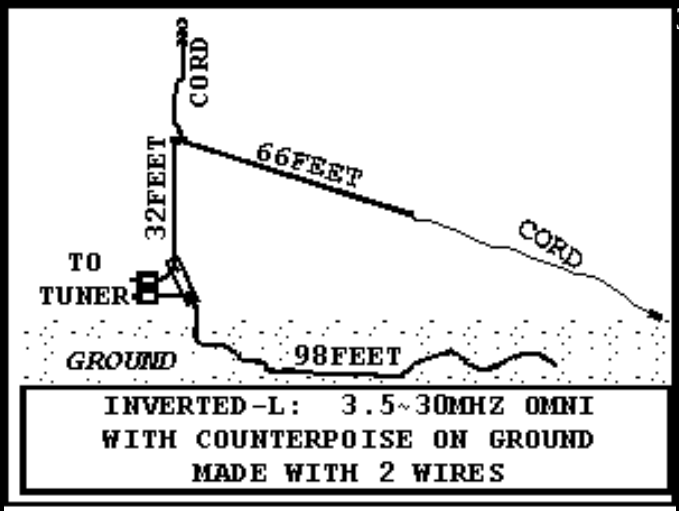


2

Virtually unlimited configurations of the MiniBac are possible. Miniback forms its own feedline, which is quickly assembled in the field to meet the requirements of your site and choice of style. No lossy, heavy coaxial cable, or bulky twin lead is used. Open wire feed makes every precious watt count.

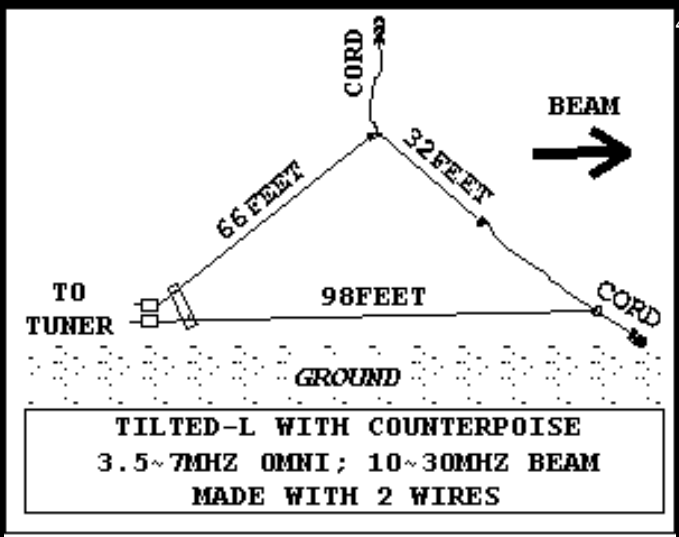
<#2-LEFT: The MiniBac forms a multi-band dipole using 2 supports, or an inverted-Vee with a single support.

3



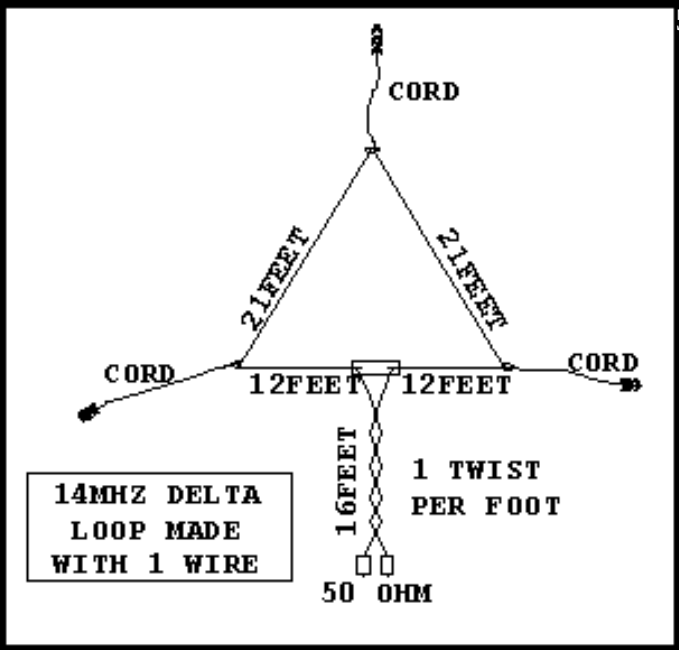
<#3-LEFT: Using a single support, such as a tree or pole, the MiniBac forms an Inverted-L with efficient counterpoise simply laid on the ground using no special alignment. This antenna configuration provides a good omnidirectional pattern, with both low angle and high angle radiation. While a tuner is suggested for multiband operation, no tuner is needed for 50ohm operation on 7MHz.

4



<#4-LEFT: Using a single support, such as a tree or pole, the MiniBac forms a Tilted-L with counterpoise raised above the ground several feet high. The raised counterpoise method provides slightly better radiation effiency. This antenna configuration provides optimum low angle signal on 10 through 30MHz as indicated in the direction of the beam arrow. On 3.5 through 7MHz, it is omni-directional with high angle radiation for communications within about 350mile radius.

5



<#5-LEFT: A single wire of the MiniBac forms a Delta Loop antenna strung from a single support tree or pole. This method provides high efficiency with good directivity on 14MHz, requiring no tuner for 50ohm match. Using the twisted pair feedline, which can be run just above ground level, this configuration may be used with good success on other frequency bands, 18 to 30MHz, but a tuner is recommended. In addition, for 3.5 and 7MHz operation, the remaining MiniBac wire can be laid on the ground as a counterpoise, similar to the #3 Inverted-L, with the Delta-Loop and its feedline used as a vertical radiator against the counterpoise.

Ham radio operators are welcome to homebrew and use the MiniBac for personal and club use. Non-commercial use of the MiniBac name for ham radio in connection with the antenna is authorized. All commercial rights are reserved. Links to this site should direct to the home page. Permission for use of drawings should be requested by email.

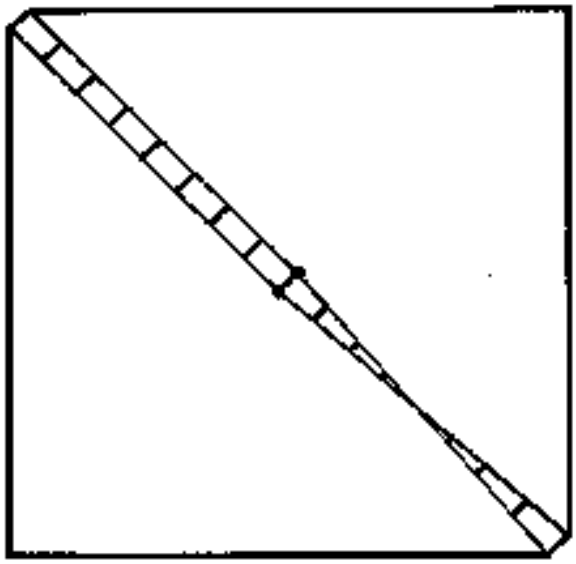
The K6STI Receiving Loop

This relatively unknown antenna does an amazing job pulling weak low band signals out of man-made noise backgrounds

DX SECRET WEAPON



Although it was prominently featured in September 1995 QST Magazine (p.33-41), I believe this antenna has been overlooked by a lot of low band DXers. Perhaps it seems a little too complicated, but I found it well worth the effort it took to design and build one. It is a terrific performer and has greatly exceeded my expectations. This is a low, medium size, horizontal loop with some *very* interesting characteristics. It has an omnidirectional, fairly low angle pattern with a deep overhead null like a vertical, yet it rejects vertically polarized RF energy and responds only to horizontally polarized energy. It offers a 25 to 30dB improvement in signal-to-noise ratio over a vertical for man-made noise. This is often the predominant noise type in densely populated urban and suburban areas. Results often seem magical as signals that are covered by noise on a vertical antenna become perfectly readable upon switching to the loop. A typical antenna is about 21 feet (6.5m) on a side and about 10 feet (3m) high. (Mine has 23ft (7.0m) sides) Height is not important as with Beverages- the antenna works just as well at 5 feet or 50 feet (1.5-15m). It is double-fed with ladder line in diagonally opposite corners to maintain good balance. The feedpoint is at the center of the ladder line. Coax from the receiver is connected through a matching network with a transformer and series resonating capacitor in the secondary, built in a weatherproof enclosure. For a 21 foot loop, there is a small impedance stepdown on 80m and a larger ratio on 160m. The antenna can be built with remote band switching, as I did with mine. It works well on 80 and has been surprisingly good on 160 (I had not expected much.) It is often my best performing low noise receive antenna.

Low band operators who have already used Beverage antennas are nearly always disappointed with the K6STI loop. Beverages will 'spoil' you for any other low noise receive antennas, but many hams do not have room for them. If you want to reduce atmospheric noise and you do have some room for Beverages or phased verticals, both of which are directive, then those antennas would be a much better choice. Likewise, the WA2WVL cardoid loop array provides good directivity over a narrow bandwidth if you have the room- about 80 feet on 80 meters. (QST, August 1993, p.31) The Ewe, K9AY, and Flag and Pennant antennas also provide good directivity in a fairly small space, but with lower receive signal levels. They might benefit from the use of a receive preamp, and so might the STI loop, to a lesser degree. (I do not use a preamp with mine, however). It is a good idea to add a

highly selective tuning network ahead of any preamp to avoid receiver front-end overload. This loop has an omnidirectional pattern and, in theory, it should provide no improvement in S/N for atmospheric noise. K6STI and W6KUT, who built the first loop, noticed an apparent improvement of 1 to 2 S-units even when there was no detectable power line noise present. I have also seen this behavior in my antenna. STI reasons that in populated areas the noise background may consist of many individual man-made noise sources which, in composite, are characterless. Anyone interested in this antenna is encouraged to get hold of the QST article and carefully read and reread it for full understanding. Topband operators might want to consider building a double size loop around 50 feet (15m) on a side if it will be used only on 160m. Matching network component values would have to be adjusted accordingly. Because I do not have room for low band Beverages, the K6STI loop has proven to be a most valuable low noise receive antenna for me.
(Revised and updated 8 Apr 2000)
(Second update 13 Feb 2002)

W7LR tried a 50ft version of this antenna on 160m. He used a "pre-war" Terman handbook (p. 52) to determine that the loop inductance on 160m is about 110uH. He calculated the resonating capacitance at 1830KHz to be 60pF. His transformer was 4 turns, antenna side, and 20 turns for 50 ohm impedance coax. The core was an FB77-1024 ferrite bead. He said it "tuned nicely" (actual resonating capacitance was close to the predicted value). There were no comments as to the actual antenna performance, only that he has tried a lot more receiving antennas since this September 1995 design.

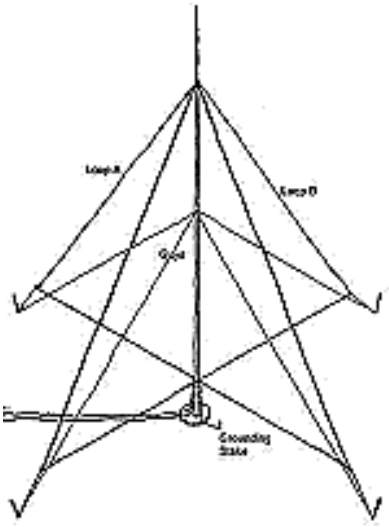
hcdx k9ay loop

K9AY is a loop developed in the early 1990's by American radio amateur Gary Breed (K9AY).
Since then DXers, ham operators and comerical enterprises, all have raved and ranted about this loop, calling it "miraculous", "stunning" and the antenna that beats anything.
While comercial K9AY can be bought at a price, this loop can easily be homemade at low costs.
Here we tell you all about it.



Basic info

K9AY compact loop for lower bands

Gary Breed, K9AY, has taken loop theory farther and describes an antenna that can be erected in almost any back yard and provides performance better than most antennas. *-- Read more --*

Kites and Aerials

Choosing your kite

6.7m fibreglass poles for sale click ***HERE***

Search G3CWI's site

I'm the world's worst kite flier. It's official. I spent most of my childhood running up and down beaches with sticks, cloth and string. I had not got a clue and neither, it seems, had any of my aunts, uncles and other relations. Perhaps it runs in the family?

So, why am I telling you this? The reason is simple, I reckon that I'm uniquely well qualified to talk about the subject. After all, if I can get a kite to work then you will be sure to be able to get it to work better!

My involvement with kites for radio started in 1981. I was getting ready to go off to Antarctica as VP8ANT. Being a great planner, I was thinking about how to make sure that I could get on the air from there and kites came to mind. I think it may have been due to reading that Antarctica was the windiest continent. Anyway, either that year or the year before there had been an article in QST about a new kind of kite. It was called a parafoil. A company called Jalbert Aerotechnology in Boca Raton (?) Florida was making them. I sent off for some information and they sent me a brochure. These kites were not cheap but they did look promising. They have several special characteristics that make them good for aerial work:

- they are very stable in flight
- they fly at a high angle
- they are light and easy to fly
- they have no rigid parts whatsoever to get broken.

The traditionalists use box kites (I think Marconi started that off) but I knew that I would never get one of them into the air!

My kite arrived and I set about testing it. The amazing thing was that I could launch and fly is easily - I have NEVER had to run with this baby. And what's more it performed exactly as the sales literature said. Bliss.

After a while I got to flying it in stronger winds and then on one sad day, the 100 pound breaking strain line broke. Off sailed my kite, landing in a field of wheat. There was no chance of finding it. I wrote to Mr Jalbert and explained that I was hoping to take the kite to VP8 and that his recommended breaking-strain line had broken. By return, he sent me a new kite - no charge. That's good service!

Anyway, some months later, the wheat field got harvested and the harvester driver actually spotted the kite and retrieved it in tact. That was 1981. I have both kites here to this day.

Don't choose a kite that is too big. Mine seems to be about the right size for most aerial applications. The bigger ones will be impossible to handle in anything but a light breeze. Bigger is NOT better here!

So here is the first lesson. Spend some money on a really good kite (a Parafoil) and it will last for a long time and do great service.

Antarctica

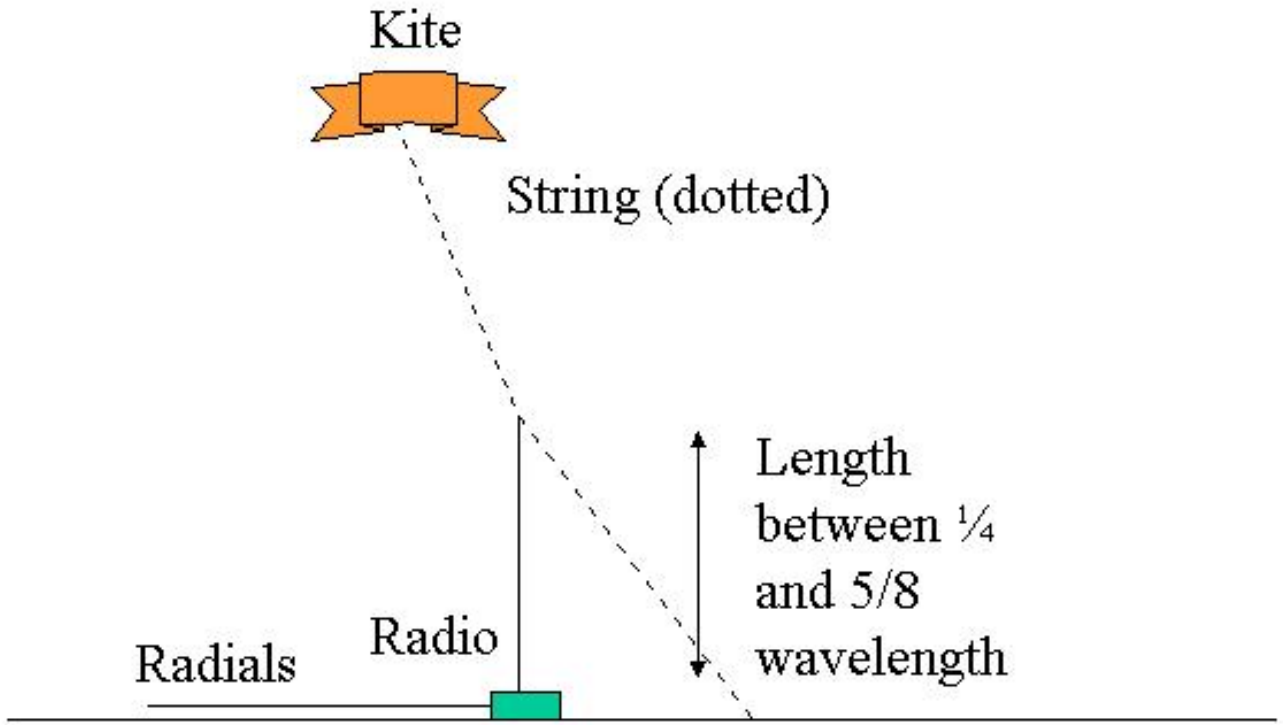
Suitcase packed, off I headed, with my kites in tow. Boy was it windy. I set about trying to break the endurance kit flying record. It was a windy day and I managed about 18 hours before the wind really got up and the string broke again. However, there was not a wheat field for some distance so I managed to get the kite back. Parafoils need the tension of the string to fly. Once the string breaks the fly like a stone. Quite a handy characteristic.

On a field trip. I launched the kite from my sledge and called the base. they were rather surprised to get a call during the day but the kite certainly enabled me to put up a good aerial. I have a picture of this event which I must scan in some time.

I also used the kite to launch an aerial to make some QSOs on 20 metres - reaching back to the UK with just 8 Watts of SSB. So the kite was a success.

Aerial types

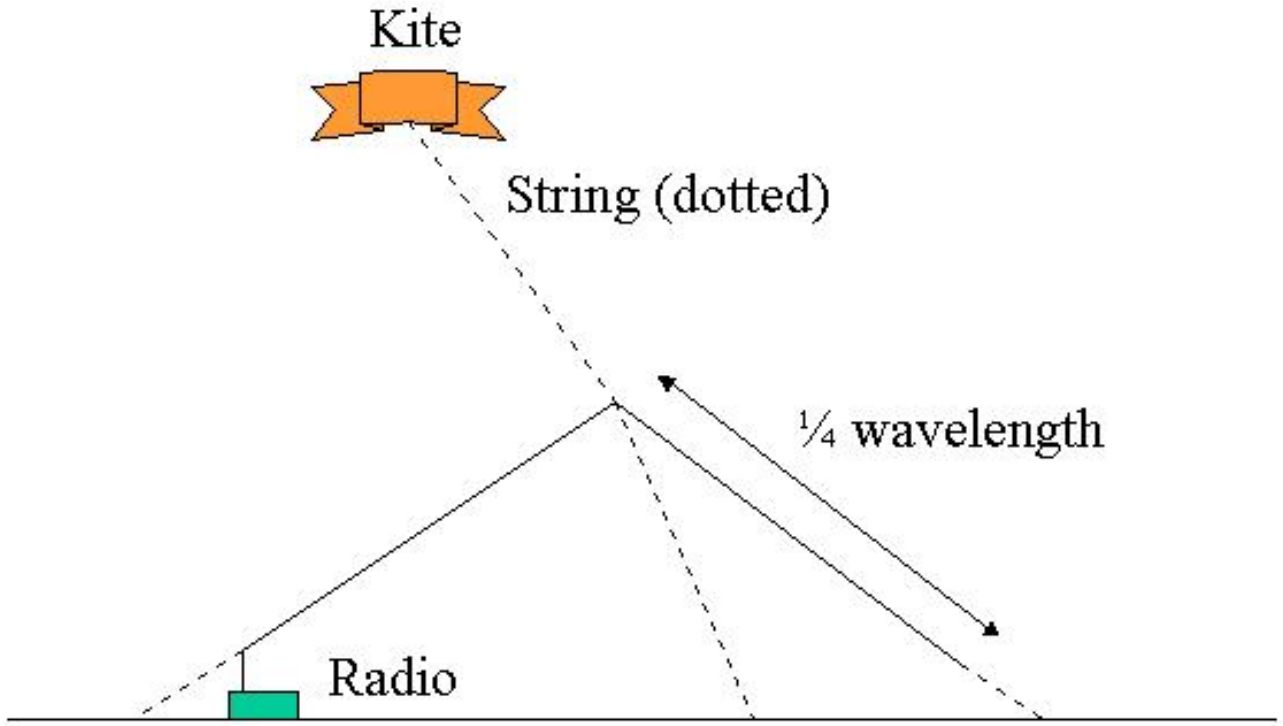
There are several choices. The most obvious is to use an end fed wire as the "string" for your kite. However, as the wind varies, the angle and direction will change (often a lot) which can be undesirable. I tend to hang a wire of the string, about 100 feet down from the kite. This gives a vertical aerial that is much more stable. Add a few radials and a tuner and you're in business.



With two kites, you can be more ambitious and I have flown a large inverted L before. However, my 80m 5/8

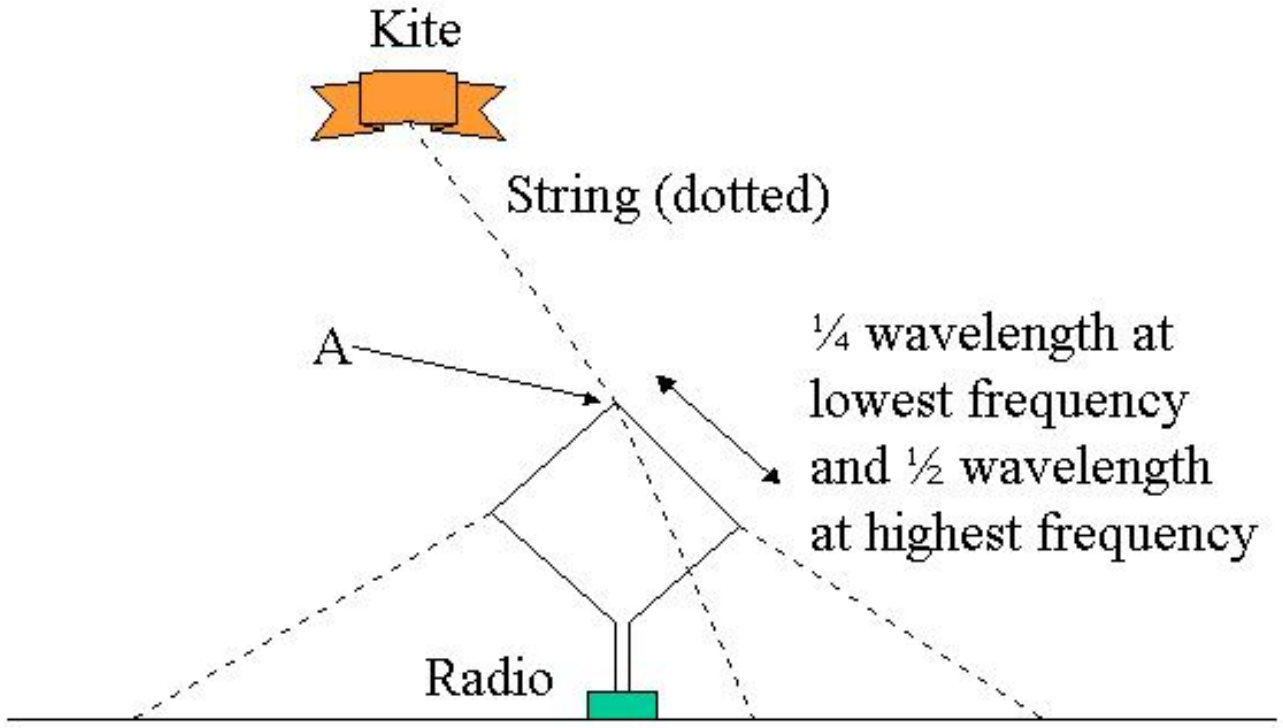
wavelength vertical seems to have been the best performer.

Some further thoughts are to use an end-fed half-wave inverted vee configuration with the feed point at ground level and the current point at the peak of the vee. This would be a good choice for near vertical incidence communications on the lower band and DX on the higher band (say 40m and 20m).



I did a test run of the configuration above on 4th July 2001. The aerials seems to work adequately. The kite needs to be well above the apex of the aerial to be clear of the vortices that exist around hill tops. Aim for 150 feet above the ground before the aerial is attached.

A further option would be a diamond aerial. This can be used on two frequencies (an octave apart) by simply opening or closing the circuit at point A. With a short at point A it would work on the lowest frequewncy (7MHz for example) while an open circuit would allow the aerial to work on 14MHz. This would be a useful scheme for K1 40/20 owners. The loop can be fed with open wire line.



Caution

Avoid power lines. Avoid aircraft (my kite has been up to over 1000 feet). Avoid lightening. Avoid static rain. Any or all of these could get someone killed.

Buying your kite

Jalbert Aerotechnology don't seem to be on the web so perhaps they have gone. There are however other Parafoil manufacturers about.

More general information about parafoil kites here.

Sources of kites on the WWW - **you** judge if they are ok!

Kites for Lifting Antennas

The Weather Service both in the US and abroad, made extensive use of kites for lofting weather instruments in the period from 1880 to 1920. Also kites were tested for man lifting in the same period, for applications like military observer. What was accomplished was just remarkable.

Versions of the winged box kite was the champion in all cases. But that was before the unspared, parafoil kites we have today were invented. The standard was a box kite called the Blue Hill Meterological Box Kite. It had a rectangular section when viewed from the front.

Today, there are special kite stores, so one is not limited to what you can build from plans in books, or the cheap paper diamond kites sold in toy stores. Any good kite store will be loaded with the fancy, and expensive aerobatic kites, but they should also have excellent load lifters, if you know what to ask for and look in the dustier corners:

---

1. **The Classic Box Kite**. This was a standard, considered by some hard to fly. Multicell box kites are complex to build, but work well. Some of the variations include a tetrahydron shaped box kite, but it is mostly good looking, not a good lifter like the classic box kite.
2. **The Winged Box Kites**. Probably the best of the rigid kites. The triangular winged box kite is a great lifter. The French Military Kite, is a classic. Dihedral wings on box kites add to stability and lift. One of the most famous man lifting kites was a several-celled box kite with small wings, the Cody Manlifter. [No, that is not Buffalo Bill Cody, but a person often confused with him, Sam Cody, an early kite/aeroplane pioneer.]. You can even purchase modern versions of the Cody Manlifter in several small sizes. It is an excellent design.
3. **The Parafoil**. A commercial company makes four sizes usually available. The sizes are rated in square feet of area and go from pocket size to a bit less than four feet wide and a bit less than five feet from front to back. They are attractive because they fly at higher string angles than the box kites, more vertical. They pull like a deamon, with the largest size recommending 250 pound test flight chord. They wad up into a stuff sack that is very easy to transport, since they have no sticks or spars.
4. **The Sleds**. In its simpliest form the sled is a flat piece of cloth tied at the right and left side to the bridal, with two spars running from front to back to hold it rigid in one axis only.

The **parafoil** along with the **sleds** have a disadvantage in gusty winds. They will collapse in the air and fall like a rock, all the way to the ground if they do not reinflate in time. The **rigid kites** are far more immune to gusty winds. But they have spars etc, that make them harder to pack, and heavier. Some of the

kites of the 1890's had so many spars, cells, cross supports, braces, etc. that they were as complex as the early aircraft. The Cody Manlifter was very picky about having the fabric tight, thus having curved edges.

The Scott Sled and its variants is a good stable kite that is spared in one direction only, front to back. The Allison Sled is a variant of it. Various versions add vents in assorted patterns which are alleged to increase stability and tolerance for wind variations. For wind measurements I have flown simple tethered sleds in the trade winds for weeks at a time. Our record was nine days that a sled stayed up, staked to the ground, day and night, through land breeze/sea breeze transitions, with no intervention. It was finally collapsed and knocked down by a nasty gusty roller of air. It took seconds to shake it open and relaunch it.

Other kites that are useful as lifters include double triangular winged box kites, Coynes, and even the Malay kite which is the stock diamond shaped kite just about everyone bought at the toy store as a kid and played with. A Malay is certainly easy to build and will loft a small antenna wire, but it is unstable without a drag producing tail, at least when compared to things like winged box kites and parafoils.

One person has made a study of sewing a type of vented sled kite that is kind of a cross between a Scott Sled and a Parafoil. He has flown some very large ones which he has made and used them to do heavy lifting, and launch a squadron of parachuting stuffed bears.

The U.S. Weather Service standardized on the "French Military Kite", a triangular winged box kite. The kite is like a classic box kite, but only with three sides to the box instead of four. It also has dihedraled wings added to one surface which greatly increases its side to side stability. The Weather Service flew trains of these kites to increase lift and stability since they sampled air at multiple levels, much like space diversity receiving. One such train of kites was flown to 27,000 feet! The pull was so great that these trains of large kites were flow on piano wire, a very dangerous practice for the amateur. The Blue Hill Box Kite was another weather bureau standard. It was a large box kite with a rectangular cross section cells about three times as wide as they were high, but otherwise similar to the standard two cell box kite. It had one fore cell and one aft cell with fore/aft spars holding the two cells in alighnment.

On the top of Mauna Kea (13,380 feet) I have flown a small sled through two changes of wind direction and been able to look up and see the kite string make a full spiral above my head as it rose the several thousand feet to the kite itself. The string was very small, but Kevlar with an incredible breaking strength that would slice off fingers before it broke. One weather service report from the 1920's reports a train of kites that made nine revolutions of a spiral as it ascended above an observer through multiple changes of wind directions.

You should not use the antenna wire as "kite string", but support the kite with a flying string and parallel or hang the antenna structure from the flying string. A kite carrying away in a wind with a trailing antenna wire is a dangerous situation. You should make sure that if the kite breaks free, it cannot take the antenna wire with it. One way of helping to insure this, is to use a stouter cord below and through the

antenna bearing section, and a lighter cord above, so if the kite carries way, it is more likely to break off above the antenna section.

Big Kite + Stiff Trades = Major Tension

One last word of warning. If you get a decent large kite, like a six foot triangular box kite or a big size 15 Parafoil, get some serious kite cord, something well over 125 pounds. Also purchase some heavy duty leather gloves with wrist protection flanges on them, like gauntlets. Do not underestimate the potential dangers of flying a large kite in any kind of wind.

These big kites are renouned as lifters for a reason. A large kite needs preparation before launching into any wind regime. A modern ripstop nylon kite in a large size is NOT the toy paper dimestore kite of your youth, flown with cheap cotton twine.

A toy paper kite will tear up in too much wind. The flimsy cotton string used will break easily and is not prone to rope burns, slicing wrists to the bone or popping off fingers at the joints. The flimsy spars of the dimestore kite will snap easily if overstressed. Thus it is relatively safe to fly such a kite.

A kite made of ripstop nylon, carbon filament spars and flown with heavy duty nylon cord is a very different item that must be respected.

The first time you try to hang onto a large parafoil in a stiff 30 mph wind, you will know what I am talking about! Rope burns can happen quickly and cut to the bone or worse. Hand protection is mandatory. Rope burns are terrible. The skin and muscle are "erased" away leaving a deep trench that is slow to heal and very, very painful.

It is well worthwhile to invest in a small parafoil or winged box kite suitable for 40 or 50 pound line and test fly it to get a feel for heavy duty kites. Remember, a kite twice as large is going to have a pull four times as great or more. Also pull goes up with the cube of the wind speed!

The large military kites were flown from special trucks that carried large drum wenches. These kites were only about three times larger than kites easily available at kite stores today and routinely lofted observers to several hundred feet in WWI.

An interesting "target kite" was used in WWII that had a metal rudder on a 10 foot tall Malay type kite with a black aircraft silhouette painted on it. It was towed behind a jeep with an "operator" in the back who used a pair of control lines to manipulate the rudder on the kite. The jeep would go around an oval course while 50 caliber machine gun trainees would blast away at the kite above.

A friend had one of these and we would fly it in Oklahoma from the ground using a 4x4 inch oak wood beam, 6 feet long, as a flight handle. We would stand behind a telephone pole and let the pole take the

strain of the kite on the 4x4 handle and still be able to loop the kite and steer it by rocking the 4x4 back and forth behind the pole. It was impressive to see the divot ground into the 4x4 where it was bearing against the telephone pole.

One report of an experiment with 160 meters raised several interesting points. The objective was to fly a kite next to the ocean and use the Pacific Ocean as a ground plane. It worked extremely well but had two major problems.

1. It picked up literally volts of signal from the local high power AM broadcast stations, blotting out the front end of the receiver. Clearly, unless you are quite far from such a broadcast site or sites, you need to have a carefully built filter box. Probably bandpass with the major rolloff being on the low side of 1.8 Mhz. Possibly even a tunable notch section in the middle as well. Of course the usual static grounding of wind generated static electricity is essential. Any kite antenna MUST have a path to ground. A choke or a high value carbon resistor should work. In the case of a 160 meter antenna, the AM broadcast blocking filter could easily be designed to have as its first component something to provide a DC path to ground.

2. A kite that has fallen into the ocean is a monster sea anchor. Rip tide can make a kite impossible to retrieve. Kites have been built with collapsible harnesses. This is probably a great idea. Basically one examines the harness that holds the kite in the right aspect to the wind stream. Find a critical part that sets the angle of attack. Make this with a link of much weaker string than the rest of the harness and the flight line. Thus a abusively strong yank on the flight chord will break the harness causing the kite to flatten out and stream. Such a harness modification would have made it possible to retrieve the kite in the ocean. Since fancy lifting kites can cost a hundred dollars of more, getting the kite back is a priority.

Finally, consider a 1/4 scale model designed for 40 meters. It will solve a lot of problems and give a lot of experience at much less expense and hazard. Anything for 160 meters is just plain BIG.

One last word, if the kite is big or flow high, you can get into trouble with the Federal Aviation Administration. Here is a sample peek at typical FAA regulations. For most up to date information you should check the FAA's own web pages:

W2IK's LADDER-LINE BACK PACK SPECIAL

GREAT FOR CAMPING OR EMERGENCY COMMUNICATIONS

BOB HEJL - W2IK

1568 HITOMETER

EVER WISH YOU HAD A VERY SIMPLE, LIGHT WEIGHT HAM RADIO ANTENNA THAT COULD BE STUFFED IN YOUR BACKPACK AND DOES NOT NEED A TUNER? HERE IS A SIMPLE DESIGN THAT I BUILT MANY YEARS AGO AND FOUND IT TO BE VERY USEFUL WHILE CAMPING OR FOR EMERGENCY COMMUNICATIONS. IT'S GREAT IF YOU DON'T HAVE THE ABILITY TO TAKE ALONG MY "IK-STIC 2" ANTENNA (TO BUILD THAT ANTENNA, CLICK ON THE RED "IK-STIC 2" TITLE)

WHEN YOU ARE CAMPING, YOU HAVE TO MAKE COMPROMISES. THE SAME IS TRUE ABOUT CAMPING WITH HAM RADIO. USUALLY YOU'LL BE OPERATING ON 20 METERS IN THE DAY AND 40 METERS AT NIGHT. THAT BEING SAID, I DEVISED A VERY SIMPLE ANTENNA IN A SINGLE FORM THAT WILL COVER BOTH BANDS WITHOUT THE NEED FOR A TUNER.

TO BUILD THIS ANTENNA YOU WILL NEED

50 FEET OF 450 - 600 OHM LADDER LINE (NOT TWIN LEAD)
2 THREE INCH PIECES OF 1/2 INCH PVC TUBING
ONE CENTER CONNECTOR (DIPOLE TYPE-WIRE TO SO-239 CONNECTOR)

UNROLL THE COIL OF LADDER LINE AND CUT THE LADDER LINE IN HALF SO YOU HAVE TWO LENGTHS EXACTLY 25 FEET LONG. EACH LENGTH BECOMES A SIDE OF YOUR DIPOLE SYSTEM. AT THE EVERY END OF EACH WIRE, STRIP OFF THE INSULATION EXPOSING ABOUT 4 INCHES OF BARE WIRE. ON ONE SIDE OF EACH LADDER LINE TWIST THE BARE WIRES TOGETHER AND SOLDER ONE END OF EACH LADDER LINE TO THE WIRES ON THE CENTER CONNECTOR.
(SEE PICTURE BELOW)

AT THE OTHER END OF EACH OF THE LENGTHS OF LADDER LINE, TAKE ONE PIECE OF 1/2 INCH PVC TUBE AND SLIDE THE WIRES THROUGH 1/4 INCH HOLE DRILLED NEAR ONE END OF THE PVC TUBE. PULL THE PVC AROUND SO YOU CAN CONNECT THE WIRES TO EACH OTHER AND SOLDER THEM TOGETHER.
(SEE PHOTO OF THE END INSULATOR BELOW)
DRILL ANOTHER 1/4 INCH HOLE ON THE OTHER END OF THE PVC TUBE SO YOU CAN HANG THE DIPOLE SYSTEM UP USING NYLON CORD.

THE SPECIAL CUT

NOW JUST ONE MORE THING TO DO. IN ORDER TO MAKE THIS A 40 AND 20 METER ANTENNA, YOU NEED TO MEASURE 16.4 FEET FROM THE MIDDLE OF THE CENTER CONNECTOR AND ON ONE WIRE OF EACH SIDE OF THE LADDER LINE YOU WILL CLIP OUT A 1/4 INCH SECTION OF WIRE. IF POSSIBLE, CLIP THE SECTION OUT WHERE THERE IS A SEPARATING PIECE OF THE LADDER LINE WEBBING SO THE ANTENNA WILL BE PHYSICALLY MORE STABLE.

THIS WILL LEAVE YOU WITH TWO ANTENNAS IN ONE SYSTEM. ONE ANTENNA'S TOTAL DIPOLE LENGTH IS 32.8 FEET (16.4 FEET ON EACH DIPOLE LEG) OR A 20 METER DIPOLE, AND THE OTHER IS THE 40 METER DIPOLE AS THE WIRE IN LADDER LINE YOU DIDN'T CLIP WILL NOW RUN THE ENTIRE LENGTH OF EACH SIDE, CONTINUE AROUND THE END INSULATORS AND CONTINUE IN A HAIRPIN RUN AROUND TO THE OTHER (LOWER) SIDE OF THE LADDER LINE ON THAT SAME SIDE MAKING A LENGTH OF ABOUT 66.8 FEET TOTAL OR 33.4 FEET ON EACH LEG (LESS THAN THE MATH OF JUST ADDING AND SUBTRACTING BECAUSE YOU LOST LENGTH WHEN YOU SOLDERED THE WIRES THAT ARE IN THE END CONNECTORS) THIS IS FINE FOR A 40 METER DIPOLE.

THERE IS JUST A LITTLE INTERACTION WITH THE TWO ANTENNAS SO CLOSE TOGETHER. IF YOU WISH TO BE REALLY FUSSY, YOU MAY WANT TO DO THE WIRE CLIP ACTION AND CHECK THE TUNING USING AN ANTENNA ANALYZER. IF THIS IS THE CASE, DO NOT CLIP OUT A 1/4 INCH PIECE YET, JUST CLIP THE WIRE, MEASURE THE SWR WITH THE ANTENNA HUNG AND MAKE ANY CORRECTIONS (DO THIS BY RESOLDERING THE CUT YOU MADE AND MAKE ANOTHER CUT DEPENDING UPON THE ANTENNA'S RESONANT FREQUENCY). ALTHOUGH THIS ANTENNA IS NOT AS EFFICIENT ON 40 METERS AS A DIPOLE STRUNG OUT INSTEAD OF FOLDED, I HAVE USED THIS ANTENNA ON MANY OUTINGS WITH GREAT RESULTS AND IT IS MORE CONVIENT TO PUT UP OR STORE. YOU CAN EASILY COIL IT UP AND STORE IN YOUR BACK PACK. IT CAN BE PUT UP AS A DIPOLE, SLOPER OR INVERTED "V". MAKE SURE YOU HAVE NON-CONDUCTING CORD TO HANG IT UP. AND BY THE WAY, SINCE THE 40 METER SECTION LOOPS AROUND, ALL YOU NEED IS 52 FEET BETWEEN TREES TO HANG THIS ANTENNA AS A DIPOLE!!!

LADDER LINE ANTENNA COILED UP FOR STORING IN A BACK PACK SO IT CAN BE USED WHILE HIKING OR CAMPING

Not Everything Good is New: The Expanded Lazy-H

L. B. Cebik, W4RNL

Very effective antennas do not have to be exceptionally large or expensive. The latest designs and construction methods have their advantages--and also their costs. They tend to obscure some older designs of high merit as we forget to remember them.

Rotatable antennas are very effective, but for those unwilling or unable to put a tower, rotator, and sizable aluminum structure in the air, fixed position wire arrays can provide excellent gain. Most designs are bi-directional, but the side rejection is often sufficient to eliminate most QRM. If we have the trees or the poles to support the ends, and if we take the trouble to align the antenna in the most favorable directions for our intended operation, a wire array can work wonders. For example, a great circle drawn through my QTH in Tennessee with one end in VK-ZL land will have its other end in Europe. A bi-directional array might be just the ticket for much of my operating.

Many broadside arrays are flat-tops--that is, they require at least two wires with considerable horizontal space between them. For most purposes, I would need 4 supports. However, a design that has been around since wire became popular is the Lazy-H, a vertical stack of two wires fed in phase. The standard Lazy-H consisted of two 1 wl wires spaced 1/2 wl apart and elevated so that the lower wire was 1/2 wl above ground.

John Schultz, W2EEY, wrote in the November, 1968, *CQ* of the "Expanded Lazy-H Antenna." Bill Orr, W6SAI, recalled this antenna in one of his many columns during the 1980s. Another 15 years has gone by, so let's recall this effective array one more time. The key to expanding the Lazy-H is to increase both the horizontal and vertical dimensions by just a little bit.

If we increase the wire lengths from 1 wl to 1.25 wl, we have stacked extended double Zepps in our Lazy-H. The effect is to give us a bit more gain per wire and a significant amount more from the pair. Then, if we increase the spacing from 1/2 wl to 5/8 wl, we achieve approximately the maximum stacked gain possible with two simple wires.

Now, let's build one of these expanded Lazy-Hs for 10 meters.

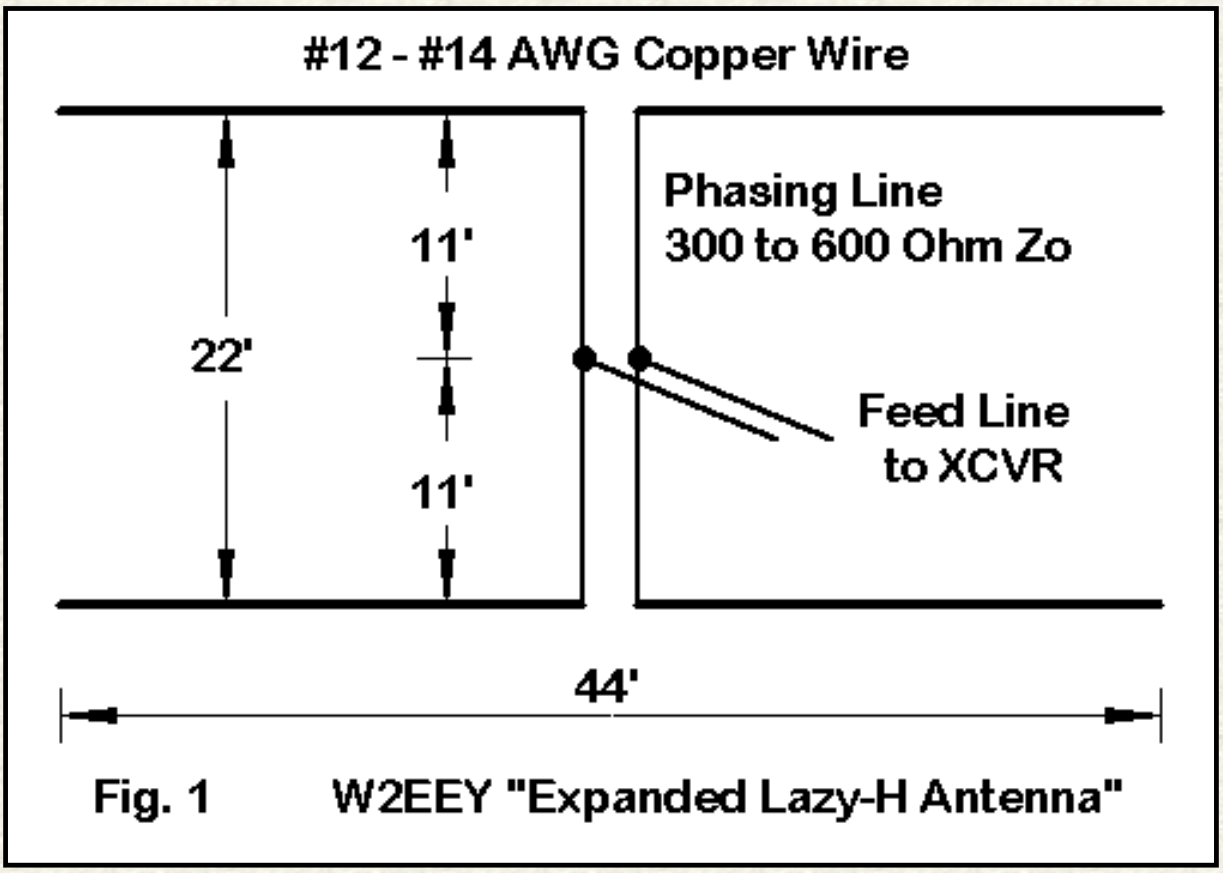

Fig. 1 W2EEY "Expanded Lazy-H Antenna"

Fig. 1 shows the antenna outline. For 10 meters, a length of 44' per wire is satisfactory and not critical: 40' to 50' will work, but the pattern on 10 meter begins to split up as we lengthen the antenna too far beyond 1.25 WL. Vertical spacing between the two wires need not be too fussy, but the recommended 22' gives us not only 5/8 wl at 10 meters but a usable spacing at other frequencies.

The recommended minimum of 1/2 wl at 10 meters is a bit low for optimal performance. I would recommend that a lower-wire height of about 44' be used, which places the top wire at 66' up. Lower heights will reduce the gain and elevate the TO angle from the figures I shall present as we think about this simple array.

The mechanical beauty of the Lazy-H design is that it requires only two supports--although fairly tall ones. The electrical beauty of the antenna is that it provides excellent bi-directional performance from 10 meters through at least 17 meters, with good performance down to 30 meters. It can also be pressed into service on 40 meters without much difficulty.

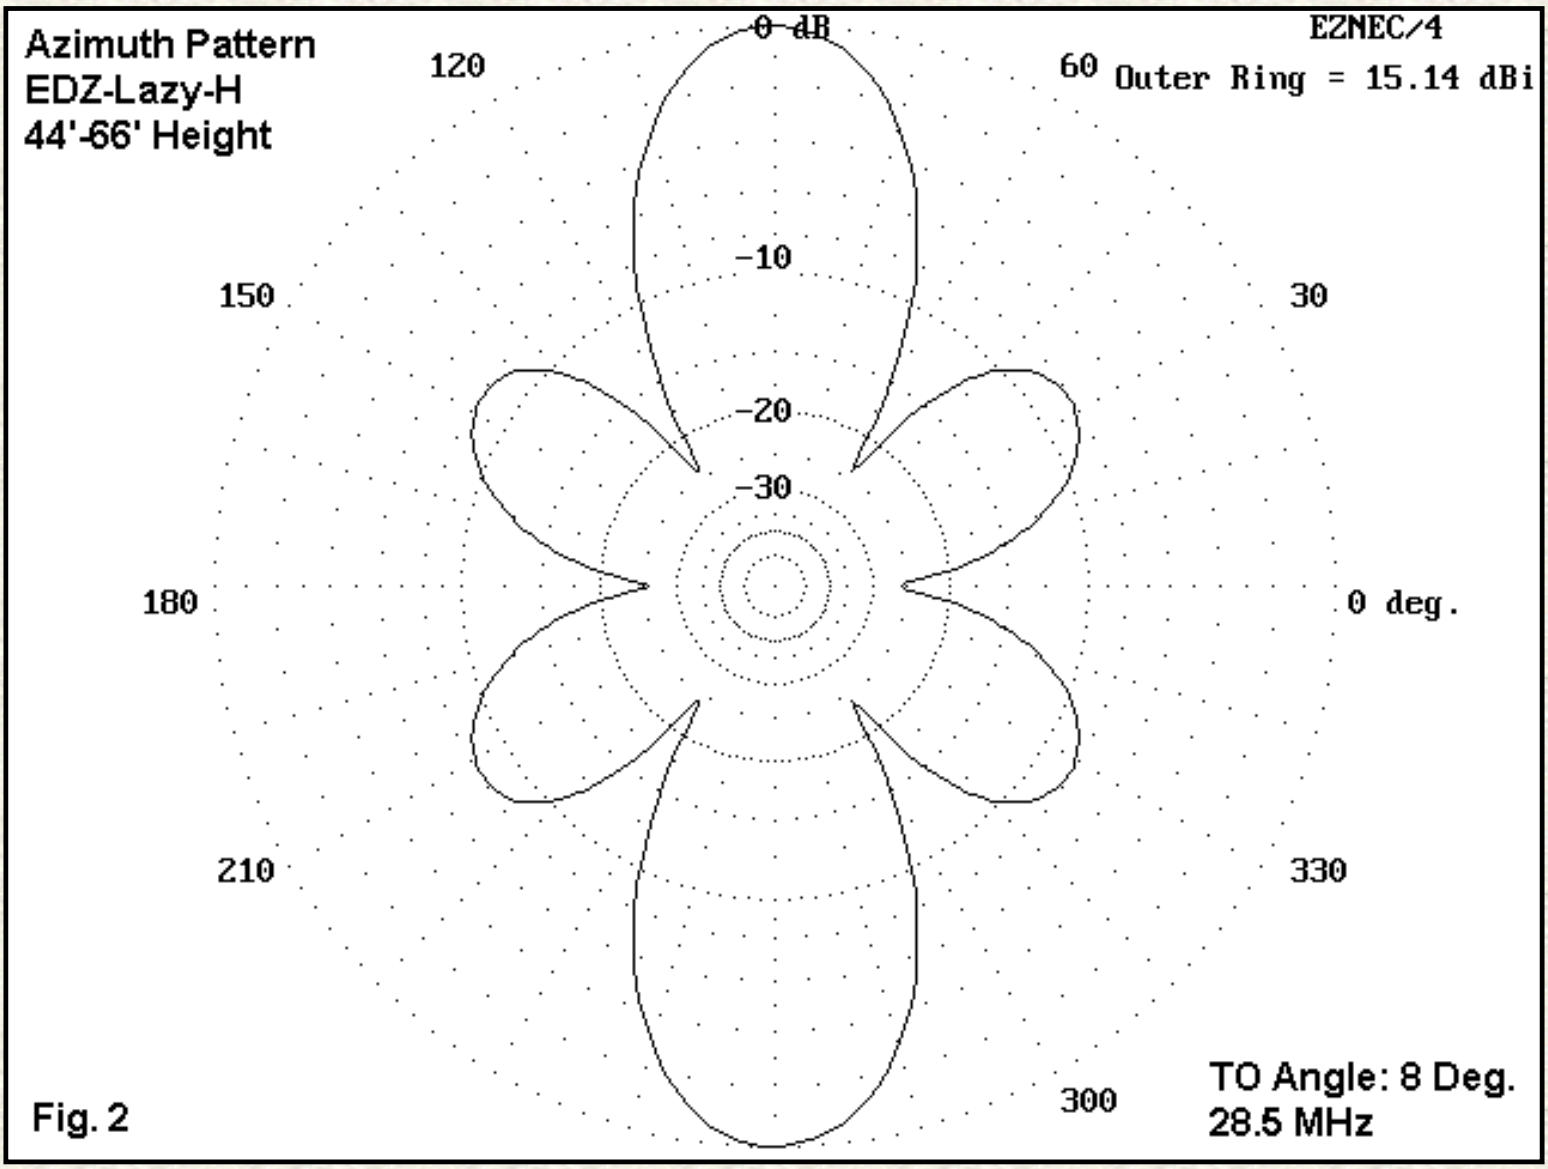

Fig. 2 shows the azimuth pattern of the antenna on 10 meters at an elevation angle of 8 degrees. The phase-fed array still retains the EDZ "ears." These ears are the beginnings of the multi-lobe pattern that emerges as the antenna wire length grows toward the 1.5 wl mark.

On all bands below 10 meters, the length of the antenna is under the EDZ mark, so the pattern is bi-directional with single lobes each way. In fact, at 15 meters, the antenna becomes a standard Lazy-H: two 1 wl wires spaced 1/2 wl apart vertically.

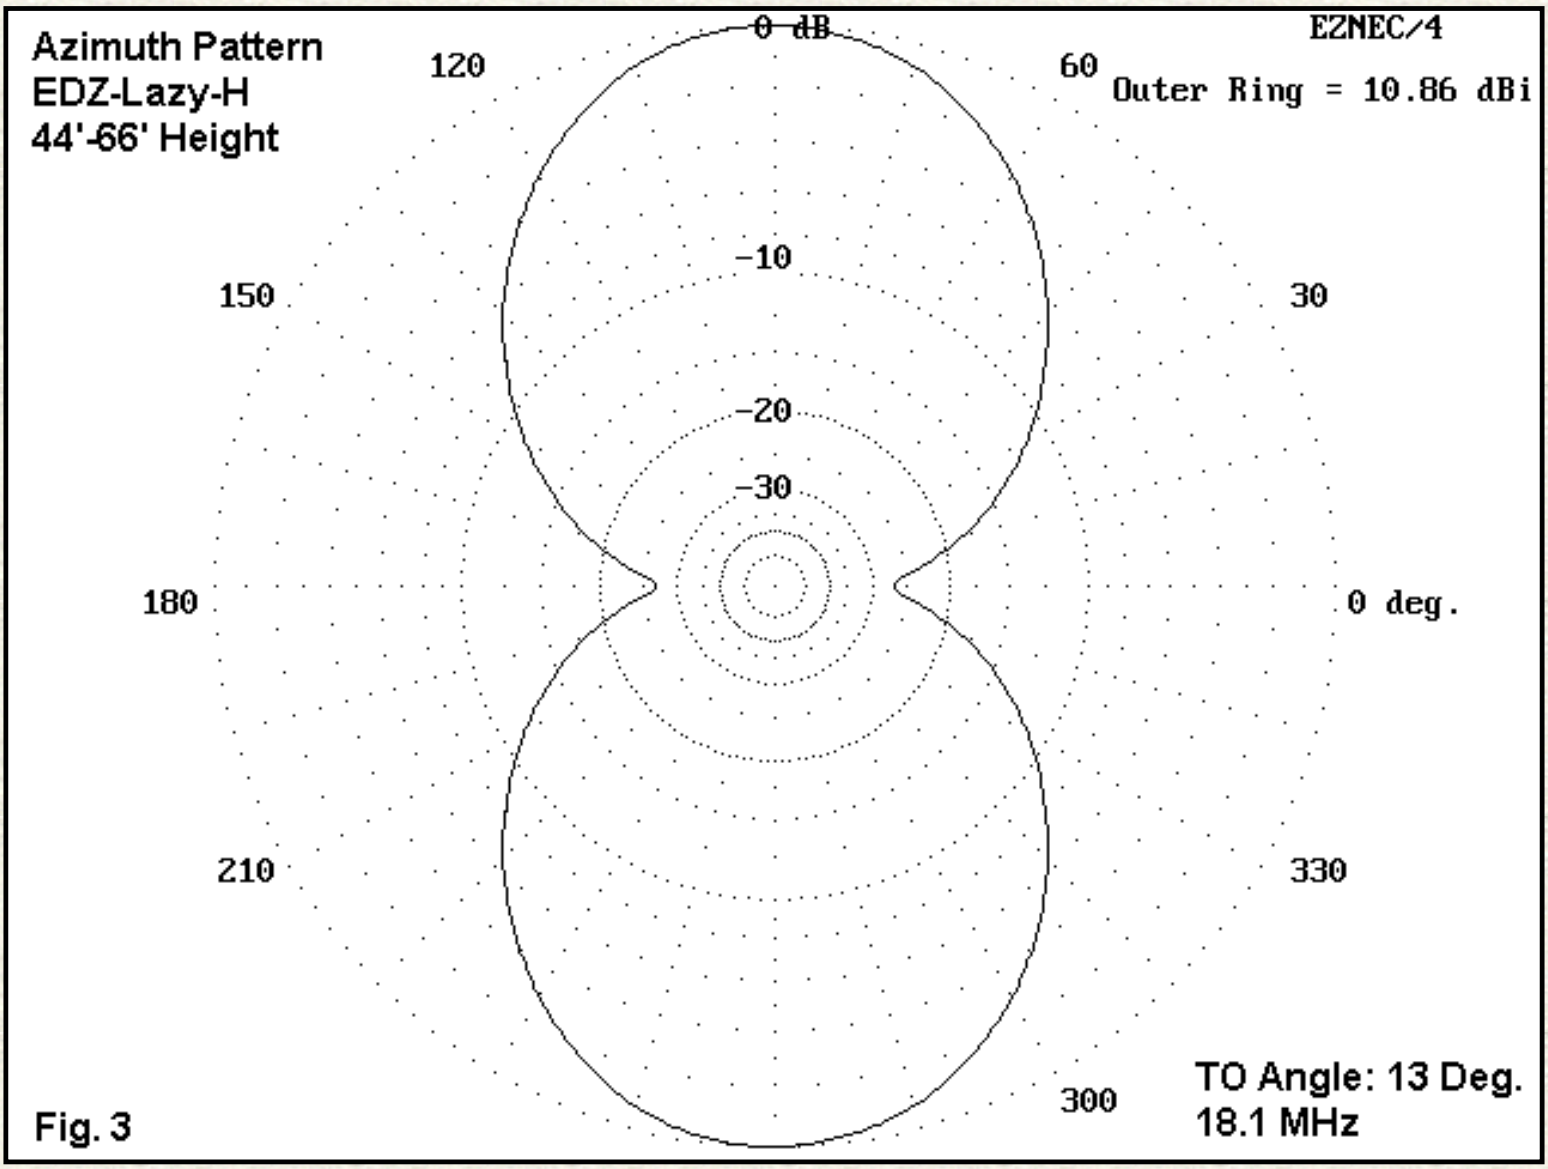

Fig. 3

In **Fig. 3**, we see the 17-meter pattern at its elevation angle of maximum radiation of 13 degrees. As the tables below will show, the lobes become wider as we reduce frequency and narrower as we increase frequency.

For a more systematic view of anticipated performance on all of the possible bands on which we might use this one Lazy-H, here is a table of modeled performance over average ground, with the lower wire 44' up. The table lists the usual gain and TO angle data, but also adds numbers for the vertical and horizontal beamwidths between the -3 dB (half-power) points. This date is useful in determining the azimuth coverage of the antenna in each direction and in estimating the elevation angles to catch the skip for varying circumstances.

Freq MHz	Max. Gain dBi	TO angle degrees	Vert. BW degrees	Hor. BW degrees
28.5	15.1	8	9	31
24.9	14.6	10	11	41
21.2	12.5	11	12	52
18.1	10.9	13	14	61

14.15	9.0	17	18	73
10.1	8.1	24	27	85
7.15	6.4	33	44	99

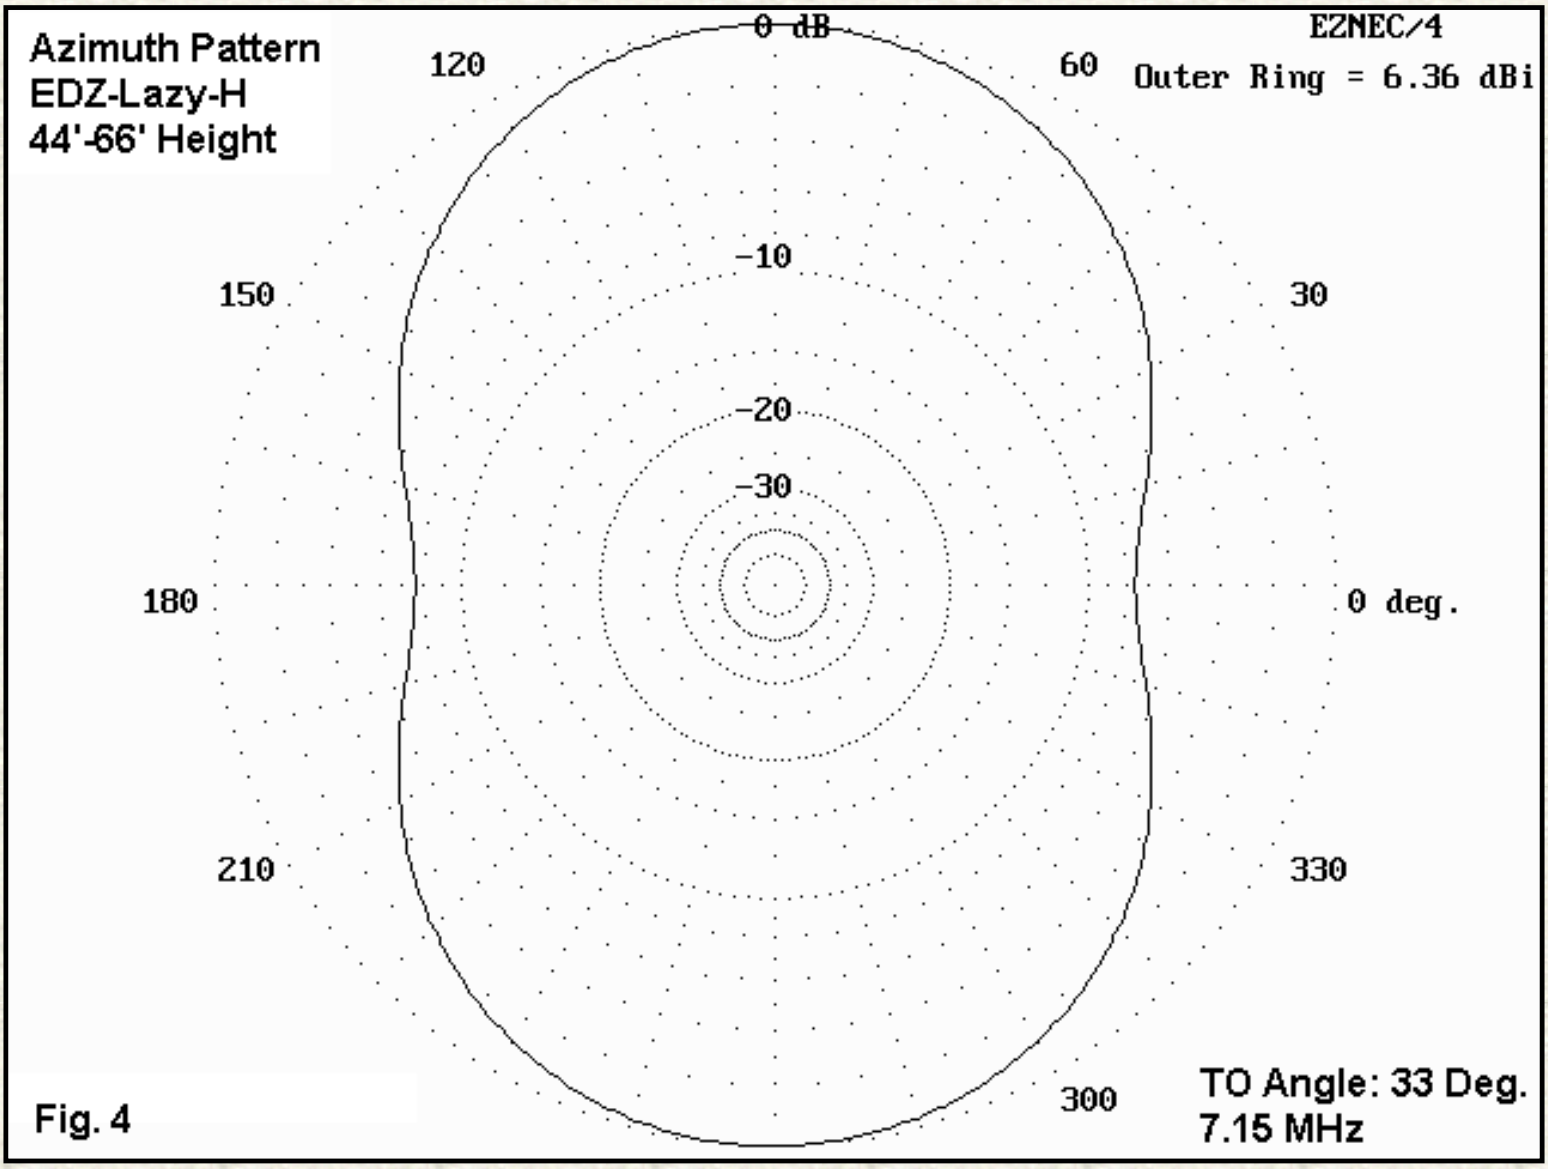

Fig. 4

By the time the antenna's operating frequency is lowered to 40 meters, the pattern becomes a broad oval with a fairly high TO angle, as shown in **Fig. 4**. However, sufficient radiation occurs at lower angles to make it usable for general purpose communications on that band.

How good is the antenna's performance? I could use any number of comparators here, but the simplest would be a single 44' wire placed 66' up in height, the same height as the top wire of the array. The usefulness of this comparison is that it helps reveal something of the array's characteristics.

Freq MHz	Max. Gain dBi	TO angle degrees	Feedpoint Z R +/- jX Ohms
28.5	10.5	7	150 - j 695
24.9	10.4	8	620 - j1700
21.2	9.0	10	4200 + j 850

18.1	8.6	12	835 + j1560
14.15	7.7	15	190 + j 490
10.1	7.6	20*	56 - j 105
7.15	7.0*	29*	24 - j 600

The starred gain entry for 40 meters indicates that the single wire at this frequency shows more gain than the array (by about 0.6 dB). In the TO angle column, the starred entries indicate that the single wire shows a significantly lower angle than shown for the array. Both phenomena are related. The array elevation angle of maximum radiation is a composite from radiation from both wires, with the lower wire radiation raising the angle of the final composite pattern. The difference is slight until the very lowest bands on which we might press this antenna into service. On 40 meters, the lower wire is just over 1/4 wl above ground, so that it raises the overall pattern angle of the array by a goodly amount and provides slightly less gain than the single wire that is about 1/2 wl up.

From 20 meters on up, the Expanded Lazy-H shows good gain over a single wire. The benefits increase the higher one goes in frequency, up to the break-up of the pattern when the wires are longer than 1.25 wl. It is certainly possible to scale the antenna for maximum benefits at a lower frequency, but that lower frequency of maximum gain will become the highest frequency at which one can use the array and still have a bi-directional pattern with a single main lobe off each side of the wires.

The single 44' wire also shows a wide variation in feedpoint impedance according to the length of the wire. The 10-meter value is typical for an EDZ. The 15-meter value is also typical, but of a 1 wl center-fed wire. Parallel feeders and a highly competent antenna tuner would be needed for this antenna. However, careful analysis of the impedance excursions along the chosen feedline can minimize the chances that the tuner antenna terminals will see either a resistance or a reactance value outside its range of adjustment.

So far, I have given no figures for the feedpoint impedance of the Expanded Lazy-H. The two elements in Fig. 1 are fed in phase by the simple expedient of using equal lengths (11') of line to a center point to which we attach the parallel feeders going to the antenna tuner. There are two controllable variables that will affect the feedpoint impedance at the junction with the main line to the shack. One is the length of the lines, which we have set at 11' each. The other is the characteristic impedance and velocity factor of the phasing lines. I shall not here explore other phasing line lengths, but instead shall show some anticipated feedpoint impedances for each band using three different phasing lines. One will be a 450-Ohm, 0.95 VF line, typical of windowed vinyl-covered lines. Another will be 300-Ohm, 0.8 VF line, typical of good quality TV line. The third will be 600-Ohm, 1.0 VF line, which might be bought or built from wire and spacers.

	Feedpoint Impedance (R +/- jX Ohms)		
Freq	450-Ohm	300-Ohm	600-Ohm
MHz	0.95 VF	0.8 VF	1.0 VF
28.5	65 + j 425	115 + j 570	105 + j 610
24.9	17 + j 115*	11 + j 140*	30 + j 140
21.2	22 - j 15*	10 + j 38*	40 - j 50
18.1	45 - j 125	16 - j 26*	90 - j 230
14.15	385 - j 395	75 - j 150	1050 - j 350
10.1	50 + j 105	40 + j 65	50 + j 155
7.15	10 - j 95*	6 - j 80*	13 - j 90*

Starred entries represent very low resistive components to the feedpoint impedance which might present larger excursions along whatever line is chosen as the main feedline to the shack. Note that the starred entries are fewest with the 600-Ohm phasing line. Once more, it is worth noting that these numbers are derived for general guidance from models. Variations will emerge from the actual construction of the antenna and from conditions and clutter at the antenna site.

One question that almost always emerges with respect to comparing the single wire and the array gain figures for 10 meters is this: how can the array deliver over 4.5 dB gain over the single wire? The answer is straightforward if we compare elevation patterns for the two antennas. **Fig. 5** tells the tale.

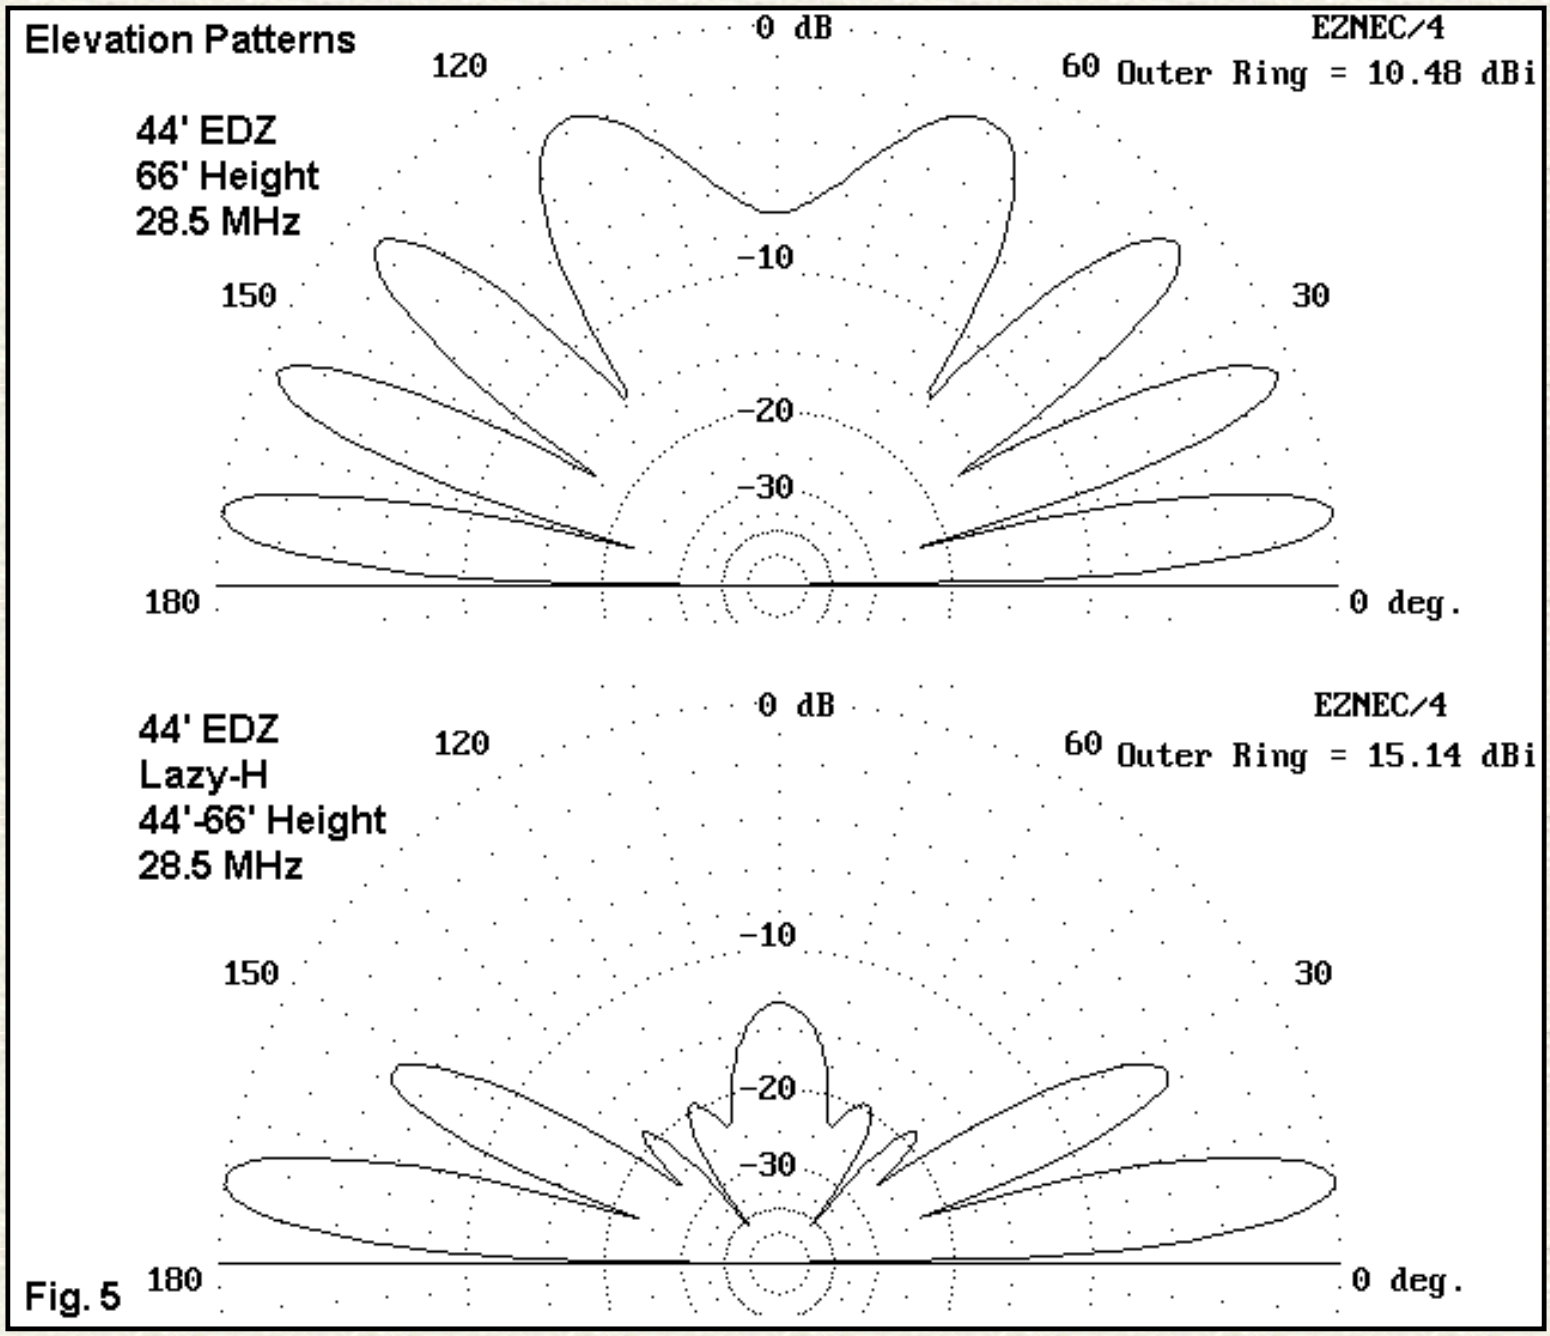

Fig. 5

Like any single-wire antenna, the EDZ at 66' on 10 meters shows an array of nearly equal-strength vertical lobes: 4 to be exact. In contrast, the upper lobes of the Expanded Lazy-H are suppressed leaving a single dominant lobe and a secondary lobe well over 4 dB weaker. All other lobes are down by 12 dB or more.

The array tends to waste far less power at very high angles of radiation compared to the single wire. This comparative pattern, with variations, tends to hold true down through 20 meters.

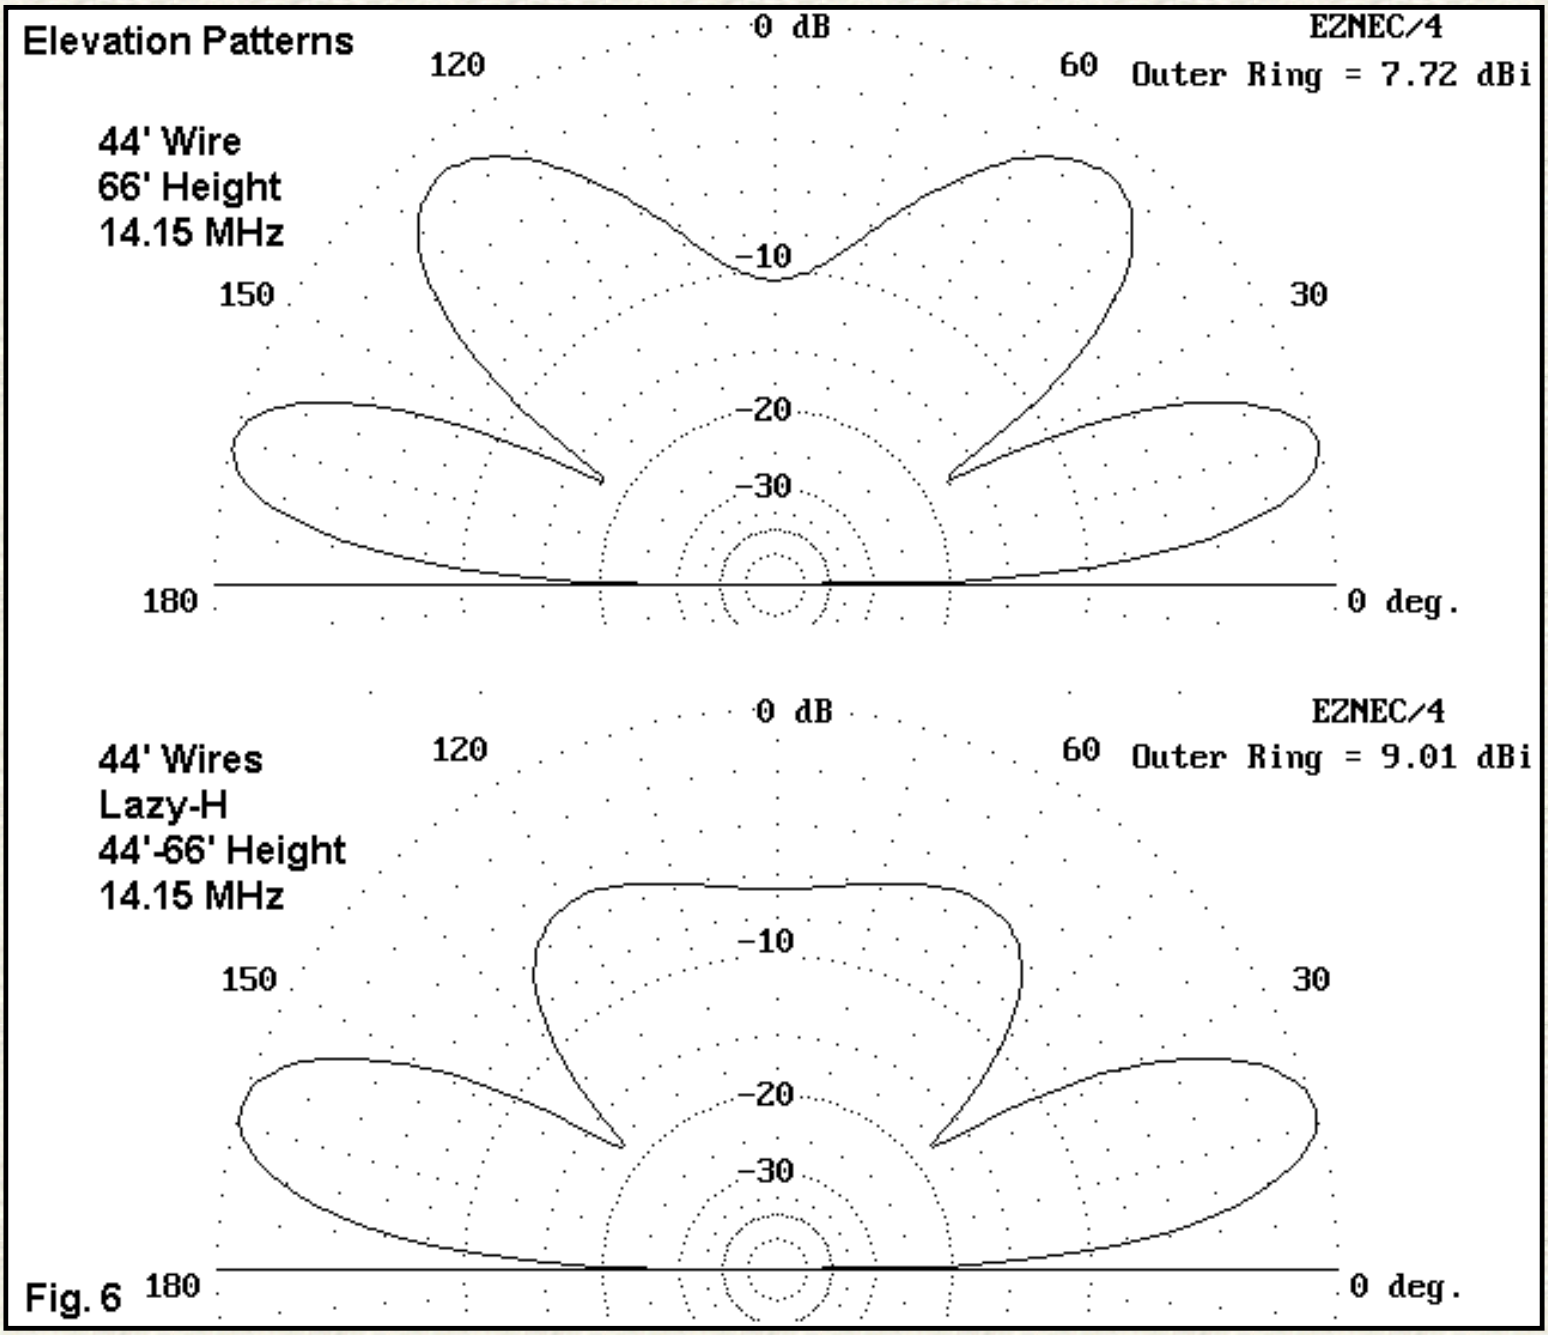

Fig. 6

On 20, the effect is less pronounced but still easily measured, as shown in **Fig. 6**. The area enclosed by the upper lobes of the single wire at the top of the figure is distinctly greater by a considerable margin than the area enclosed by the upper lobe (barely discernable as a double lobe) of the array. The difference in area (assuming that the azimuth patterns are comparable, as they happen to be in this case) is a rough measure of the added power appearing in the lower lobes. In this case, that additional power shows up not only in the maximum gain, but as well in the vertical beamwidth. The phased feeding of vertically stacked horizontal wires has benefits hard to match in a typical flat-top wire array.

Along side the benefits come some limitations. The Lazy-H requires a pair of tall supports and is suited to the antenna farm with more tall trees than money. It is possible to lay out more than one of these

inexpensive antennas in order to cover additional regions along the horizon. It is likely that no special treatment will be needed to detune unused arrays to prevent them from altering the pattern of the array in use. Either leaving the shack end of the unused feedline open or shorting it will introduce to the wire feedpoints sufficient reactance to detune the wires. However, this is a facet of multiple array installation that the builder should keep in mind. Sometimes Murphy dictates that nothing will work to prevent interaction short of greater physical separation of the arrays.

The Expanded Lazy-H is an outstanding bi-directional array for 10 meters in the design given here. Its performance holds up well down through 20 meters, and we can press it into service on lower bands. It takes up very little room horizontally in the yard, although a couple of optimally spaced tall trees certainly can aid the installation process. The wires for the elements and the phasing lines, as well as the feedline to the shack and the UV-resistant support ropes, are certainly inexpensive compared to the cost of a tower, rotator, coax, and commercial aluminum antenna. It is a design worth recollecting every 15 years or so just to make sure that we do not forget it.

Can the extended Lazy-H be converted into a directional beam for some or all of the bands that it covers? To find out--at least in principle--see **"Curtains for the Extended Lazy-H."**

AMSAT-NA 2001 Annual Symposium issues call for papers: The first call for papers has been issued for the AMSAT-NA 2001 Annual Symposium, set for October 5-6 in Atlanta, Georgia. Papers may be presented by the author during the symposium or simply offered for inclusion in the *Symposium Proceedings*. Subject matter should be of general interest to Amateur Radio operators involved in satellite communications. Suggested topics include operating

techniques, antenna design and construction, spacecraft design and construction, current mission status, proposed satellite missions, telemetry acquisition and relay, satellite microwave projects, etc. An outline abstract of the proposed paper should be submitted as soon as possible. The final date for abstracts is June 30, 2001. Completed papers must be received no later than August 15. Electronic submittal is preferred. The format must be either *MS Word*-compatible or plain text. For security purposes, Symposium Chairman Steve Diggs, W4EPI, asks authors to condense the document file and send it as an e-mail attachment to w4epi@amsat.org.--*AMSAT News Service*

Array Solutions acquires RF Applications marketing rights: Array Solutions has acquired the exclusive marketing rights to RF Applications VFD, P-3000 and P-5000 wattmeters and the IBS-1 Intelligent Band Switch. RF Applications will continue to manufacture and support these products and will honor all existing warranties. "We are excited that Array Solutions has elected to add our products to their product line," said RF Applications President Bruce R. Knox, W8GN. "We feel that our products need better exposure to the marketplace, and Array Solutions' market presence is a perfect answer to that need." Array Solutions President Jay Terleski, WX0B, said the RF Applications' power-measurment devices will be an important part of the company's vertical array-phasing products it's introducing this year. RF Applications has announced that it no longer will manufacture its P-2000A, P-5000A and P-2000CW wattmeters. The WinWatt will continue to be marketed and sold exclusively by RF Applications.

California ARES team gets into a stink--and the nose knows! (This is not a story for the squeamish, so if you're of a sensitive nature or just ate, perhaps you should just skip to the next item--*Ed.*) Amateur Radio Emergency Service members in Ventura County, California, recently got into a stink--quite literally. As Ventura County ARES District Emergency Coordinator and RACES Radio Officer Dave Gilmore, AA6VH, explains, this story may sound like just so much horse manure--and you'd be right. Three and a quarter acres of it, 15 feet deep, and all on fire. Manure from an area race track is mixed with hay and used to compost mushrooms. The compost piles have been known to spontaneously combust, and that's what happened recently. "The smoke and smell even traveled to Los Angeles County to our west and south, and to Santa Barbara County to our north, Gilmore said. Fire officials asked Ventura County ARES/RACES to help determine the direction of the smoke cloud. "Unfortunately, it was foggy and hazy, making it hard to determine where the smoke ended and the haze began," Gilmore said. "The only way to tell was by sniffing the air." Hams were sent out to sniff various areas and report back. Gilmore says that those on "sniff patrol" periodically were forced to refresh their olfactory capabilities. "After a couple of whiffs, most people get used to even foul odors and can mistakenly believe the odors have gone when they actually have not," Gilmore explained. In addition to fire officials in two jurisdictions, air pollution and health officials got into the act. For a variety of very good reasons, it was decided the best way to put out the fire was to cart off the burning manure to a nearby field to disperse and extinguish. "Unfortunately the dispersal and movement of the fuel would cause a temporary increase in the amount of smoke produced by the fire," Gilmore said. By the second and third days, ARES/RACES members were stationed to report when the smoke and smell became intolerable, so that operations could temporarily halt until the smoke level decreased. After the weather cleared, one operator was stationed atop a nearby hill to observe the smoke trail and direct the operators around as the smoke plume shifted. By the third day, Gilmore said, enough of the compost had been moved to decrease the smoke level to the point where it no longer posed a problem.--*Dave Gilmore, AA6VH*

Crowd welcomes HRO-Anaheim back to original location: A huge crowd was on hand to

HRO Vice President Robert (left) and President (and Robert's father) Bob Ferrero, W6KR and W6RJ, flank HRO-Anaheim Manager Janet Margelli, KL7MF, as she cuts the ceremonial ribbon to signify the return of HRO to its original location at 933 North Euclid in Anaheim. [K7JA Photo]

celebrate the return of Ham Radio Outlet to its original location at 933 North Euclid in Anaheim, California. That location was destroyed by fire in January 2000 and the store has been in nearby temporary quarters since then. Representatives from Alinco, ARRL, ICOM, Kenwood, NCG, Pryme, RF Parts Co, Sangean, US Tower, and Yaesu were busy showing off their latest wares, Gordon West Radio School handed out Amateur Radio leaflets to passers by. HRO-Anaheim is the largest Amateur Radio store in the Los Angeles area. Ham Radio Outlet has 12 stores throughout the US, five in California. "It was great to welcome so many of our local customers to our Grand Re-Opening event," said HRO-Anaheim Manager Janet Margelli, KL7MF. "Their support through the long and arduous rebuilding process has been greatly appreciated by all of us in the HRO organization."

Dayton Contest Dinner tickets on sale: The North Coast Contesters have announced that tickets for the ninth annual Dayton Contest Dinner now are on sale. Sponsored by *CQ* magazine, the master of ceremonies will be *CQ* Contest Editor John Dorr, K1AR. Featured speaker will be WRTC-2000 Chairman Tine Brajnik, S50A. The names of 2001 Contest Hall of Fame inductees will be announced by the *CQ Contest* Editor Bob Cox, K3EST. The dinner will be held Saturday, May 19, 6:30 PM, in the Van Cleve Ballroom, Crowne Plaza Hotel, Fifth and Jefferson streets (next to the Convention Center), in downtown Dayton. Tickets are $30. Seating is limited to 300, no reserved seats. For tickets and additional information, contact Craig Clark, W1JCC, Radio Bookstore, PO Box 209, Rindge, NH 03461; Place orders by telephone weekdays 10 AM to 6 PM Eastern, 800-457-7373 (toll-free) or 603-899-6957, or by FAX 603-899-6826 anytime, or via e-mail to nx1g@top.monad.net. Credit cards are accepted but no CODs. E-mail orders must include charge card, call sign and return address information. Tickets will be sent via first-class US Mail no later than May 8. Deadline for ticket orders is May 7, 2001.

EMCOMM 2001 is March 31: The second annual Emergency Communications Conference will be held Saturday, March 31, 2001, at Bishop Quinn High School in Palo Cedro, near Redding, California. The all-day event begins at 9 AM; registration gets under way at 8 AM. EMCOMM 2001 will include seminars and workshops on topics such as search-and-rescue radio communications, emergency antennas for VHF and HF, choosing batteries and emergency power sources, public relations and working with the media, an overview of the incident command system and SEMS, "mutual aid" practices, and handling formal traffic. The National Weather Service will offer a presentation on SKYWARN. EMCOMM 2001 is sponsored jointly by ARRL Sacramento Valley Section Amateur Radio Emergency Service and the California Office of Emergency Services Auxiliary Communications Service. Anyone interested in volunteer emergency communications is welcome. For more information, visit the Sojourners Net Web site, http://www.qsl.net/k6soj or write EMCOMM 2001, c/o D.W. Thorne, K6SOJ, PO Box 16, Macdoel, CA 96058.--*Donna Ferguson, N6SVV*

FCC chairman touts "enforcement model": Speaking at the CTIA 2001 Wireless show in Las Vegas, Nevada, this week, FCC Chairman Michael Powell said the FCC is rethinking its business model. According to an *Infoworld.com* report Powell told the gathering that the FCC is "reviewing the optimal organization and structure" with an eye toward a more-responsive FCC. "We are putting increasing emphasis on an enforcement model as opposed to a regulatory model," he said, in order to speed up the FCC's decision-making process. "When you cheat, we'll get you at the back end." Powell also said there's a delicate balance for agencies such as the FCC between fostering innovation but not imposing it.

First QSO reported between ionic fluid antennas: The Live-Wire Group has recorded the first liquid antenna-to-liquid antenna contact on Saint Patrick's Day, March 17--and that's no blarney! The Live-Wire Group currently is experimenting with the liquid antenna concept. Participating in the 17-meter SSB contact were WH2AAT in Orange Park, Florida, and N9ZRT in Green Bay, Wisconsin. Both stations were using 10-foot tall by two-inch wide "columns of ionic fluid" (in this case, concentrated saltwater). Also participating in the QSO was W8ZU in Glen Rock, Pennsylvania, who was using a conventional antenna. Members of the Live-Wire Group have been experimenting with the Ionic Fluid Antennas (IFAs) for more than six months, and they report excellent results on the antenna's performance. In most cases the liquid antennas are operated in the vertical position. The RF is fed into the base of the antenna through several three-inch long copper probes that are exposed to the conductive liquid. Live-Wire members continue to experiment with this antenna concept in various forms including liquid dipoles and "pumpable-to-resonant-length" verticals. For more information, contact the Live-Wire Group, http://www.wireservices.com/livewire.html.

The 10-foot tall, two-inch diameter IFA antenna on N9ZRT's jeep. [N9ZRT Photo]

M0BMU wolfed in Massachusetts: There's more transatlantic news on the LF front. John Andrews, W1TAG, has successfully copied a WOLF digital signal from Jim Moritz, M0BMU, in the UK. "WOLF has successfully crossed the pond," Andrews exulted in an e-mail to the LF reflector after only a day of listening. Andrews reports receiving "two lines of clean copy" between 0135 and 0200 UTC on March 19 just below 137.5 kHz. Moritz also was pleased. "Many thanks to John for this report and his perseverance," he said. "Now QRSS is not the only way to get across the pond on LF!" QRSS is very slow-speed CW that's been used for LF contacts, while WOLF is a robust digital mode. Moritz reports using a Racal-Decca 5501 Class D power amplifier (1200 W PEP output) with a Racal 9084 signal generator as a synthesizer plus homebrew phase-keying, waveform-generating and amplitude modulator circuits. His antenna is a 40-meter long inverted Vee, 16 meters high in the center and 9 meters off the ground at the ends. He estimated his ERP at 1 W. "I also received a report from ON7YD, who was able to obtain perfect copy on my signal from a short recording," said Moritz, who plans to run additional tests on 137.500 kHz.

National Weather Service gets a MARS station: For unstinting public service by Amateur Radio

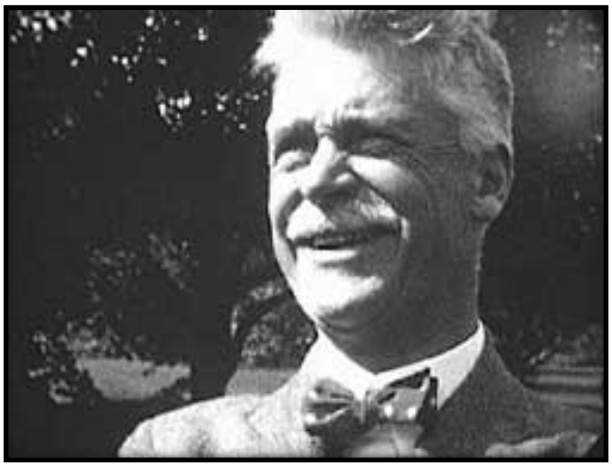
there's no better example than the SKYWARN partnership between hams and the National Weather Service. But even that wasn't enough during the 1998 ice storm that knocked out telephone communications across large areas of the Northeastern US for up to several weeks. During that emergency the NWS forecast office in Taunton, Massachusetts, outside Boston, lost contact with the NWS office in Gray, Maine, near Portland. Although dozens of SKYWARN members were activated throughout the long outage, their normal mode is VHF, and Gray is way out of VHF range of Taunton. Thus Taunton was unable to access Gray's vital weather data from northern New England. The Army Military Affiliate Radio System (MARS) and NWS have taken a first step in avoiding such problems in future. Army MARS has licensed a club station at the NWS forecast office at Albany, New York, AAT2CAA. This facility will make it possible for hams with MARS licenses to operate directly from the forecast office when links are needed beyond VHF range. As 1998 proved, it happens. All three MARS services--Army, Air Force, and Navy-Marine Corps--participate in the National Communications System's Shared Resources system linking federal agencies. Even if another NWS office lacks a MARS presence, Albany's traffic can now be relayed either by voice or digital mode through some other federal agency when needed.--*Bill Sexton, N1IN*

New address for VK4 incoming QSL bureau: There's a new address for the incoming VK4 QSL Bureau. It's GPO Box 199, Wavell Heights, 4013 Brisbane, Queensland, Australia.

Pacific Section to hold first-ever section convention: The Pacific Section will hold its first ARRL-sanctioned Pacific Section convention in Honolulu, Hawaii, October 13, 8 AM to 4:30 PM (gates open at 7:30 AM), at Pearl Harbor Community Park, next to the *Arizona* Memorial visitor entrance. Tickets are $2 each ($5 for family). All clubs will be given space for a display for the cost of paid admission tickets for all exhibitors. Tables will not be supplied. There will be a picnic area, vendors, flea market, displays, technical talks, amateur exams, and a lunch wagon. Several forums are scheduled, including an ARRL forum with Pacific Division Director Jim Maxwell, W6CF, and others. For more information, visit the Koolau Amateur Radio Club Web site.--*Bob Schneider, AH6J*

SETI@Home tallies 593,000 computing years: The Search for Extra-Terrestrial Intelligence@home project has completed its 593,000th computing year. SETI@home analyzes radio signals from space for signs of alien signals and uses idle PC time to do the processing. Users install the software on their home computers, where the program works in the background--exploiting the computer's processing power when its owner isn't. SETI@home is able to marshal the power of hundreds of thousands of PCs, processing more information than any supercomputer. The world's most powerful computer, IBM's ASCI White, runs at a speed of 12 teraflops, or 12 trillion floating point operations per second, and costs $110 million. In contrast, the SETI@home project runs at about 15 teraflops and has cost only $500,000. No conclusive evidence of extraterrestrial intelligence has been found, but project scientists say there are signals that may prove to be extraterrestrial. The answer, of course, is *out there*. For information on SETI or to obtain a copy of the software, visit the SETI@home site, http://setiathome.ssl.berkeley.edu/.

Southeastern VHF Society Conference set: The Southeastern VHF Society holds its fifth annual conference April 20-21 at the Holiday Inn Select-Brentwood, Nashville Tennessee. The program includes presentations by antenna specialist L.B. Cebik, W4RNL, VHF author and *QST* columnist Emil Pocock, W3EP, and EME enthusiast Bob McGraw, K4TAX. For more information, visit the SVHFS Web site, http://www.svhfs.org/.



This image of Hiram Percy Maxim is from a 16-mm movie frame taken at George Eastman's home at the introduction of *Kodacolor* movie film in 1927. It's one of the few images that depict Maxim laughing.

TV program on HPM scheduled to air: The life of Hiram Percy Maxim will be profiled in original films and interviews Tuesday, April 3, 7:30 PM, on Boston TV station WCVB-TV5 on the *Chronicle* news magazine. The program deals with recently discovered early films of New England. "Few people today realize that Hiram Percy Maxim was not only the founder of the ARRL but also the founder in 1924 of the Amateur Cinema League," says program producer Art Donahue, KA1GGG. "He chronicled his own life in hundreds of 16-mm movies from 1924 until his death in 1936." Donahue says the films were donated by his daughter, Percy Maxim Lee and his grandson, Hiram Percy Maxim II, to the Hartford, Connecticut, Public Library and Northeast Historic Film in Bucksport, Maine. The program uses this footage along with interviews with Percy Maxim Lee, Perry Williams, W1UED, the ARRL's former Washington, DC, representative, and David Weiss of Northeast Historic Film. Also shown is Maxim Memorial Station W1AW at ARRL Headquarters. The program also can be seen on many cable systems throughout New England and the Canadian Maritimes.

Visalia International DX Convention contest dinner set: The Third annual International DX Convention contest dinner will take place Friday, April 20, 8 PM, in the Oak and Maple rooms at the Holiday Inn-Visalia, 9000 W Airport Drive, Visalia, California. (Note: This is *not* the main banquet on Saturday evening, and the fee is not included in the convention registration cost.) Prime rib, $29; chicken princess, $23. No reserved seats. Tickets are available only from Champion Radio Products, 888-833-3104 (toll-free); Fax 530-758-9062; e-mail dinner@kkn.net; or write Champion Radio Products, 1816 Poplar Ln, Davis, CA 95616. Credit cards, checks and money orders accepted. Credit card users should supply card number, expiration date, and name as it appears on credit card. Deadline to order is Friday, April 13. No tickets will be sold at the door. Tickets will be mailed only to those supplying an SASE with their order; otherwise, pickup at the door. There will be a short program on contesting, guest speaker, and door prizes.--*Bernie McClenny, W3UR*

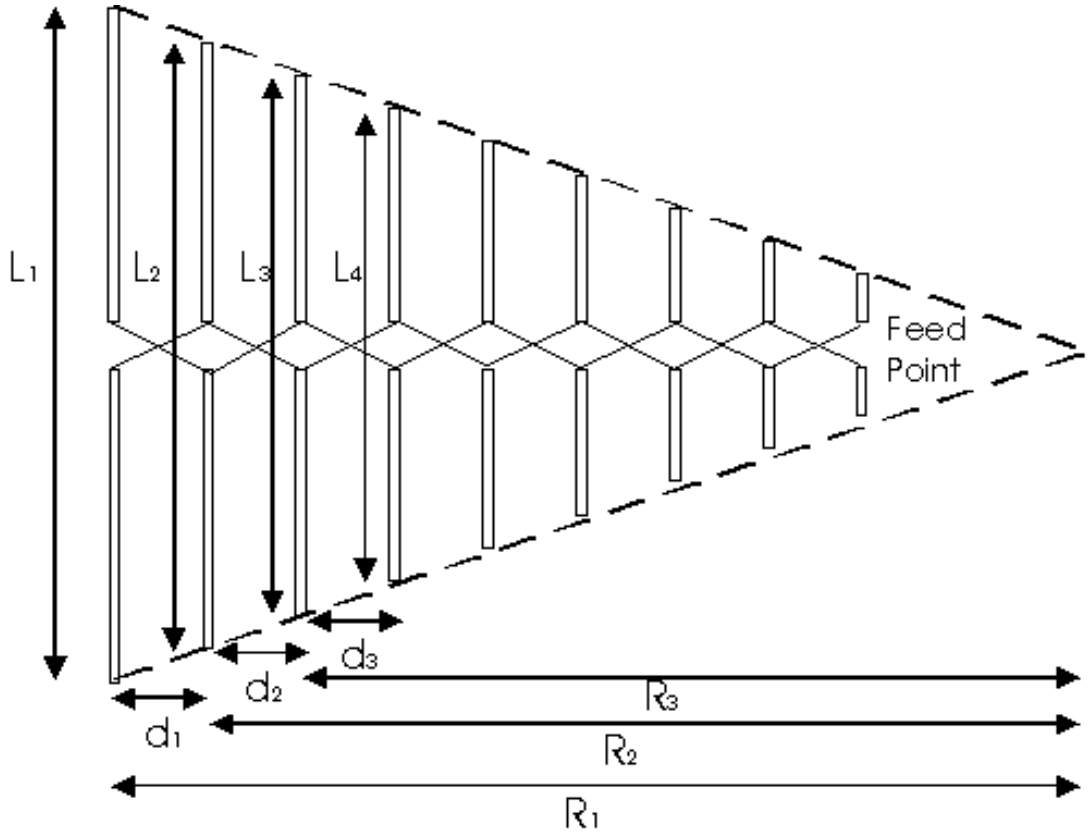
This is a Java applet which calculates the dimensions and spacings of the elements needed to build a log periodic antenna, given tao, sigma and the lower and upper cutoff frequencies.

All lengths and distances are given in meters. Look below for a diagram and a brief explanation describing what are all these numbers and parameters...



In a nutshell, The log periodic is a broadband antenna whose caracteristics vary as a periodic function of the logarithm of the frequency (with period Log(Tao)). As Tao approaches unity, we can neglect these response variations and regard the antenna as "frequency independant". Sigma is a spacing factor, and together with Tao, determine the directivity of the antenna.

Long Wire Antenna

The long wire antenna is used as a field expeient antenna. To construct a long wire antenna you will need the following:

1. WD-1/TT, WD-1A/TT, or WF-16
2. Electrical Tape
3. 400-600 ohms terminating resistor
4. Insulators or material to construct field expedient insulators
5. Radio set
6. Knife
7. Suspension line
8. Measuring device
9. Compass
10. Signal Operating Instructions (SOI) with frequency and call signs
11. Large open area
12. Fabricated suspension (tree, Camouflage poles, etc.)
13. Calculator (optional)

To erect the antenna follow these steps:

1. Determine azimuth from the transmitting radio to the receiving radio.
2. Determine the length of the wire using the following formula:
    - **NOTE:For a quarter wave antenna divide 234 (contant) by the operating frequency in this case 9.00 MHz (234/9=26.0 ft.)**
    - **For a half wave antenna divide 468 (constant) by the operating frequency, in this case 18.00 MHz (468/18.00=26 ft.)**
    - **For a full wave length antenna divide 936 (constant) by the operating frequency , in this case 8.35 MHz (936/8.35=112 ft.)**
3. Measure and cut the antenna to the desired length
4. Split the WD-1 at the near end, attach one piece to the bottom end of a whip antenna and screw it into the antenna connector on the RT. Connect the piece to a screw on the RT case for a ground.
5. Suspend the antenna antenna using one of the following methods:
    - Run the antenna wire from the radio set to a nearbby tree. Attach the end of the antenna wire to an insulator. Attach a wire or rope from the other end of the insulator to the tree and tie it off.
    - Use a pole that is at least 9 feet high to suspend the antenna in the same manner. However you will have to use guy ropes to secure the pole.

The antenna is bi-directional. To make a uni-directional antenna place a 600 ohm resistor across the insulator.

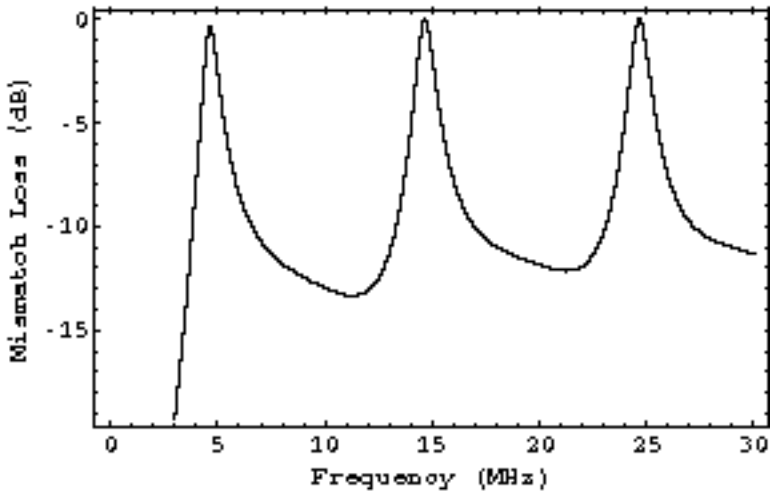
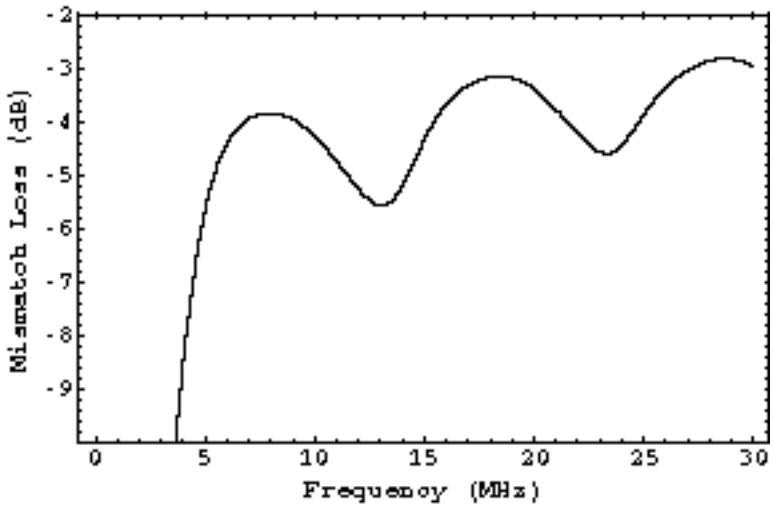
Actually, a fixed matching transformer can dramatically reduce the wild swings in antenna efficiency that a coax fed wire antenna exhibits. Let us calculate:

The following graphs are based on a 15 meter vertical antenna, fed at ground level, using a conical approximation. The antenna's characteristic impedance is assumed to be 620 ohms, which is typical for a thin wire. For more on the conical approximation, see Chapter 8 of "Antennas" by John D. Kraus (McGraw-Hill, 1950).

The first graph is for an antenna fed directly from 50 ohm coax. The horizontal axis is the frequency in MHz, the vertical axis is the mismatch loss in dB. The well known "quarter wave" resonances near 5, 15 and 25 MHz are visible as sharp peaks where the mismatch loss closely approaches zero.



The second graph assumes a matching transformer with a 9:1 impedance ratio at the feedpoint, presenting the antenna with a load resistance of 450 ohms. At most frequencies, the mismatch losses are considerably lower for this case. The variation in the mismatch loss is also reduced:

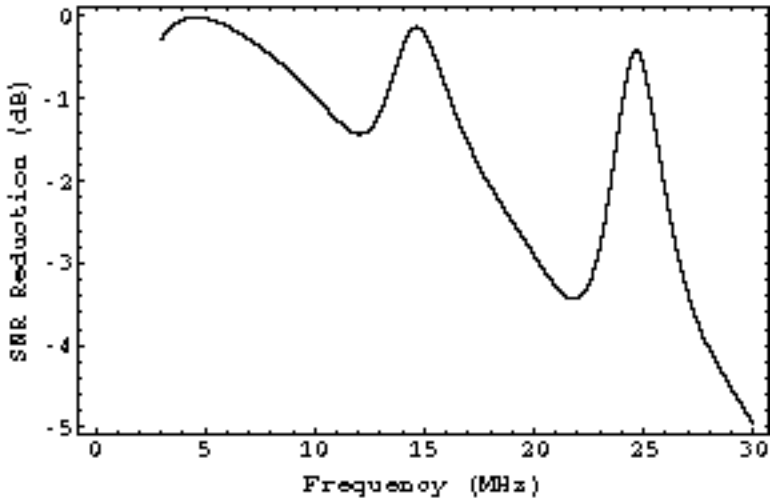


Well, so what? In the absence of interference, the signal to noise ratio is the main determining factor for the audio quality of the signal. The mismatch loss affects both signals and noise, so if the receiver was

noiseless the losses would not affect the signal to noise ratio. Real receivers, however, are not noiseless: if the loss is too high, receiver noise will become dominant, and overally system sensitivity will suffer.

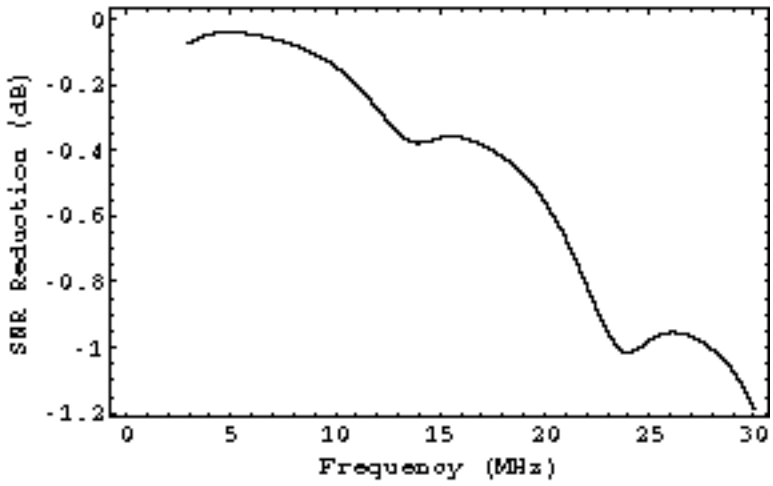
The following results assume cosmic noise of 29 dB above thermal at 10 MHz, declining with increasing frequency at -23 dB per decade. No man made or atmosperic noise is assumed. I assume a receiver noise figure of 10 dB.

First, here is the signal to noise impact of the mismatch losses for a 50 ohm coax feed without a transformer:



Losses in signal to noise of 3-5 dB are likely to be noticeable. The largest impact is in the quiet bands above 15 MHz.

On the other hand: the loss in signal to noise with a 450 ohm feed is much smaller:



You are unlikely to be able to notice losses in signal to noise in this range.

The results depend on the assumptions. A real longwire isn't usually vertical: this tends to degrade its performance a bit at the low frequency end, while improving it at high frequencies. This is good, because in the model the signal to noise is declining as the frequency increases: the increase in performance cancels part of this.

No man made or atmospheric noise is included. If they are significant, the precision of the match becomes less critical. Man made noise can be significant at any frequency, but atmospheric noise is more significant at the lower frequencies.

A receiver noise figure of 10 dB is mediocre for a solid state receiver or a tube receiver with a triode RF amplifier. Tube receivers with pentode RF stages may be a bit worse than this, and something like a Hallicrafters "Sky Buddy" (no RF stage, pentagrid converter) might have a noise figure >30 dB. The better (smaller) the noise figure, the less you have to worry about matching. Sky Buddy owners will want to tune their antennas very carefully.

I haven't included cable losses here. These are not terribly important unless you're using an ATU at the receiver end. If you are, using a fixed transformer to get the match roughly right at the antenna end will reduce the cable losses, because cable losses increase with increasing SWR.

My own experience concurs with the results of this theoretical analysis (or I wouldn't be writing about it: I'd be trying to figure out what was wrong!). I have experienced "deaf bands" with coax fed antennas lacking matching transformers, but my transformer-fed antennas work well across the HF spectrum (and

even down to longwave). I don't bother with an ATU.

See "Low Noise Antennas" at "http://www.anarc.org/naswa/badx/" for more on matching transformers and on keeping conducted noise from contaminating a "longwire antenna".

John Doty "You can't confuse me, that's my job."

LOW NOISE RECEIVE-ONLY COAX-LOOP ANTENNAS

for 160 - 10 meters HF bands

Station WN6F listening post

Last Update: 29 March 2004

After doing battle with locally-generated EMI / RFI for nearly two decades, I decided to do something about it. This antenna's main advantage is that it packs a lot of low-angle directivity into a small package. This makes nulling out many urban noise sources easy while enjoying good medium to high-angle skywave reception.

NEW !! (If you are interested in an easier-to-construct wire-only loop that has better performance, check out my general-purpose wire-loop page).

The directional small loop is also useful for significantly reducing static-crashes on the lower HF bands at times; this depends on mother nature of course. The larger loop is for 80 meters and the smaller loop is for 40 meters.

The project is described in four parts:

- General construction and usage (this page)
- Operational analysis of this small loop
- Alternate loop winding methods
- Miscellaneous notes and experiments

They are easy to build, and the only tools you'll need are wire cutters, some coax, and a tuner. You can make them for yourself or friends in a matter of minutes. Part of my design goal was to use a minimum of easily available parts. You won't need a well-stocked junkbox or any exceptional mechanical skills to build this antenna.

Winding the loops out of coax (providing a main antenna loop and an interior coupling loop) in the following fashion is very convenient and has six purposes:

1. The small wavelength outer-conductor loop (at 0.10 or smaller wavelength in circumference) provides the horizontal low-angle bidirectional directivity with deep nulls.

2. The gap in the braid at the top center of the loop allows common-mode reception of signals (both wanted and unwanted) on the outer skin of the loop braid to transition to the inner-skin of the braid. Rotational directivity nulls out the unwanted noise.

3. The current on the inner-skin of the braid now acts like a normal transmission line via the differential-mode to the center conductor.

4. This specially-wound loop acts as it's own balun, which is necessary when using unbalanced coax as the feedline. This helps to ensure that the feedline does not become part of the antenna. If it did, you'd lose much of your directionality, or have very strange nulls.

5. The large amount of distributed capacitance makes the loop somewhat

resistant to unbalance and detuning from hand-body-object capacitance than more traditional balanced wire loops.

6. The larger outer conductor diameter of the braid increases the sensitivity of the loop over that of a small-gauge wire.

Prove it!: Attach a clamp-on ferrite RF cable choke on the feedline and arms of the loop. When chokes are placed anywhere on the arms of the split-braid loop, severe detuning and attenuation takes place. When placed anywhere on the feedline after the loop output, no detuning or attenuation occurs.

HF loops built in this way are typically used for direct wave direction-finding. I'm more interested in using them as near-field noise-nullers to enhance the signal-to-noise ratio of skywave signals. This helps make up for their inherently lower gain than more traditional long wire antennas. A balun-effect is created by the way we wind the antenna back onto the feedline to help prevent common-mode noise ingress and maintain an accurate directional pattern.

2004 update: See below for smaller TWO-TURN Loops!

I'm using these antennas indoors right next to the operating position to make it easy to rotate and tune. Remote mounting is certainly possible, preferably with an antenna tuner or preamp located near the loop, although in that case I'd advise using a plain wire loop if you want to keep the tuner near the operating position.

As an example, let's build a single-turn 0.10 wavelength loop for 40 meters: (it will also function well as a .05 wavelength loop on 80m with retuning)

WHAT YOU'LL NEED:

- For 40 meters, you'll need about 15 feet of coax (loop and some extra length for tuner connection, plus pigtail wrap.) I prefer to use 50-ohm RG-58. For convenience I picked up a 50-foot jumper at Radio Shack (#278-971A) which is already connectorized so I could build a few of them. You could also use 75-

ohm coax without any difficulty. Try to get the lowest capacitance cable that you can find.

- An antenna tuner can be used to tune the loop system to resonance. I've used L-type tuners and T-type tuners without any problems. I'm currently using an MFJ-16010 random-wire tuners which are small and use two SO-239 connectors which makes them easy to hook up and mount to a mast if desired. Note that on 160 meters, you'll need a lot of inductance, and the 16010 model doesn't seem to have enough when used with coax-loops.

- Optional: A 10 dB gain or more preamp can be used to help bring up the signal level. If your receiver has a preamp, and all it seems to do is bring up the noise level along with the signals, you are in for a treat. With this directional antenna, the preamp finally becomes useful in amplifying the signals, and not the noise.

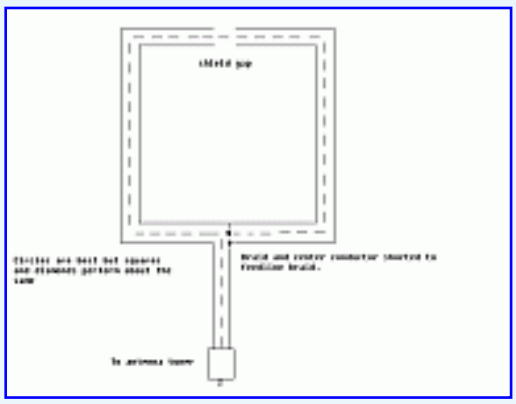
Use the largest coax diameter you find practical. I use RG-58 since it is easier to work with, but the larger conductor size of RG-8 / 11 should perform a little bit better.

LOOP SCHEMATICS:

My best artistic attempts at drawing the schematics.

Click on the images for a larger picture.

(Internet-Explorer users: IE has an option that automatically reduces the size of graphics. If the enlarged schematics look distorted, be sure to view them full-size, typically with F11 Key)



HOW TO MAKE IT:

(Click on any of the images to enlarge them.)

1) First, at one end of the coax, let's short the braid and center conductor together with a pigtail. RG-8 was used to make it easier to see, although I like to use the smaller RG-58 or RG-6. After removing the outer covering, I bunched the braid back a bit to allow me to cut into the inner dielectric and then just pushed it back down when I was done. Take care not to cut or score the inner conductor with the knife, especially when using the smaller cables; when you wrap the pigtail around the braid in a later step, it has a tendency to snap at the cut or score when you wrap it.

(It might be easier to build the loop by following these instructions backwards if you already have a connectorized piece of cable.)

2) We need to create a 1-inch gap in the coax shield. Measure 7 feet from the shorted end, and make a small cut mark on the coax. A half inch on either side of the mark, cut through the outer covering exposing the braid. Then cut the braid out to expose just the inner dielectric. Try not to cut into the inner dielectric as this will mechanically weaken the antenna when you eventually mount it. The photos show some exposed braid at the gap just for clarity, but my antennas just have a clean cut. Note that this is just a true gap, you do not short anything at the gap! (Make sure there aren't any fine strands of shield wire still connected across the gap after you cut it!)

KEY POINT: The gap allows common-mode reception of radiated energy (both wanted and unwanted) on the outer braid skin to transition to differential-mode currents on the inner braid skin, which is coupled to the center conductor via differential-mode. Rotation nulls the unwanted common-mode energy exposed to the arms of the loop.

3) Measure another 7 feet from the center of the gap, and remove about 1 inch of the outer coax covering ONLY. You should just have some exposed braid.

4) Take the shorted pigtail end of the coax, and wrap it around the exposed braid from the previous step. This is the weakest point of the loop mechanically. Try not to make a radical bend at the point where the brittle center conductor is immediately shorted to the braid; it has a tendency to break if you do. Wrap at a point just a little bit further down the pigtail to avoid breaking the center conductor.

KEY POINT: This finishes the self-forming balun and helps ensure that the unbalanced feedline does not become part of the balanced loop, thereby unbalancing it, and turning the loop into a noisy random wire.

(NOTE: don't be tempted to use an ordinary "tee" connector here. It won't work properly.)

You now have a highly directional low-band 40 meter loop and the rest is a small length of feedline that goes to the input of a tuner. Of course the jumper from the tuner output to the receiver can be any convenient length.

For 160 through 40 meter operation, you can mount the tuner anywhere from 6-inches to 6-feet away from the output of the loop. This allows you some flexibility if you want to keep the tuner on the desk and not on the mast. For smaller single-turn loops on 20 meters and above, try to keep the tuner no more than 6-inches away from the loop output - the closer to the loop output the better.

Note: Here is a very small loop for overall visual reference.

To construct a 20 meter loop, try a loop circumference of 7 feet. The gap is not critical for any band, and can stay at 1 inch. For 80 meters, try a loop circumference length of 27 feet or so. For 20 - 15 meters, try a 3-foot circumference; I'm amazed that this actually works as well as it does.

Note that when we cut loops for 0.10 wavelength, they will also perform well at half their frequency as a 0.05 wavelength, although sensitivity will be down somewhat. The positive tradeoff is that the nulls will be VERY deep at 0.05 wavelength.

Design Your Own!

UPDATE: MAJOR ERROR IN MY EARLIER DESIGNS!

My apologies go to earlier readers of these pages. I incorrectly assumed that since we are using coax as antenna elements, that they would be subject to a cable's velocity factor. Since the loop element is really the outer braid skin, **it is not subject to velocity factor.** Only the inner differential-mode of coax is subject to velocity factor, and NOT the common-mode outer surface conductor of the braid, which is what we are using as the antenna!

My standard formula for calculating the loop circumference for the frequency of interest at 1/10th wavelength *without any VF*, is:

(1005 / freq mHz) * 0.10

TUNING NOTES

This formula should get you in the ballpark, although if you can't get a definite peak with your tuner on the lowest frequency of interest, it is likely that the antenna is too long, or the distributed capacitance of the cable used is too high for your tuner to handle. Try using a more advanced tuner, or reduce the loop circumference length.

You can cut a new loop with a cable that has lower capacitance specs, or just make the existing one shorter. Fortunately it is easy to make a pre-cut loop shorter. Let's cut off two feet from the existing loop circumference as an example:

- Unwrap the shorted pigtail from around the exposed braid. Cut away a foot from this arm of the loop and create another shorted pigtail.
- Measure a foot from the center of the old exposed braid, and cut a new 1-inch exposure of braid.

- Wrap the new pigtail around the new exposed braid section and re-shape the antenna into the smaller shape. Tape up or heat-shrink the older exposed braid section.

- Try to be as accurate as possible and strive for balance when re-sizing the loop. Balance is important!

USAGE:

You can create the loop with any shape you want, but circles are best, and squares and diamonds do nearly as well. Triangles, and extreme rectangles don't do as well, but don't let that stop you. The key is to enclose as much area as possible. For mounting, any sort of cross-brace should work, but I've also placed them on the back of non-metallic doors, hung them from ceilings, etc.

Tune the loop-system (loop and feedline) to resonance with the tuner. Since loops are high-q, you should hear a definite peak in the background noise. Better yet, tune to some locally-generated noise and peak on that. As you change each setting of the inductor, rotate the tuner capacitor(s) s-l-o-w-l-y.

The directivity pattern is a bidirectional figure-8 pattern at low angles, with maximum gain in the plane of the loop, and the nulls are broadside to it. It is just the **opposite** of an ordinary dipole. The loop seems progressively more omnidirectional to medium and high skywave angles.

If you want to see the directional azimuth and elevation angles, check out my general-purpose wire-loop page. The patterns are almost exactly the same as compared to these coax-built loops.

You don't have to have the loop perfectly vertical, use whatever angle you need to null the local noise or storm-related static crashes - skywave signals will still be heard well. In one case, I have a noisemaker downstairs, so I had to rotate and tilt the loop at about 45 degrees to null it - it didn't attenuate the desired band signals at all. At times I've been able to track a storm all night and reduce the static crashes, and then sometimes not depending upon how localized the storm is.

You might notice that even though you've nulled out the noise, signal levels on a tuned loop seem to be about 2-to-3 S-units down from a standard 1/2-wave dipole mounted up at least a quarter-wave above ground. This is normal for a *tuned* small

loop given its short wavelength. You can compensate with a preamp, but you might find that with the noise level so low, you won't need one. If your normal antenna isn't mounted up at least a quarter-wavelength, the comparative loss might be even less!

Note: many modern radios that have built-in selectable preamps might have much lower sensitivity with the preamps off than other radios that don't have any preamps at all. This is a good design feature. Accordingly, with radios that have selectable preamps, it is likely you'll want to run with at least the first preamp turned ON.

The important point to remember is that your noise floor will be so much lower than your old noisy antenna that it more than makes up for brute signal strength.

Connector Quality Issues

Make sure your connections are snug. If you lose the ground, you'll end up with a random-wire because you've lost the electrical balance. I mention this because as you insert or remove the connector from the tuner or receiver, when only the center-conductor is making a connection, you'll hear noise or signal level come up a bit. Unfortunately, you will have lost all the directivity that this antenna provides. Keep those connections tight.

A caution about crimped PL-259 connectors: sometimes the crimp is so tight that when you screw them fully into the chassis jacks, they don't actually make good contact with the chassis-connector center conductor. A **VERY GENTLE** squeeze with a pair of pliers on the center-conductor pin will help ensure good physical contact. I've run into this problem a lot with cheaper cables and sometimes it is not immediately apparent because you can still receive signals (poorly) due to capacitive coupling of the center pins.

Another drawback of cheaper connectors is that when you mate the dielectrics of the cable plug and chassis jack together, they sometimes don't allow the shells to make contact, especially if the "teeth" are short. You might only have a very poor shell-to-chassis connection via the rubbing of the cable's screw ring to the shell.

TWO-TURN LOOPS!

To turn a large loop into something more manageable size-wise, try a continuous TWO-TURN loop. Each turn should have a 1-inch gap at the top of the turn, and at the bottom of the turn you attach the exposed braids and shorted pigtail together.

Turn spacing: you might want to put a coax-diameter's width of space between the two turns. I did this by winding one turn on the front of the mast and the other turn on the back.

(Click on any image to enlarge)

For example, my 40 meter single-turn diamond loop has a 14-foot circumference with an approximate 4-foot diameter.

I turned it into a two-turn loop by starting with a new 14-foot length of coax, and depth-winding a second continuous turn around a 2-foot circular diameter instead of a square 4-foot diameter. At the top of the loop are my two turns with the 1-inch gaps at the center. At the bottom output of the loop I made sure the exposed braids and shorted pigtail are connected together. From this point, I left about 6 inches of coax terminated with a PL-259 connector which attaches to my portable MFJ-16010 tuner.

(Note: I recently placed the tuner on the desk with a 3 foot jumper instead since this loop was designed for the lower bands. For smaller single-turn loops designed for 20 meters or higher, the length of feed from the output of the loop to the tuner should not exceed 6 inches - the closer to the output the better.)

Try to make all your measurements, cuts, and braid connections as symetrical as possible. Making the loop balanced is key to good noise rejection.

Here is how I made it:

- I used a 15 foot length of coax to allow for a short 6-inch run to the tuner and

some left over to make the shorted pigtail.

- Six inches from the end of the connector, make a 1-inch cut around the coax to expose only the braid.
- Measure 3.5 feet from the center of the exposed braid, and cut a 1-inch gap (1/2 inch on both sides of the mark) through the braid to expose the dielectric.
- Measure 3.5 feet from the center of the exposed dielectric, and cut around the coax for 1 inch to expose only the braid. (1/2 inch on both sides of the mark.)
- Measure 3.5 feet from the center of the exposed braid, and cut a 1-inch gap (1/2 inch on both sides of the mark) through the braid to expose the dielectric.
- Measure 3.5 feet from the center of the exposed braid, and short the shield to the center conductor. Leave about 4 extra inches or so of this shorted pigtail.
- Wrap the coax into a two-turn loop with the exposed braids parallel to each other at the bottom, and the exposed dielectric gaps at the top. Use tie-wraps, tape, etc.
- Wrap the shorted pigtail around the centers of the exposed braid sections at the bottom so that all the braids are in contact. Solder or tape together.
- Put the loop on your support, attach your tuner to the connectorized end and enjoy!

The results of this two-turn loop are great! Signal output levels between my single and reduced-area double-turn loops seems about the same.

Casual MF BCB DX'ing and LF

If you bypass the tuner, you might be able to use a loop cut for 80 or 160 meters in an untuned mode for casual MF BCB and LF reception. It is handy to null out the local broadcasters.

With the loop untuned, I've finally heard low-frequency CW beacons. So there IS life down there! For serious use, I'd definitely recommend specialized antennas for these bands, but at least an untuned loop might whet your appetite to go "lowdown".

Other Sources of Info

I am indebted to all the Amateur Radio operators, SWL's, BCB DX'ers, VLF'ers and other experimenters that provide me with information and encouragement with this project. They participate in the **Yahoo!® Loop group** and also on the **rec.radio.amateur.antenna** newsgroup. All errors and misinterpretations belong to me however ...

If you're interested in loops, whether they be shielded, unshielded, magnetic, loopsticks, etc, you can find a great discussion forum for loop antennas on Yahoo!® by clicking here.

Be sure to visit the K7ZB site with his pics and nice build of this loop, along with other interesting antenna solutions.

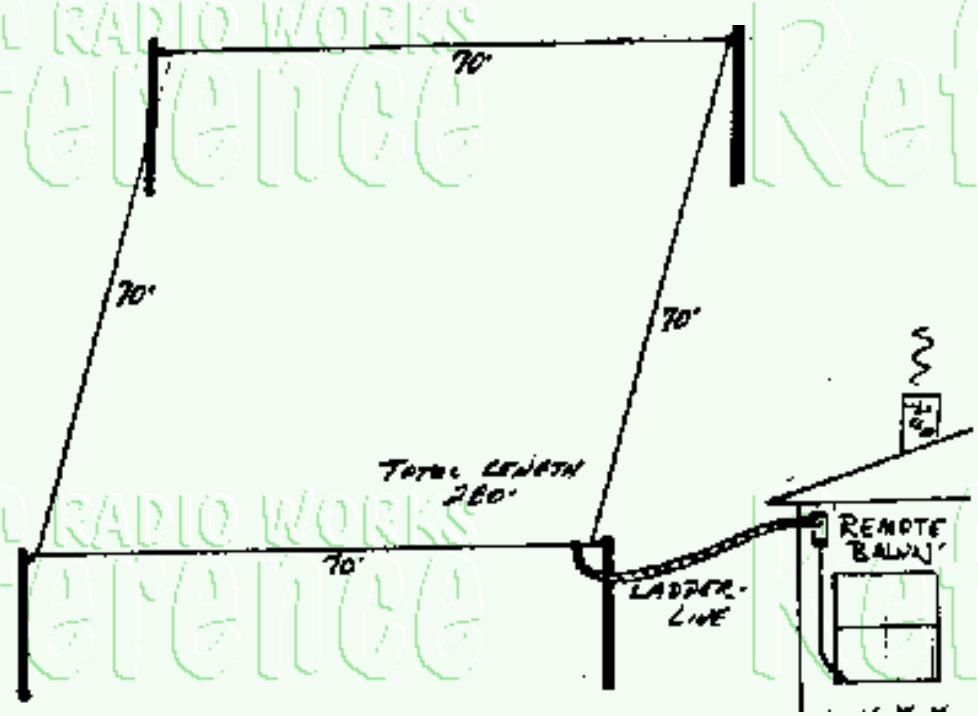
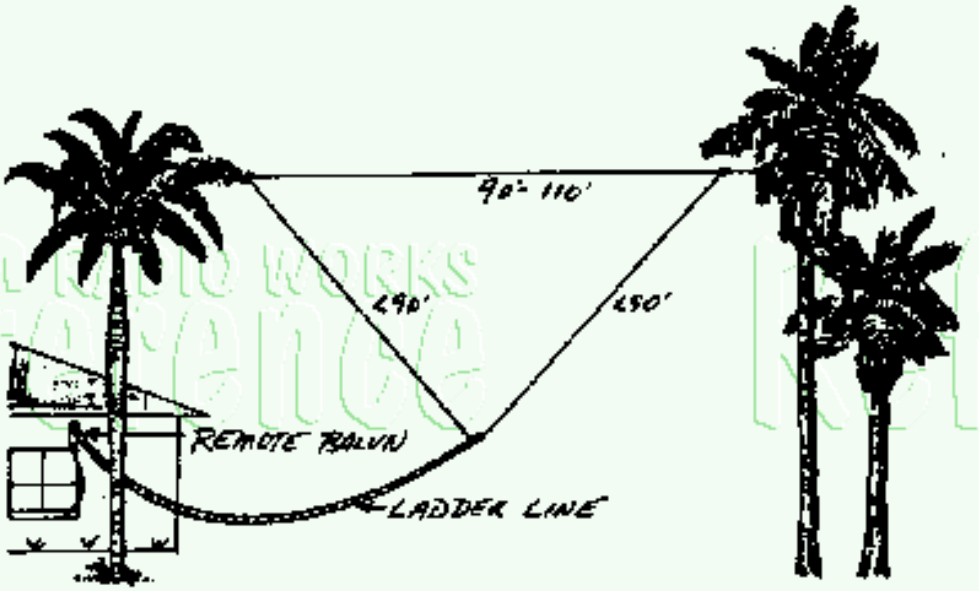
LOOP ANTENNAS





Full-wave loops are very popular antennas. They are especially useful on 80 and 40 meters where they perform well at modest heights. These are closed loops that are one full wavelength long. Horizontal loops may be fed at any convenient spot. For best performance, make your horizontal loop into a square, especially if it is to be used on several bands.

The Vertical Loop is a good DX antenna. The shape can be a circle, square, rectangle or a triangle. The larger the area of the loop the better it will work. Feed square and rectangular loops at a corner. For best results, triangular loops should be supported apex-down. This puts less of the antenna parallel with the ground and increased the effective height. Feed triangular loops either at a corner or in the case of apex-down loop, at the apex.

Use ladder line and a wideband transmatch (a naturally balanced tuner, like a Johnson Matchbox) for multiband operation. The RemoteBalun 4 is recommended if you will have problem getting ladder line to the operation position. Multiband operation is possible when feeding the loop with coax. The losses will be slightly higher, but the convenience of the coax may be worth the slight signal loss.

The design frequency, the feedpoint impedance, will be between 80 and 150 ohms. Coax fed loops will usually have an SWR between 2:1 and 3:1. You may feed this antenna with a 4:1 balun. If the loop is in the shape of square or large rectangle, the SWR can be below 2:1, but will not get much below 1.5:1.

If you decide to feed your loop with coax, I'd suggest using RG-8X or RG-213 and a high power, high performance 1:1 or 4:1 Current-type balun. Experiment with full-wave loops. You may find them to be excellent multiband antennas.

Antenna wire can be #14 hard-drawn antenna wire. Use #12 wire for large loops on 160 or 80 meters.

Center Frequency	Total Length in feet	Center Frequency	Total Length in feet	Center Frequency	Total Length in feet
3.5 MHz	287	10.12 MHz	99	28.0 MHz	35' 10"
3.6	279	14.0 MHz	72	28.5	35' 3"
3.7	272	14.2	70	29.0	34' 8"
3.8	264	18.12 MHz	55' 6"	29.5	34' 1"
3.9	258	21.0 MHz	48' 10"	---	
7.0 MHz	143	21.2	47' 6"	---	
7.2	139	24.93 MHz	40' 4"	---	

With this particular antenna, a RemoteBalun 4 and Ladder Line are used to permit multiband operation. If you have a naturally balanced tuner (i.e. a Johnson Matchbox), the RemoteBalun 4 is not needed. Click on the Balun Index do check out the the RemoteBalun's application notes.

g4fon

Welcome to my web site, my name is Ray Goff.

I was brought up in Farnborough, Hampshire and first became interested in radio at the tender age of eight while staying with my older cousin for a weekend and we built a crystal set together. This interest developed throughout my teenage years, to the extent that in my late teens I was running a lucrative business mending all the neighbourhood TV's and Radios.

At the same time I became interested in short wave listening after my father produced an old German Torn Eb TRF receiver, which he soon augmented with an R1155 set. This was the end of the 1960's and I had already joined the local Farnborough and District Amateur Radio Society.

In 1969 I started evening classes to pass my RAE exam. The course was held in a local school under the tutelage of John Hardy, G3KND. I passed the exam at the first attempt in May 1970, but was determined to hold out the for the 12 WPM Morse

test and a full license.

By 1973, while at university, it became clear that despite my best efforts, including help from another student, G3VMO, I was not going to pass the test in the foreseeable future, so I applied for a Class B, VHF only privileges license and received the callsign G8HMH.

Briefly back in Farnborough again, I joined another evening class led by Colin, G3XUU, to learn Morse code and in November 1976, finally passed the Morse test at a coastal radio station in Southampton and upgraded to my Class A license, G4FON.

From 1981 to 1984 I was G4FON/W9 while living in Chicago and then G4FON/W1 until 1989 while living in the Boston area.

In 1989 I returned to the UK and now live in the centre of Oxford which presents problems for HF operation. After a number of years of inactivity, I can now be found on 20, 30 and 40 metres CW, usually in the QRP section of the band.

This website reflects my main interests; QRP CW operating,

homebrew construction and the contesting. You are encouraged to look around and make use of anything you find. I would love to hear about anything you find useful, so drop me an email

On this website you will find a CW trainer which I wrote to build my CW speed back up, construction notes for homebrew equipment and aerials and a logging programme for the Palm OS. You will also find my latest programme, a Windows based CW Contest trainer.

More recently, I visited the Farnborough and District Amateur Radio Society for a meeting and renewed some old friendships and I am an active member of both the Oxford and District Amateur Radio Society and the Newbury and District Amateur Radio Society.

RF Toolbox

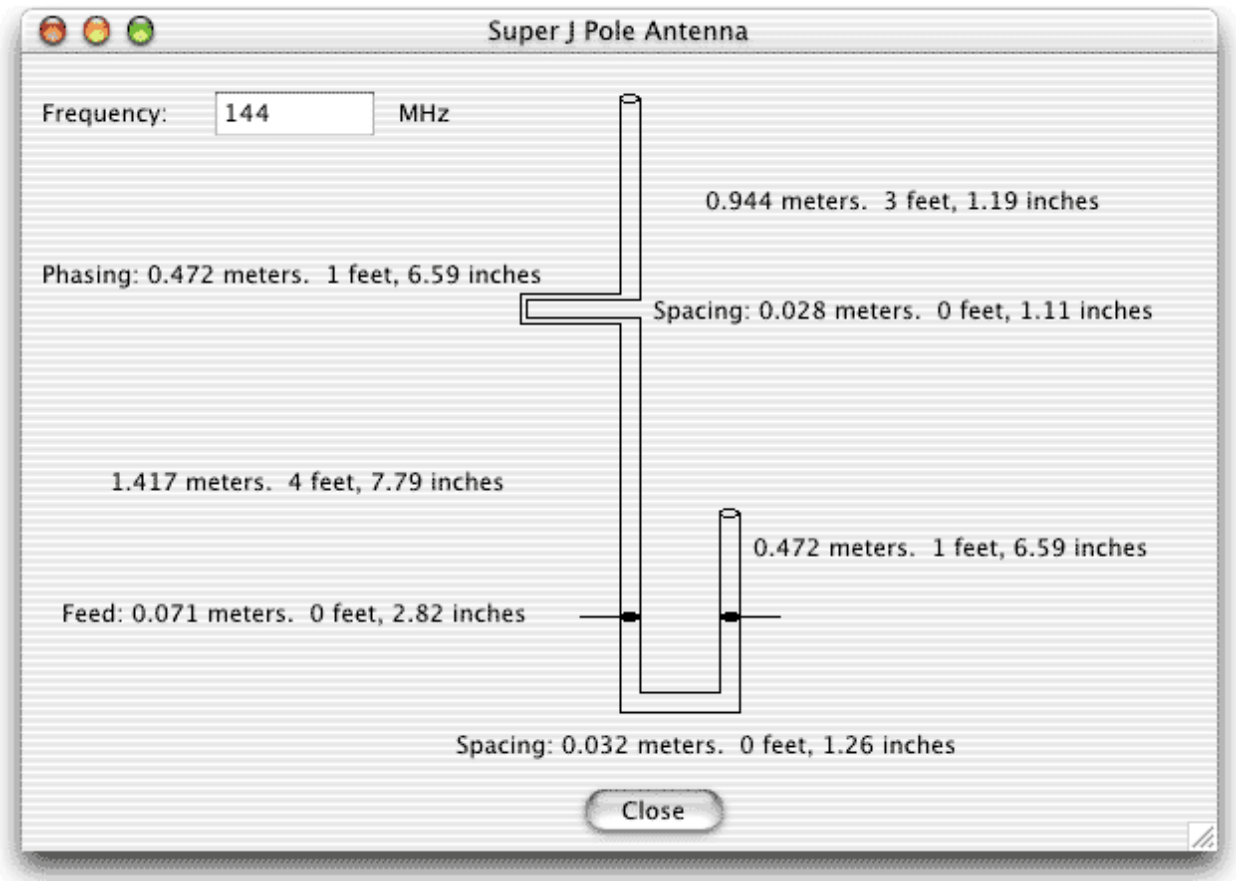
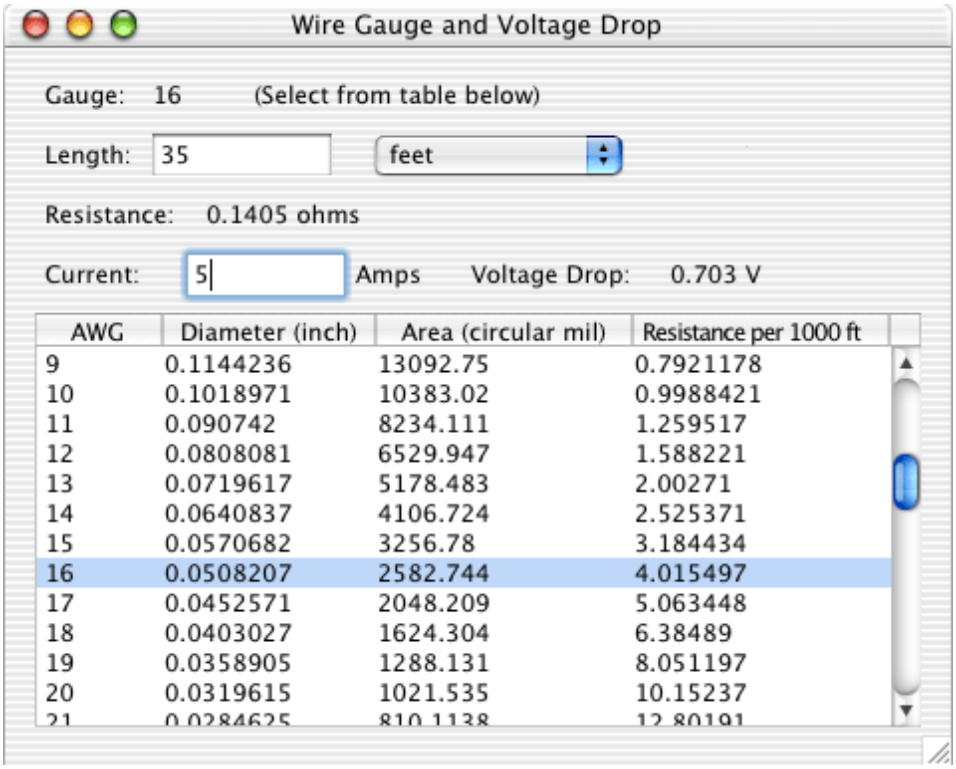
RF Toolbox is an antenna design and electronics/electrical tool package. It takes you step by step through the design of the following types of antennas:

- Dipole
- Fat Dipole
- Yagi
- J-Pole
- Super J-Pole
- Log Periodic
- Cubic Quad
- Vertical

It also performs the following calculations:

- Coil Design
- LC Filter Design
- Transmission Line Loss
- L Matching Networks
- Pi Matching Networks
- Impedance Calculations
- Wire Gauge and Resistance and Voltage Drop
- Wire Inductance Calculations





AWG	Diameter (inch)	Area (circular mil)	Resistance per 1000 ft
9	0.1144236	13092.75	0.7921178
10	0.1018971	10383.02	0.9988421
11	0.090742	8234.111	1.259517
12	0.0808081	6529.947	1.588221

Welcome to W2BRI's Magnetic Loop Site

Magnetic Loop Antennas for HF & Above

Last Updated October, 18th 2003
New Review of the AOR ARD9800 Digital Voice Modem!

New!

W2BRI gets the digital voice bug. Aside from my love of magnetic loops, I have been focusing my attention towards a new mode of communication for ham radio, digital voice.

Here is a link to my Digital Voice site.

My **new review** of the AOR ARD9800 Digital Voice Modem is ready for your reading pleasure!

Introduction

My current passion in radio has become the Magnetic Loop Antenna, also referred to as STLs, small transmitting loops. This site is dedicated to these antennas, and I strive to make this

Site Menu

A. Magnetic Loop Antenna FAQ

In this section you will find theoretical and practical information regarding mainstream beliefs, practical observations, and down to earth theory about these antennas. This FAQ will answer many major questions.

B. My 80 Meter Magnetic Loop Antenna

Find out about my largest magnetic loop for 40 and 80 meters. This page tells the story about how I came to learn about magnetic loops, and my experiences with this wonderful antenna.

---

the most comprehesive site possible. Magnetic Loops should not be confused with full size resonant loops commonly found in many radio operators backyards. The Magnetic Loop antenna has some special properties which distinguish it from many antenna designs like the dipole.

A major advantage of the magnetic loop is its high efficiency and small size. The magnetic loop is typically smaller in circumference than 1/4 wavelength of the desired operating frequency. There are many more advantages I plan on describing on this site and some disadvantages. The antenna is ideal for restricted operating areas and for portable operation. They can work close to the performance of a full size dipole antenna (sometimes exceeding a dipole) and do not require radials. They can be mounted low to the ground, and will exhibit a high level of performance. However, they tend to be very expensive devices when bought commercially. They can be homemade with relative ease, and this site will teach you how to build your own if you so choose.

Loop antennas are elegant antenna systems, but they are far from simple. The Magnetic Loop is a complex antenna and will not simply work as a plug and play solution. If one desires using the loop antenna effectively, a decent understanding of the antenna's characteristics are crucial. A Magnetic Loop can work very well for an operator if they understand the different variables necessary to make it work well. My intention is to elucidate many of these issues on this site and make it easier for operators to use these antennas successfully. I also intend to discuss some of the myths related to loop construction, and hope to clear up some possible misconceptions others have encountered in with this interesting antenna.

My hope is to open up the technology to more operators. I will welcome phone calls and questions at 818-505-0222 or by email at brian@standpipe.com, but perhaps you'll find the

C. How to Build Your Own Magnetic Loop Antenna

If you wish to build a Magnetic Loop antenna and have questions about how to make it work, this section is for you. This five step project plan explains all the steps to creating your own magnetic loop from basic plumbing materials. The article features step by step instructions and how-to pictures to guide even the most basic beginner in Magnetic Loop construction. The article also features a section on capacitors and loop tuning. It is a must read.

D. Images and Notes from other Loop Builders

You are not alone. There are many others out there building and experimenting with Magnetic Loops. This section features great articles and pictures of other loop builders and their experiences. If you are serious about what's going on out there in the world of Magnetic loop, then this section is essential. If you are interested in submitting an article, please send me an email at brian@standpipe.com

---

E. All About Variable Capacitors

Many of you have asked for this section and here it is! Where to buy your vacuum variables, what to watch out for, and how to use them. This section also covers air variables, sources to buy them, and additional info. Enjoy.

---

answer to what your looking for on this site and build it yourself!

I am always looking for original artciles, images, and info on Magnetic Loops. Please email me at:

brian@standpipe.com

if you would like to submit content for the site.

If you are interested in the topic of project management, I write a monthly article which can be found at www.allaboutpojects.com

F. Loop Software Page

In this section you'll find some very easy to use loop modeling software. It's as easy as pie to plug in your desired parameters and see how well your antenna will perform theoretically. There is also a very cool homebrew capacitor design program. Check it out!

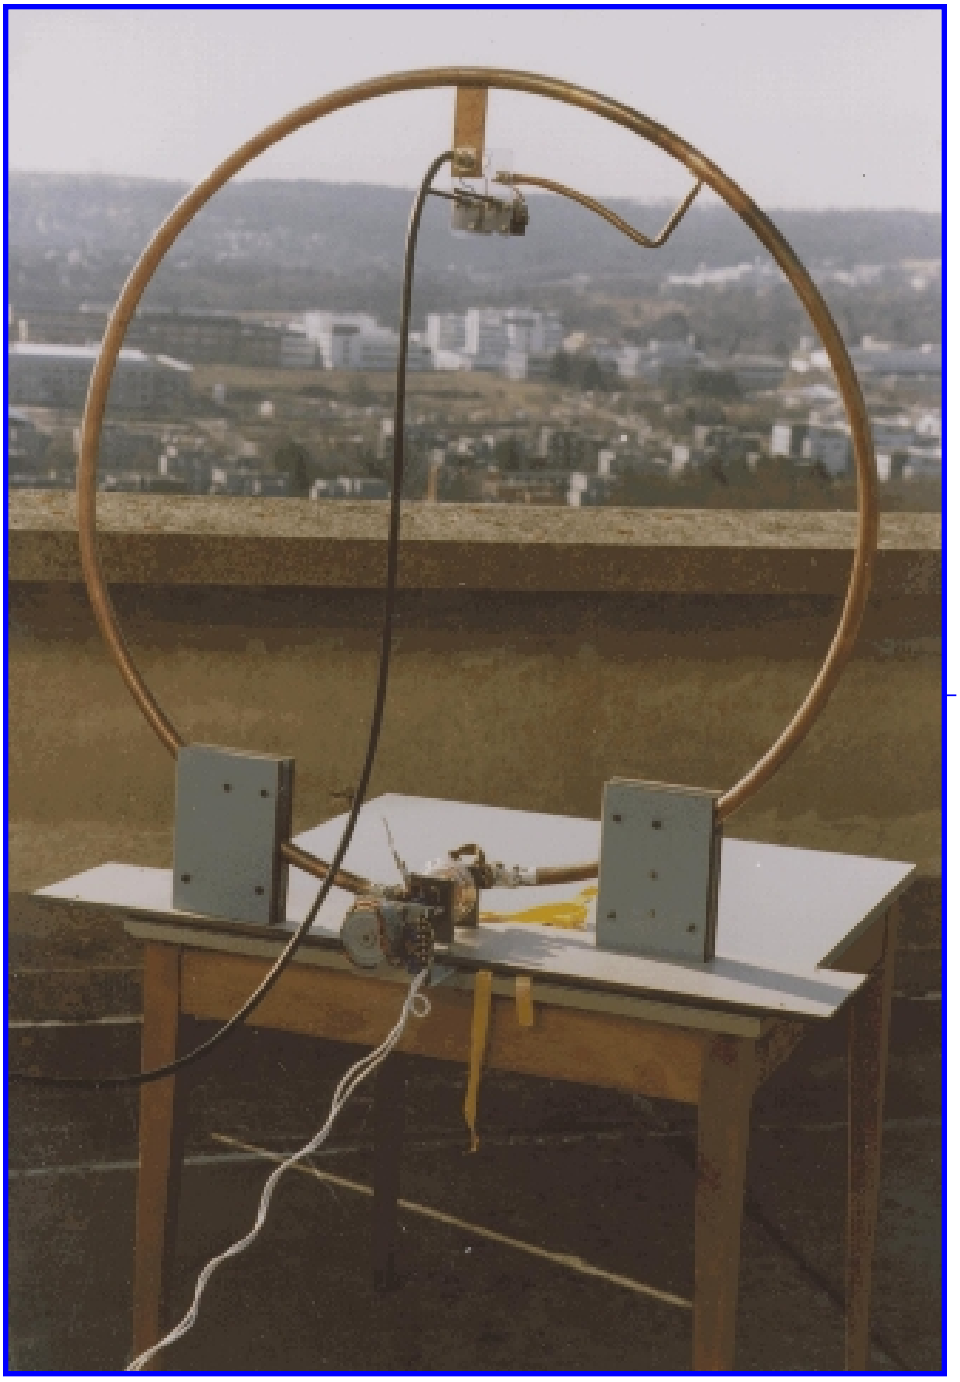
Wellcome on DJ3TZ's Small Tuned Loop Antenna Page !



My first homemade STL ``Mag-1".

(Mni tnx to Markus DL5OBZ for the photo! Click for a larger version (719kB).)

I intend providing more detailled information here, but so far there are only some links.

Links to other ham radio small tuned loop (STL) pages:

- Guenther DH7BZ gives details about his homemade STL and practical experience (in german)
- Visit the homepage of Carl GW0TQM with plenty of information on almost every topic related to STLs, including many references and links. (page still active?)
- A collection of homebrew antenna links maintained by Rod AC6V, with many pointers to STL pages.
- An article archive also covering loop antennas, maintained by Willian Eric WD8RIF, including STLs.
- Peter VK3YE gives a detailled description for a homemade STL
- Stephen AA5BT describes STL construction
- Tony ON4CEQ describes his homemade STLs. Don't miss the photos!
- John G3PTO describes the G3BGR Magnetic Loop, lots of antenna links
- Jindra OK1FOU gives a detailed description of his homemade STL
- Harry SM0VPO/G4VVJ describes his 160m/80m loop and a remote antenna tuner
- Frank G3YCC describes the STL published by Tom GM3MXN and the "Rock Loop"
- Jess Dypin N0TFI also presents information about the "Rock Loop" (page still active?)
- Don't miss the "Loop Antenna Discussion" article archive
- Minowa 7N3WVM describes a STL made from printed ciruit borads
- David PA3HBB/G0BZF describes practical experience with building and using loop antennas
- Folkert PA3CQR gives information about his STL covering 10 - 17m

---

Capacitors:

- Click here for references to articles about homemade HV variable capacitors in amateur radio magazines
- Tony ON4CEQ describes in detail how to make your own air variable butterfly capacitor
- RF Parts offers high power air variable capacitors
- Jennings is well-known for their vacuum variable capacitors

---

There are several programs to compute STLs:

- FTP site with lots of ham software, includes STL programs
- Many ham-related computer programs written by Reg G4FGQ, including STL computation

---

No time to build your own loop? Click here for links to STL manufacturers and reviews of their products:

- Small Tuned Loops by WiMo Elektronik
- AMA (german abbreviation for "tunable magnetic antenna") loop antennas made by Kaeferlein electronics
  Click here for references to reviews in amateur radio magazines
- The High-Q Loop Antennas by MFJ
  (Their pages also contain the manuals.)
  Read the experience of Bob VO1DRB/WA6ERB/VE2DRB using this antenna for QRP operation
  Click here for references to reviews in amateur radio magazines
- AEA seems to be off market, but you might find their Isoloop Antenna on a flea market or so.
  Experience report ``Work the World with an AEA IsoLoop'' by Don W6TNS
  Click here for references to reviews in amateur radio magazines
- Broadcast band RX loop by Kiwa Electronics

Did any link change? Are there any good pages missing? Let me know!

Any comments? Click here to read and sign my guestbook

Please do not bookmark this page but only my start page http://www.qsl.net/dj3tz/index.html as the structure of my pages might change.

Magnetic Loop Antenna = Mag-Loop, Small Transmitting Loop

Felix Meyer

(Update: March 8, 2003, Dec. 17.03, Jan 5,04, Jul. 4,04)

The magnetic loop antenna is an extremly efficient short wave antenna for the small size it constitutes. It consists of a loop radiator made of copper or aluminium tubing and a tunable capacitor.
The size of the antenna is very small as compared to the size of a traditional antenna as dipole, beam, quad or vertical. The diameter of the loop is in the range of 1/10 to 1/100 of the wavelength.
The antenna works with the magnetic component of the EM field, which extends to the both EM components on larger distance. For that reason the antenna operates well close to ground and radiates a much stronger

signal than a dipole when both are close to ground. Surely, a full size dipole mounted in its optimal hight radiates better than a magnetic loop, but due its efficiency at low height the magnetic loop is an excellent portable antenna or may be used well as indoor antenne when external antennas are not permitted.
The capacitor of the antenna needs to be remotely adjustable to allow a frequency tuning range from 1:2 or 1:3. When properly built, the SWR is below 1.1 on the tuned frequency over the full tuning range.
The bandwidth is always very small and covers only a few KHz. The high Q of the antenna allows a selective receiption and suppresses effectively QRM of nearby BC stations, as well as other QRM.
Here I am using 2 loop antennas, one for 3.5 to 10 MHz and one for
14 to 30 Mhz, both antennas with only 85cm diameter, below the roof.
The 14 to 30 MHZ antenna with 50 W output allows for regular worldwide contacts with good results.
The antenna can be built easily as homebrew project if one can find or build a suitable capacitor.

Below you will find a loop calculation program for your own design together with detailed instrucions for magnetic loop antennas from 3.5 to 30 MHZ.

Calculation program LOOPABXE.EXE click for free download (new version Dec.31, 2003) with
calculation of multiturn loop, calculating all electric data.

Control through Coax

Magnetic Loop Antenna : Construction hints

The following instructions should be observed
for successful construction and operation of magnetic loop antennas:

DANGER : IMPORTANT NOTES !

The radiated field is very concentrated and may produce health problems.
Therefore, one has to keep distance to antenna of at least 5 meters
if the power exceeds 10 watts.

Coupling to the loop is done mostly at the lower side of the loop and the
tuning capacitor is placed on top. Due to mechanical stability I installed the capacitor with motor on the bottom and the coupling loop on the top without having any deficiency in HF radiation.

There are several coupling loop constructions. The simplest one is by forming a loop of installation wire (bare or isolated), or using a coax cable (type RG58). The diameter of the coupling loop is about 20% of the diameter of the transmitting loop. One end of the coupling loop is soldered to the center conductor of the coax, and the other end of the coupling loop is soldered to the braid of the coax.
There are several types of feeding: either capacitive coupling or inductive coupling. The easiest one being just a simple wire loop as you see here.
Here you see a capacitive coupling and here you see a gamma coupling.
The position of the coupling loop is inside the loop, exactly opposite to the capacitor. At this point, the voltage of the transmit loop is zero.
The distance between coupling loop and transmit loop varies from 0 to 6 cm.
By changing this distance, the lowest SWR is adjusted. Fine adjustment can be done by changing the form of the coupling loop, wider or smaller.

A good coupling loop is the symmetrical loop which you see on this picture.

The environment close to the loop influences this adjustment.
With proper adjustment a SWR lower than 1.1 can be reached.

Main loop and coupling loop should not be connected directly, as RF coupling to the feeding coax may appear easily and can produce RF interference (TVI/BCI), therefore no direct connection between center of main loop and coupling loop.
However, the main loop may be charged by static electricity and discharges by producing QRM bursts. This can be eliminated by inserting a small coil between the center of the main loop and the coax braid of the feeding coax.
If this connection is done without a coil, radio interference (RFI) may be

**produced due to small misbalance.
Coil data: 40 turns of .2 to 0.5 mm enameld copper wire at 1cm diameter
wound over 2 cm length.**

**The main loop may be made of tubing (copper or aluminum) or thick coax cable. If coax cable is used (RG213 or RG8 or similar) the inner conductor and the braid (= shielding/ground) is soldered together at both ends. These ends are then connected to the capacitor.
Very high current flows in the main loop. Therefore, thick and short copper wires are required to connect the capacitor.**

**In tubes, the current flows only on the surface due to the skin effect,
therefore the use of foil is an interesting method.
Very efficient and lightwight loops can be built by using a thick plastic
support and placing copper foils over this structure. The foil can be placed
in narrow strips in the direction of the loop circumference, as placing
the foil in one step produces crumpling.**

**The form of the main loop may be square, n-square or round.
The round form is most efficient as the losses are minimal.
(Best ratio of L:R).**

**Nearby environment affects the SWR.
In free field, the body of the loop should be 2 loop diameters above ground.
Good are 5 loops diameter hight, higher elevation gives only small signal difference.**

**If the loop is installed below the roof, then keep 10 to 30 cm space below
roof brick and avoid nearby lines and metallic constructions.
Note that the roof above the loop should not be a closed metallic construction.**

It's important to observe that the feeding coax below the loop is kept

**in the symmetric center between the two half loops straight downward at the length of one loop diameter.
By not observing this rule, RFI may be generated !**

**In any case, I recommend to insert a broadband current choke into the feeding coax, about 1 m away from the transmitting loop, as surface currents
on the coax cannot be prevented completely.**

**The loop capacitor needs to withstand high voltages and high currents. Butterfly capacitors are a very good choice as they have no sliding contacts. Variable vacuum capacitors are an excellent choice.
100 watts RF power produce about 4000 volts on the capacitor (see program). Required distance between plates is ~ 1 mm per 1000 V.
Suitable capacitors are made by HB9TJX (address at end of page).**

**A DC motor with strong reduction (about 2000:1) serves to control the capacitor. Suitable motors can be found in airplane or car model shops.
(E.G: Robbe No.4103 with 2430:1 reduction).
Grill motors may serve also fine.
Please note that there is a high voltage isolation required between motor and capacitor.**

I recommend to use pulsed DC current to control precisely DC motors. By adjusting pulse ratio properly, small increments may be controlled perfectly.

**A suitable circuit diagram is included for that purpose.
(Switch: FAST/SLOW; keys: RUN und BACKWARD).**

**The remote control motor may be fed through the same coax feeding the loop, hereby no separate control cable is required.
See link under: Control through coax.**

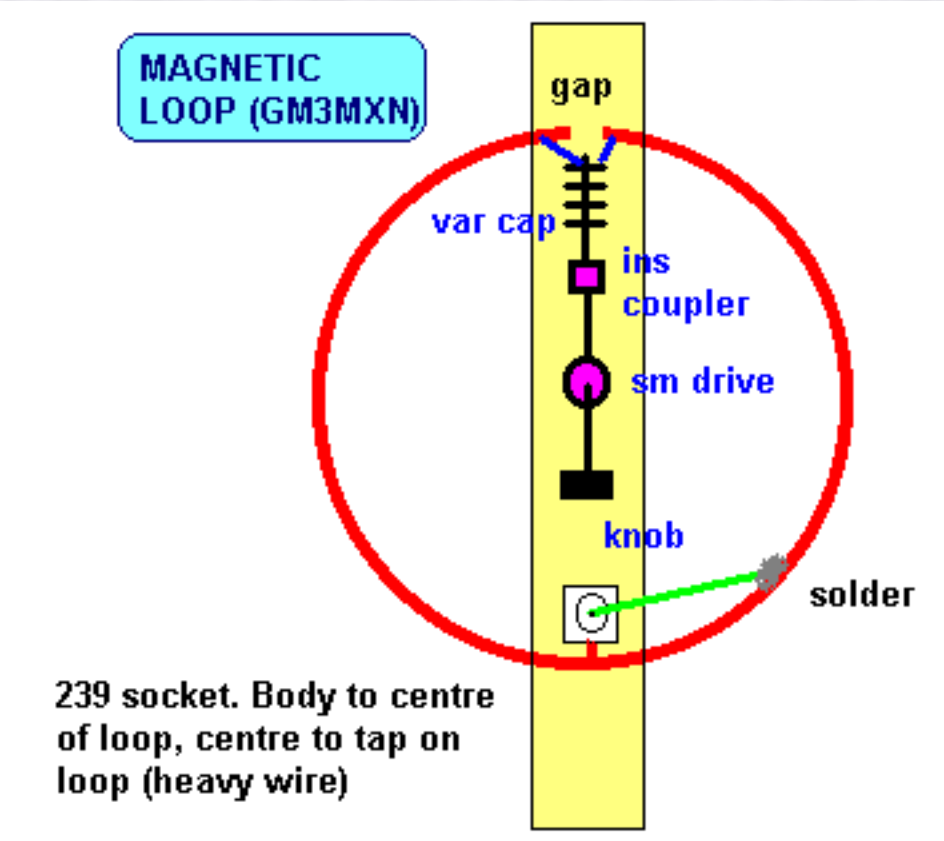
A Magnetic Loop Antenna



Various articles have appeared describing magnetic loops for HF use, some with complicated methods of remote tuning and the antenna can be quite a useful and interesting project.

The article in Sprat 61 my Tom, GM3MXN describes a loop useable from 7 - 21 mHz, using half inch copper tube 3 feet in circumference. As shown, there is a gap at the top of the loop, which may be about 3/4 inch, either side of which is connected to the tuning capacitor, which can be about 250 pF. The inner of the SO239 socket at the base of the loop is soldered onto the centre of the loop, with the inner forming a gamma match to the tube, about 9 inches from the earthy connection. This is adjusted for minimum SWR. As show, the loop can be mounted on a wooden support and is fed with 50 ohm coax.

Notes

Tuning of the capacitor is very critical, and it may be advantageous to use more than one slow motion drive, which is what I did in my version.

It should be noted that a high potential is present across the gap, and even at QRP levels can be dangerous. Certainly with higher powers, this situation can be **LETHAL**. I would personally not recommend the use of such a loop in the shack because in my opinion even, QRP levels can produce what may be dangerous amounts of RF, which has been blamed for brain damage. Suffice it to say that I

know of one local who did use a mag loop indoors and wondered why the paint next to the loop was bubbling (!), and another who used a handheld VHF/UHF handheld, always with the rig next to his head. He died of a brain tumour. Whether there is any medical evidence or not, I think it wise to avoid situations of RF close to the body. *Is it worth the risk?*

For high power use a wide spaced capacitor is needed to avoid flash over.

Maximum radiation is off the ends of the loop, not broadside on, as in a quad or delta loop.

It will be necessary to retune the variable capacitor when QSYing, even slightly, as this is a high Q system. I used one on 40 meters and it proved fairly directional and quiet.

Other versions have used coax inner instead of copper tube. It is important to ensure that the loop is made from low ohmic material. If a square version is attempted, using say plumbers' connectors, ensure each joint is very well made, electrically.

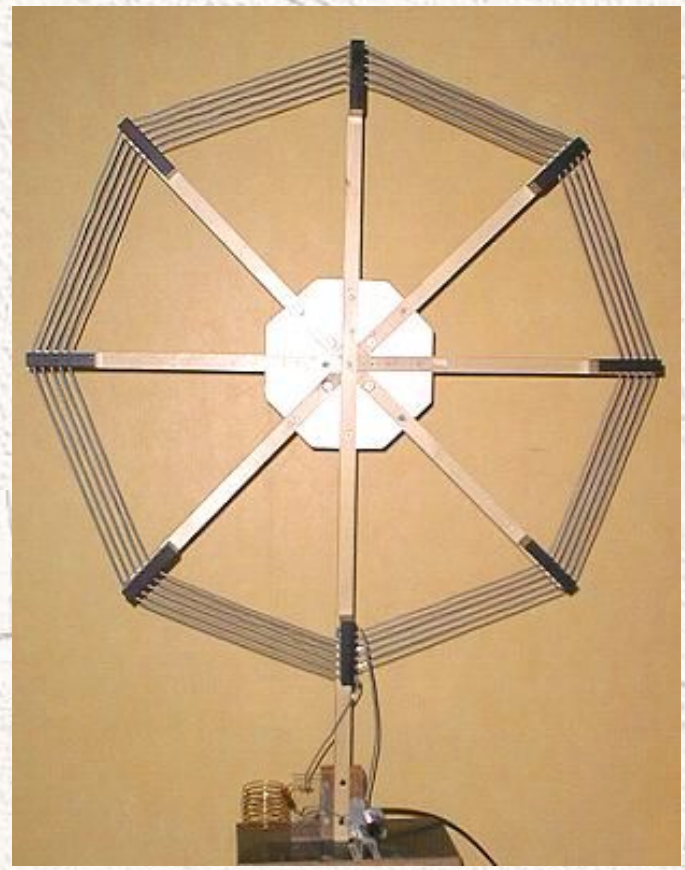
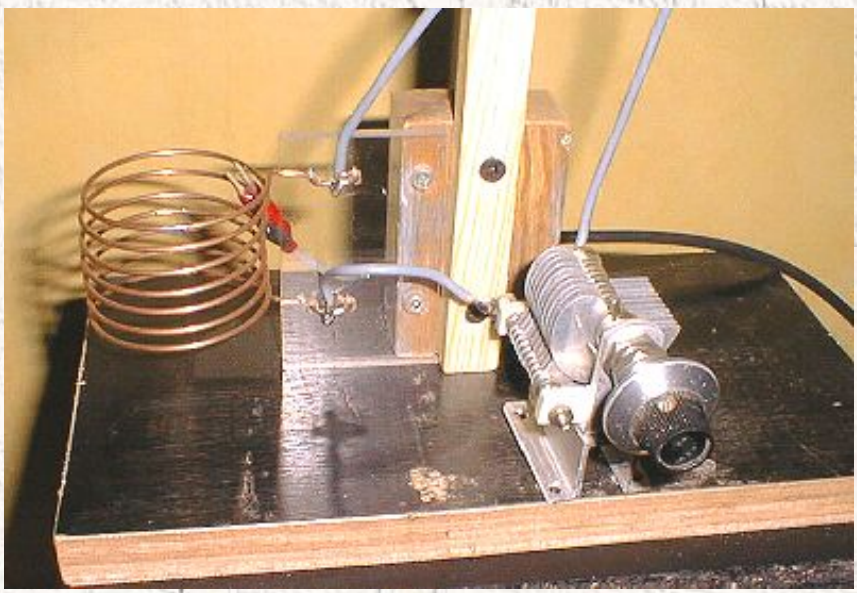
Magnetic Loop Antenna's.

Why is an Magnetic Loop antenna so special, this antenna is picking only the MAGNETIC part of the ELEKTRO MAGNETIC radio wave. The big advantage of this antenna is that the electric interference from the big city (streetlights, television's , cars etc...) have no influence on the received signal. With the loop you can hear other stations that you can't hear if you use a DIPOLE, with a dipole the stations are buried in the noise.

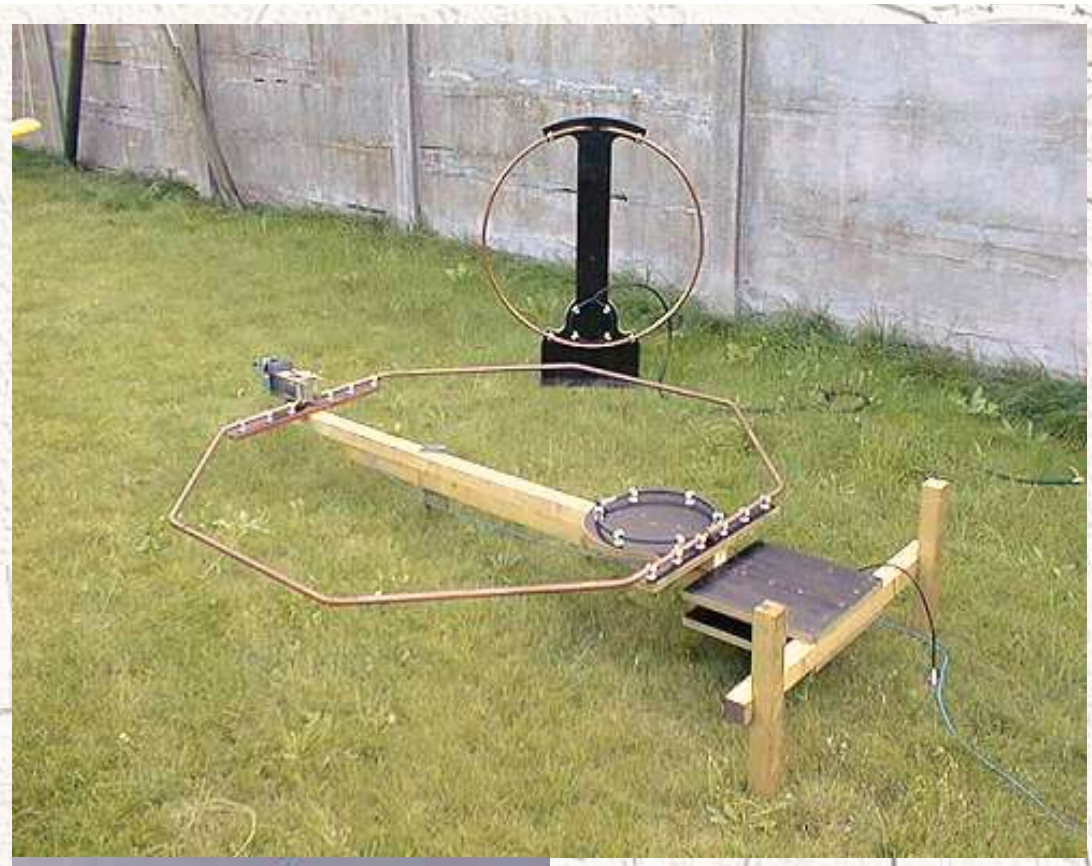
Multi Turn Magnetic Loop.

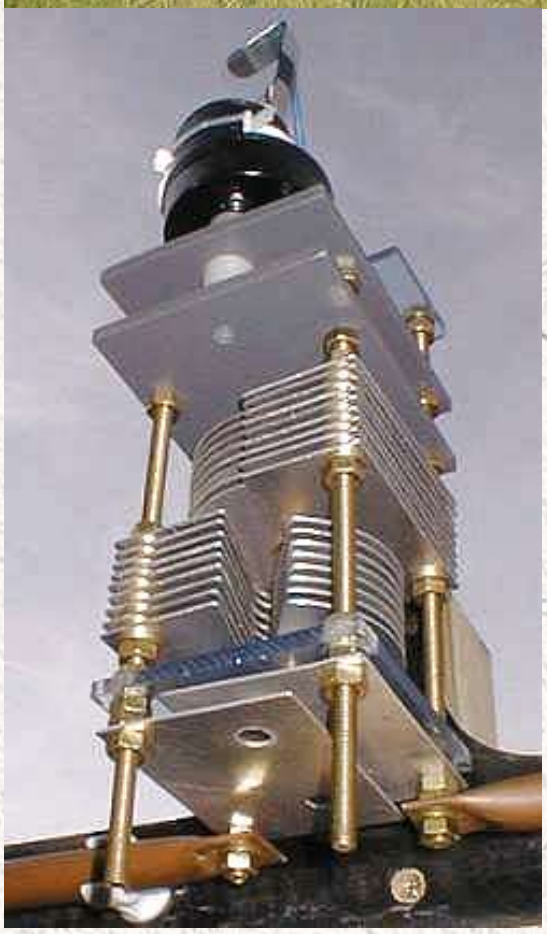
This is the first loop I build from a article in the QST from February 1996, it's 30 Inch-diameter, and it's designed by G2BZQ/WØ for 80 M.





Single Turn Magnetic loops





The first one turn loop that I built was made from 75 Ohm TV Coax and with a small explanation in the RSGB handbook for radio amateurs. I used the outer screen from the

coax and the results of the loop where good.The next loop I built is a octagon loop in 15mm copper tube with a circumference of
4.8 meter (16 feet).
The frequency range of this loop goes from 14 MHz to 7 MHz and works fine. The biggest problem is the tuning capacitor, if you transmit with a power
of 100 W you need a capacitor with a voltage rating of 5000 Volt.
A capacitor which can handle this voltage is hard to find over here and if you find one they are very expensive.
The first capacitor I built was a design from GW3JPT from a article in the RADIO COMMUNICATION from February 1994. It is a split stator capacitor with a capacitance of 140 pF and with a voltage rating of 6000 Volt.
The capacitor is remote tuned with the use of a small BBQ spit motor.

The second capacitor I built is my own design and it's a butterfly capacitor because the losses are lower than a split stator.
The capacitance is 5-65 pF and the voltage rating is 7200 volts. I used
it for the small loop with a dia. of 800 mm (2.66 feet) and the frequency range of this loop is from 28 MHz to 14 MHz. The Aluminum plates of 1 mm
for the capacitors are cut with a JIG SAW.

Most asked Questions:

I`d like to talk a little more on your setup. it seems like something whichI could get together if only some more data was available. do you have anynotes etc still laying about since its build ?

The theory for calculating the loop is very simple.The circumference of a magnetic loop is 1/4 wave of the designfrequency.

Example for 14 MHz.

300 / 14 MHz = 21.428 m is 1 wave

21.428 / 4 = 5.357 m is 1/4 wave circumference

5.357 / 3.14 = 1.706 m diameter.

The recommendations are that you can tune the loop from the design frequency to the frequency divided by 2 to keep the effiecency acceptable.

14 MHz / 2 = 7 MHz

I made the small loop (800mm / 31.5 ") from soft copper tube on a role that you can buy in a plumbershop and it's easy to make a nice circle if you draw on the ground a circle with a rope and a piece of chalk.

For mounting the loop to the hardboard I used plastic clamps
that they use for mounting copper tube on the wall.

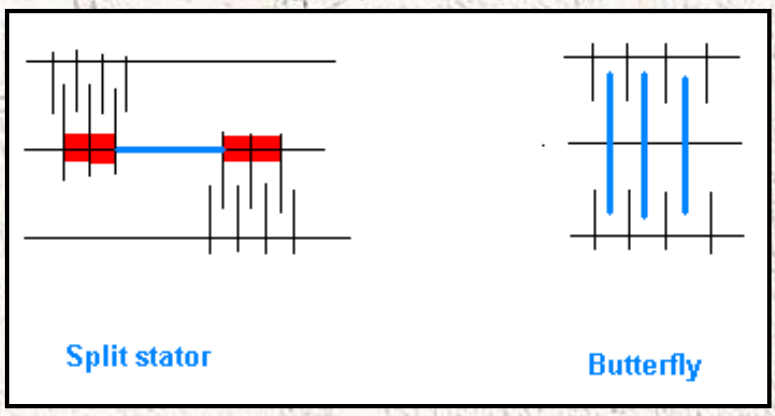
---

why is a butterfly capacitor better?

For high voltages and currents the use of Capacitors with wiper contacs is not recomended. That's why they use capacitors in serie's.The pro for serie's capacitors is that the voltage rating is doubled.The anti is that the value of capacitance is divided by 2.

For the split stator capacitor the 2 capacitors are connected in series by the shaft (bleu) and the red spots on the first drawing are losses.

For the butterfly capacitor the 2 capacitors are directly connected in series by the rotors and gives less losses.



Do you know of anyone that has built a similar loop that outperformed a garden variety dipole?

Compare antenna's is very difficult , sometimes I have for 60 % better signals in RX and TX on the loops then on the dipole.

In Theorie is the performance of a magnetic loop - 0.4 dB lower then a dipole or a vertical .

I have over here a homebrew trap dipole from 40-20-15-10m and the height aboveground is only 7 m(23 ft), for a good performance on 40 m the dipolemust have a height of 1/2 wave above ground (66ft). I don't have a radiation angle on 40 m and it's only good for contacts in Europe and not good for DX, now the 1.5 m loop tuned to 7 MHz with a effiecency of 38 % (38 w ERP) and a angle radiation of about 20 degrees performs better than the dipole because the vertical magnetic loop only 1 M above ground as a angle radiation and the dipole don't.

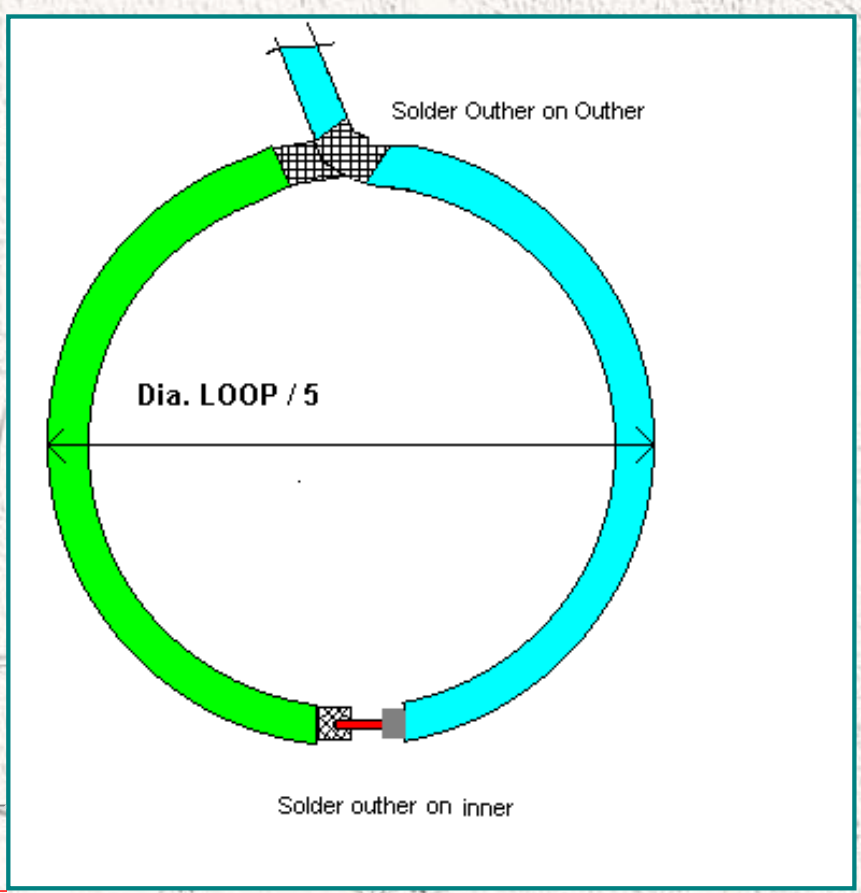
Another advantage is that the reception on a loop is mutch better, on 20m I have with the dipole S5 noise from the big city, if I switch to the loop I have S1 noise and hear stations who are buried in the noise when I use a dipole.

Coupling loop dimensions?

I find that the best way to feed the loop is with the shielded 1/5 Faraday loop made from coax RG213 or RG8, I tried the gamma match bud I had problems to keep the VSWR low on all Bands, the shielded loop gives on all bands VSWR 1.1 and reduce more noise pick-up then the gamma match.

I found out that if you use a 1/5 Faraday loop, that the loop is to big, making the loop smaller with 0.5 inch by the time in circumference and checking with a field strength meter you can see that the radiated power increase.

The place off the feeding loop is placed at the electrically neutral point on the loop and that is 180° from the capacitor and I have the best results with the feeding loop close to the ground and the capacitor far from the ground.



I was wondering if you worried about the resistance of the mechanical joints (copper pipe bolted to the capacitor) significantly reducing your radiation efficiency as I think the radiation of these antennas can get as low as .01 ohms

Soulder or weld the capacitor plates is always the best, but I'm afraid if you make the spacers and the plates in ALU that with welding everything is gona bend from the heat

and I know from practice (I work in a maintenance workshop) that welding ALU is coarse. Another possibility is using all brass or copper and solder, there are hams that using double PC board for the plates.
I made a QSO in phone with Florida, RPRT 5-5 and the other station used a vertical antenna, with the small loop (800mm and theoretical effiecency 41 % on 14 Mc) vertical in the garden and the states side is through the house. I was very happy with the results , so I think that a capacitor
maded with torqued compressed joints is good enough for using 100 W.

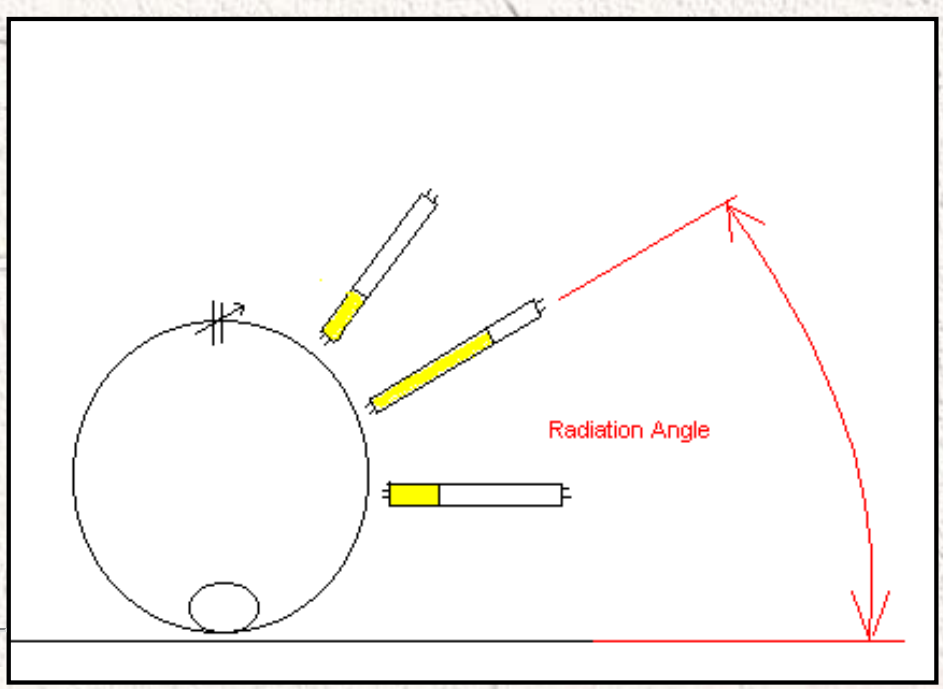
Have the dissimilar metal joints weather well?

To keep the oxidation low on the dissimilar metals I used a thin coat of vaseline after assemble the capacitor and with the tupper ware a like plastic box it is good protect against all wheather conditions.

How to find the radiation angle of the antenna?

Can it be found practically?

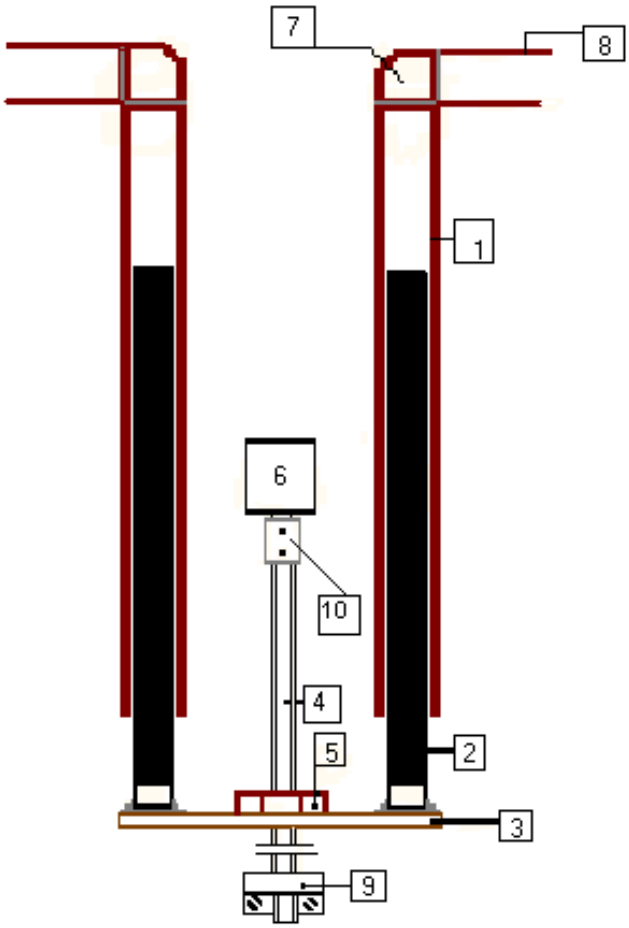
Finding the radiaton of a magnetic loop is very easy, with a TL-lichgt tube you can see it, with abt 10 w power on the the loop with the TL-tube in the plain of the loop at right angle to the circle you see the tube lightning, there where the the light is the farest on the tube thats the radiation angle.



When you refer to washers, nuts and rods you use the term "M6".Please forgive my ignorance, but to what does "M6" refer? Does this mean 6mm?

M6 is (M=metrical) and 6 is indeed 6 mm threaded rod and
you can compare the size with W1/4" (6.35mm) .

A very easy to build Piston Capacitor.



1) Copper tube

2) Coax RG8 or 213

3) Double PCB

4) Threaded Rod 1/4"

5) Brass nut

6) Motor with reduktion or stepper motor

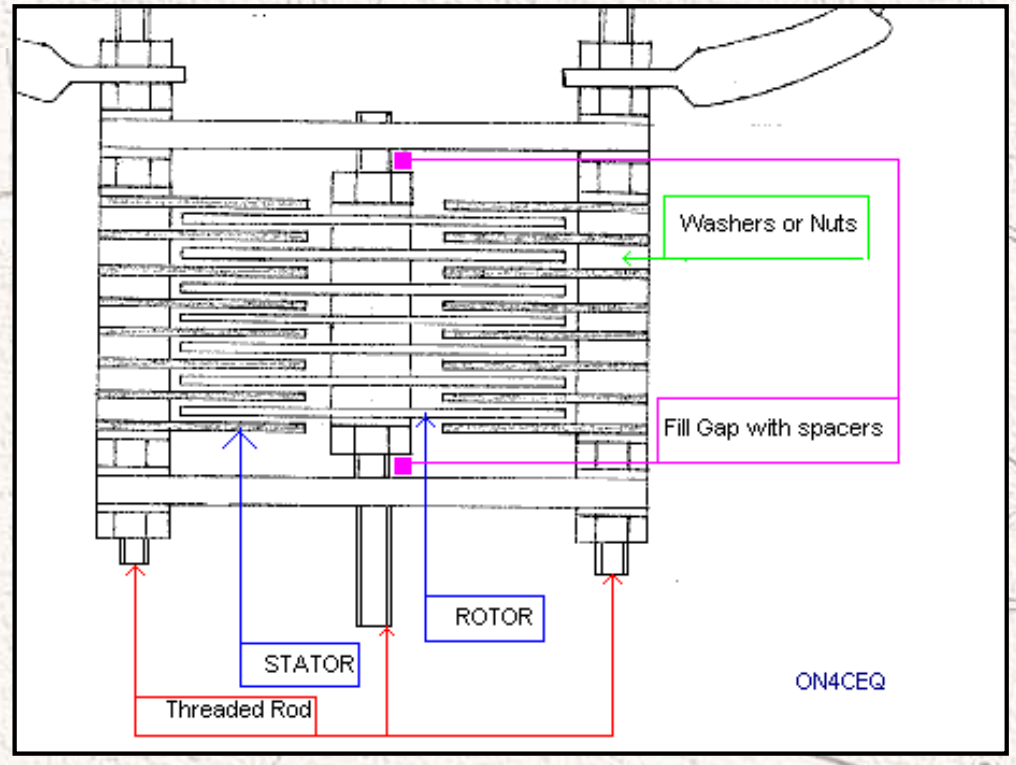
7) Copper Elbow 90°

8) Loop

9) Bushing from old var resitor

10) Couple shaft (PVC)

How to build your own Butterfly Capacitor.



The best material for the front and the back is CLEAR PVC 3 or 5 mm thick as alternative you can use GREY PVC or 2 sheets pcboard together with the copper removed .

The best material for the washers, nuts (M6) and threaded rod (M6) is brass or stainless steel,(NON MAGNETIC MATERIALS for the losses).

For the spacing of the vanes you can use 2 washers M6= (6Kv) or a nut M6 =(12 Kv) if you use aluminum plate 1 mm thick.

If you use a nut then the best thing to do is remove the thread by drilling withØ 6.2 mm.
The effective area for the vanes is 11.7 cm² and with the formula

for 2 washers = (0.0885 x 11.7 cm²)/ 0.1 cm = 10.35 pF for 1 air gap.

for 1 nut = (0.0885 x 11.7 cm²)/0.2 cm = 5.17 pF for 1 air gap

Example:

If you you make a capacitor with 2 washers as spacing and you make 5 rotor vanes and 6 stator vanes then you have 10 air gaps.

10.35 pF x 10 = 103 pF + 10 pF stray capacitance = 113 pF / 2 = 56 pF

The final result is a capacitor with a value from 5 - 56 pF.

Home Brew dual band antenna

Generally speaking, this is a dual band design focused with better performance on UHF. It can satisfy needs on most situation. If you always work in hot areas where out-band cross modulation are causing trouble to your reception, this antenna might even improve the selectivity slightly. If you always work at marginal signal area and have to squeeze the last drop of energy from your system, this is not a suitable candidate.

Basic design theory

This antenna is just a 1/4 wavelength resonator for both UHF and VHF band. It provides no GAIN as compared to other multi-section design. Yet it has the advantage of better stability against surrounding influence (e.g. different mounting method, unexpected reflection by surrounding objects, difference in stray capacitance between test bench and operating field). The antenna consists of two sections. The lower section is a conductor cut to resonant on UHF band. The upper section is a coil which serves two purposes. For UHF band, this coil is a RFC (radio frequency choke). It blocks UHF frequency energy to

flow through upper section. For VHF band, this coil enhances the inductance provided by lower section. The resultant inductor, together with surrounding stray capacitance will form a VHF resonant circuit and becomes the VHF antenna. To get a better understanding on the tune up procedure, it will be helpful to review some basic rules onantennas.

- Antennas are LC circuits. The LC components control their resonant (operating) frequency. Inductive component is formed by metal conductor of the antenna's body while capacitive component refers to stray capacitance between the antenna body and its surrounding grounded conductor.
- Increasing either L or C component can lower the resonant frequency while reducing them causes the opposite effect. Inductor can be increased by adding physical length of the antenna element or by making it as a coiled structure. Capacitance can be increased by using a larger surface area on the antenna body, by adding capacitor hat or by reducing physical clearance between inductive section from ground. In this issue, we mainly alter the inductive section of the antenna to achieve tuning. That is done by cutting length of the conductor and by changing length of coil structure.

Mechanical structure and material consideration

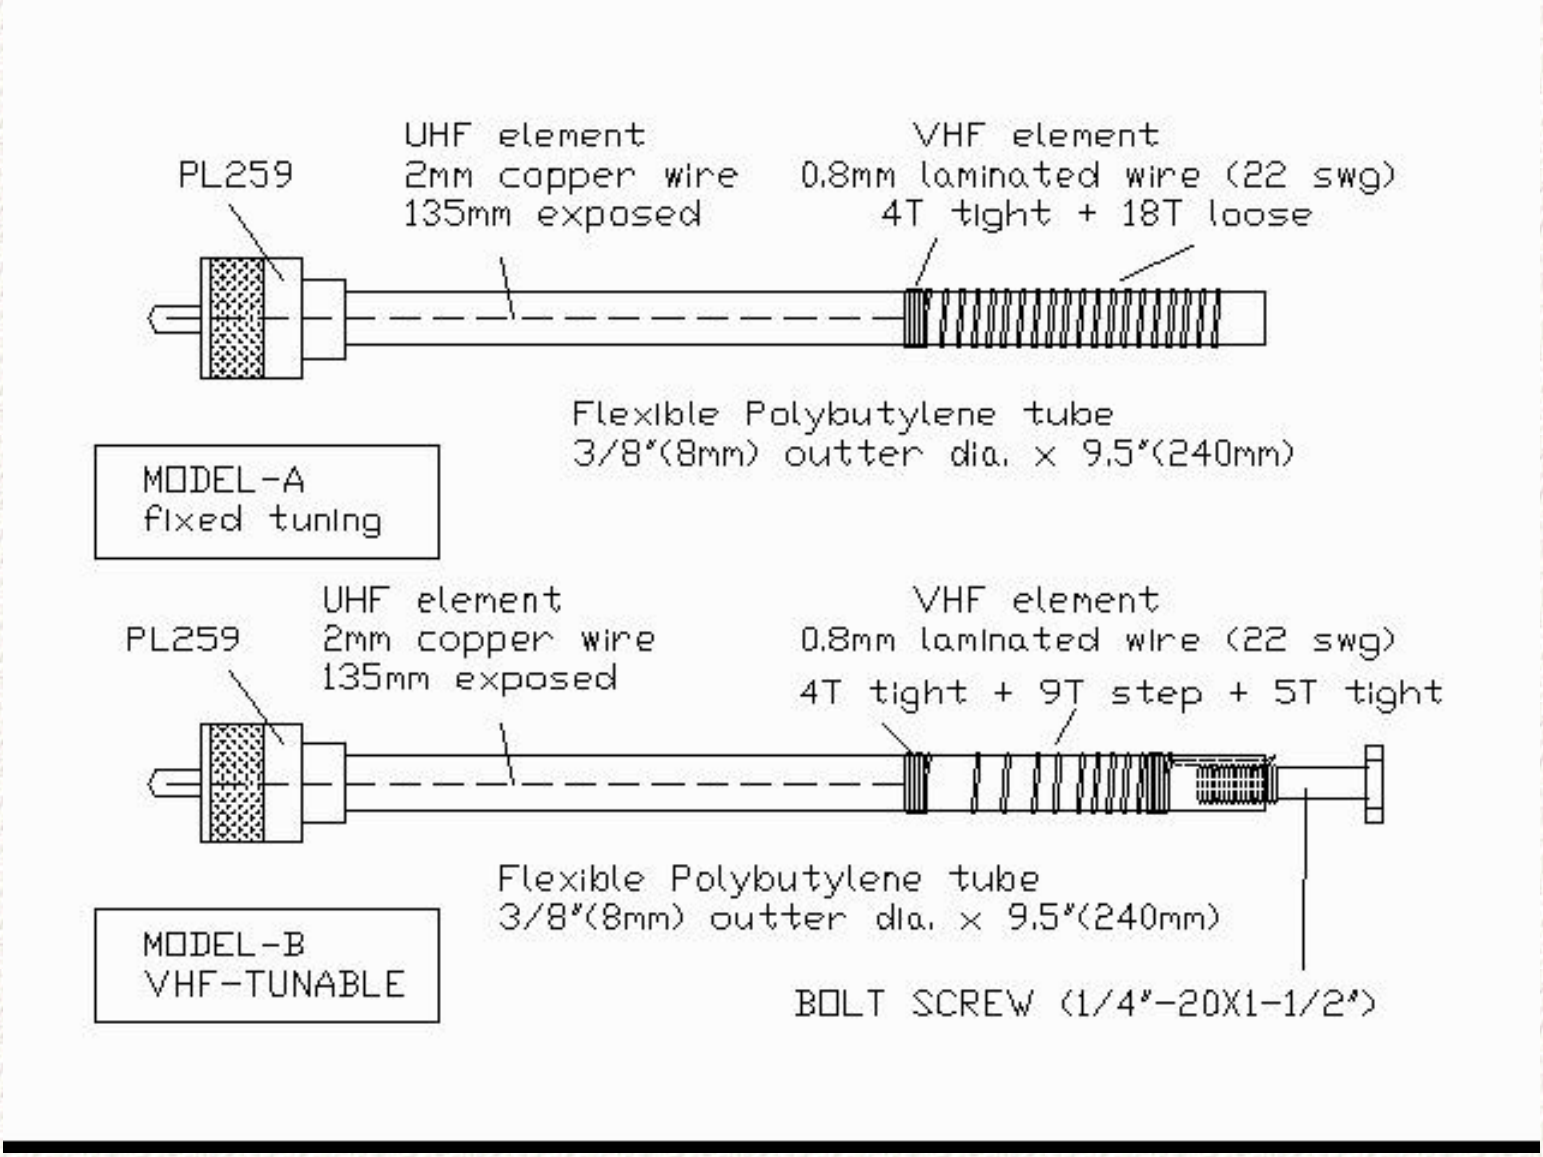

Fig.1 shows two possible structure of this antenna. Model(A) being the fixed style and model(B) being VHF adjustable. The lowest section of the antenna is a PL-259 plug. The center pin of which is soldered to a 2mm diameter copper rod. I got this copper rod from core conductor of RG-8U coaxial cable. It should create an exposed section (clear off from metal shield of the PL-259 plug) of about 135 mm. More detail will be discussed in tune-up section. This copper rod is hidden inside a tube which acts as the coil-form for the upper section. To avoid absorption of RF energy emitted from the antenna, material of this tube must be carefully selected. I used PVC faucet tube for this part. They are polybutylene - those gray color PVC plastic which is cheap and easily obtainable from most hardware stores. You can use any other tubes provided their external diameter can fit into the barrel of the PL-259 plug plus it does not absorb radio waves. We can use a microwave oven to check out if a certain material will absorb R.F. energy. Material placed inside an operating microwave oven will generate heat if they absorb radio waves. Place the material under test inside the microwave oven together with a cup of water (for safety). Execute heating process for say 1-2 minute and check surface temperature of the object under test. If the material stays cool as compared to the cup of water, we can assume that it do not favors radio wave absorption and will be suitable for the job. A small hole (1 mm) is drilled on the tube just besides tip of the UHF section. A piece of laminated copper wire (22 swg) is soldered to the tip of the UHF section and is leaded to outside of the tube through this hole. The rest of this wire is wound on the upper part of the tube and forms the VHF section. After proper tuning is completed, the whole antenna is sealed within a piece of heat shrink coating down to the neck of the PL-259 plug. A rubber cap can be placed on top of the antenna in order to prevent water from entering inside of tube.

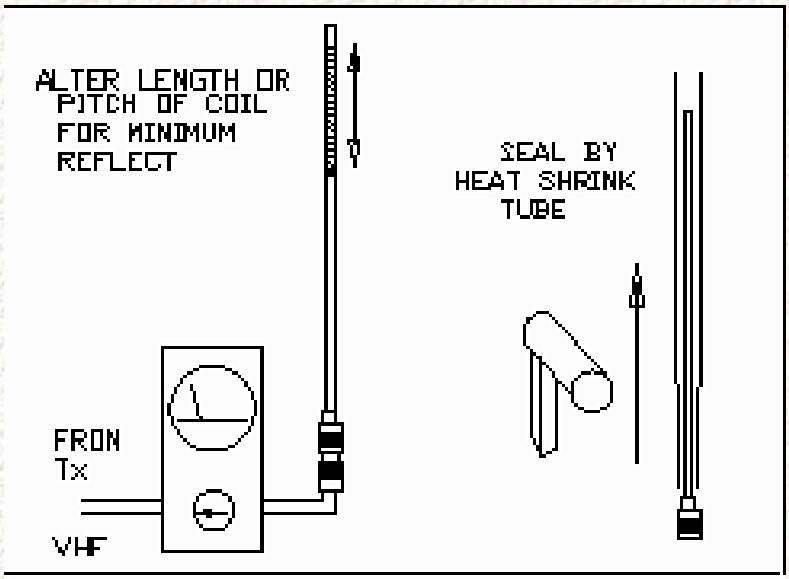
Constructing procedure and tune up



Cut out a piece of 2 mm copper rod. Let's starts with a length of about 160 mm. That should cover future cutting job and the length hidden inside the PL-259 barrel which is not counted for radio emission. Insert it into the center pin of the PL-259 plug and make a smooth soldering at the tip of the pin. We now have a UHF antenna. Before attempting to tune it, prepare two pieces of 2 mm copper rods also, they should be of length 140 mm and 500 mm respectively. They will serve as the temporary ground planes for UHF

and VHF test. By using a reflectometer (SWR meter), check out the reflect power from this simple antenna when UHF power is fed. Cut the length of this section slowly (in 2-3 mm step) and observe changes on reflect power at lower end of target frequency band. Without attachment of a good ground plane, it is impossible to obtain zero reflect status so just go for the lowest possible value. Using the low end frequency for testing is a safety precaution. That prevents you from over cutting the antenna without notice. After you felt satisfied with the cutting progress and has slightly over cut the rod (reflect power increase again upon further cutting). Change test frequency to middle of operating band and proceed further cutting with high care. Once reflect power increased again (indicating slight over cut), pick up the earlier prepared 140 mm section and touch it to the PL-259 plug of this antenna. You should see the reflect immediately drops for a lower or even 1:1 value. This confirms that the section is properly cut and is ready. Cut out a piece of faucet tube (240 mm in length). Insert it into the barrel of the PL-259 plug. Make a mark on the tube where it just clear out from the PL-259 barrel. Remove the tube and put it side by side with the UHF antenna while the mark is aligned with the top of the PL-259 plug. Make another level mark for the tip position of the UHF section. Drill a 1 mm hole on the tube at that mark. Prepare for a piece of 1 meter long 22 swg laminated wire . Push it through the above mentioned hole and force it to run through the lower section of the tube until it made its way out from the bottom. Solder this wire to the tip of the UHF section and pull the wire back into the tube. That will bring the UHF section into the tube as well. Pull out any excess wire inside the tube until the tube is seated tightly inside the PL-259 barrel again. Wind the laminated wire on the tube for 22 turns. These turns should be in a pattern as shown in fig.1. The first 4 turns which forms the RFC for UHF band must be tight. The later 18T should be interleaved and evenly spread along until reaching end of the tube. That should make a coil of approximately 80-90 mm in length. Place the antenna on the reflectometer again, recheck the SWR or reflect status on UHF band, there should be no change as compared to earlier test result. Change frequency to lower end of target VHF band and repeat the test. Tune the VHF response of the antenna by altering length and pitch of the 18T section. Generally speaking, start with evenly distributed pitch and try to control the resonant frequency with coil length. If that cannot work out, try to rearrange the pitch unevenly - tighter pitch near the bottom and looser pitch near the top. Such treatment can further lower the operating frequency. Like tuning job in UHF band, go for the lowest possible reflect on the middle spot of your target band and confirm proper tuning by adding of VHF ground plane (500 mm long copper rod). Once both bands are confirmed in tune, seal and secure the whole antenna with heat shrink tube. The antenna is now ready for application at mobile vehicle environment. If you want future tuning possible in order to match different field environment, you can try model(B), the VHF tunable configuration. In that case, another 1 mm hole should be drilled on the tube near top portion of the coil. The 22 swg wire should be leaded back into the inner side of the tube. A section of contact wire 10 mm in length at top end of tube should be formed. A 1/4" metal bolt is screwed in to fill up the tube. Its pitch should bite through the laminated surface of that 22 swg wire and make a contact with the wire. The bolt will become an extension of the coil and by adjusting the bolt length (in/out or even changing length of bolt), the VHF resonant point can be adjusted.

Conversion for base station application

This antenna can be used at base station configuration also. The trick is to provide sufficient ground plane system in order to form those essential stray capacitance for proper tuning. Fig.3 shows a simple

dual-band ground-plane design and corresponding mounting for base station.

This mount can be used with other UHF/VHF mobile antenna design also (as long as they use PL-259 base connector). It is a very good test bench if you have needs to compare efficiency between two mobile antennas or just want to convert another mobile dual band antenna for base station application. The materials for this mount are all easily obtainable pipes and sockets used in electric power installation. We need a piece of electric conduit (metal pipe for protection of electric cable). Length is not critical, say 20" will be fine. It should be of the 0.5" diameter series. These pipe are measured for their inner diameter. Find also the EMT connector (set screw type) for the same family and put them on both ends of the conduit. The reason for using this dimension is because - the inner diameter of such EMT connector will perfectly fit a SO-239 socket (UHF female bulkhead receptacle solder type). You can tap threads on the inner wall of the EMT connector so that the SO-239 can be screwed in. I used a short cut, just hammer the SO-239 into the connector. The only weakness of this method is - the socket cannot be removed easily or frequently. Anything must be done right at the first move and cannot be repeated for correction. By putting two SO-239 socket on each end of the conduit and have them connected inside the pipe, a female to female adapter is formed. The upper socket is for mounting of the antenna, the lower one is for connection of feed line. The length of the conduit serves another purpose - made possible mounting of the whole antenna on another vertical pole easily with two hose-cramps. We also need a piece of 4" round-pan (top cover for those circular shape power junction box). It provides a flat platform where the ground-plane elements can be mounted. The ground-plane elements are made of threaded stainless steel rods (size 10-24). Holes at 60 degree separation are drilled on the vertical edge of this round-pan. The threaded rods can then be mounted through these holes with two nuts (inside and outside the round-pan's edge). Length of ground-plane elements control their resonance frequencies. Different materials needs different lengths to achieve resonance. Our earlier mentioned value 135mm at UHF and 500mm at VHF are only good for copper conductor. For steel, the length will be different. Togerther with situation that these rods are mounted 2" away from the RF socket, their dimension will be much shorter. Practicle test indicated that UHF ground elements in this design is best at length 70mm while VHF elements at 350mm. This length refers to rod's length between their tips and mounting point at round-pan. Since these rods are mounted with two nuts, their effective length can be adjusted. To play

safely, the rods should be cut with 30mm extra length. That comes out as 100mm for UHF and 380mm for VHF. Adjusting procedure on their final length will be discussed later. The SO-239 connectors has to be connected inside the conduit. I made a mistake at the beginning. Feeling that both sockets are tightly hammered and in good contact with the pipe, their ground points should have been connected nicely. I used only single core wire to connect their center pin rather then using coaxial cable to join them. But I forgot one thing, the two EMT connectors were secured on the metal pipe with only two set screws ! That is not a good contact for radio waves. I was surprised by the test result of such prototype - SWR reading of nearly 1.8:1 even with proper 50 ohm dummy load teminated. After modifying the connection back with standard RG-58AU cable, SWR for this section normalized to 1:1. Drill six holes on the edge of the 4" round-pan and punch out the center hole on the top surface. Mount the round-pan on the upper EMT connector, Secure it with the nut which comes with the connector. Cut threaded rods to proper length (three at 100mm, three at 380mm) and have them mounted on round-pan in alternate pattern. One UHF element followed by a VHF element then vice versa.

Construction of the mount is now almost finished (awaiting final tune up). It is not a bad idea to paint the whole thing - for protection against water damage in future. Try to do it after all ground-rods are set. We need good metal contact surface between the round-pan and the rods. Tuning of ground-rods are similar to tuning of main element. The longer the length, the lower the resonance frequency. Since we have three rods for each band, we can set one rod on the lower frequency limit, one on high limit and one for the center spot. This will create a flatter responce of the antenna in the entire operating spectrum. Always remember to work on one rod at a time (with the other five removed). Set up one test frequency and alter the rod's lenght for minimum reflected power. Then mark the length and change for another rod

with another test frequency. Put them back onto the round-pan with proper tested length after all key spots (three for VHF and three for UHF) are checked out. Reflection from near by objects can distort the above measuring result. These tests must therefore be done in open space, try to obtain clearance of at least 5 meter from any objects which might cause reflection. Always try to use high quality feed-lines to avoid creation of fake image of low reflection when reflected power are absorbed.

More detail on this antenna can be found in Radio Fun May 1994.

HF MOBILE ANTENNA (HB9ABX)

Felix Meyer

update 27th May 2003 / details July 27, 2004

This mobile antenna is designed for all HF bands from 10 to 80 meters an proved to be very efficient in my travels in South America on 15 and 20m for contacts to Europe and within South America.
The antenna is my own development.
Compared to commercial HAM Antennas the performance was always much better, due to the larger size and lower loss in coil.

Comparing with the Screwdriver type antennas always resulted in 2-4 S-points advantage in favor of this antenna!

In field tests we compared 3 different mobile antennas, all at the same location, at the same time, each one with 100 W power.

The 3 antennas were:

- HUSTLER mobile antenna (10 - 80 m)
- YAESU ATAS-100 (10 - 40 m)
- HB9ABX mobile antenna (10 - 80 m)

In all tests the signal of the home made antenna was the strongest!

- 1 S points (up to 10 db) stronger than HUSTLER
- 2 to 4 S points stronger than ATAS-100/ATAS-120

These results in the ground wave (5 to 10 km), as well as in the far field at 70 km to 1000 km distance.

For 10, 15, and 20 m the antenna consists of a fixed lower part and an extensible whip (telescopic antenna of 15 to 80 cm length) on the top.
For 20, 40 and 80m a second segment is added and at the top follows the whip.

Both parts are made of fiberglass rod of 10 mm diameter and 175/165 cm length, on which a piece of enameld copper wire (CuL) of 1.5mm diameter is wound. Aluminium tubes are used to join the parts together.
On both fiberglass rods equally spaced windings of emameld copper wire of 1.5 mm dia are wound. The lower part holds 320 cm wire (79 turns) and the upper part holds 470 cm wire (120 turns).

The loading coil is wound on a plastic tube of 7.5cm diameter and 17 cm length.
The same type of wire (1.5 mm CuL) is used for the coil as for the antenna.
The coil has 33 turns in total, coil length is 12 cm.
Seen from the bottum of the coil, there are taps at 21, 27, and 33 turns,

which are shorted according to the operating frequency.

Settings of the antenna in operation:
10m : Lower part + whip + tap 3 + bridge from tap 3 to the whip
15m : Lower part + whip + tap 3
20m : Lower part + whip + tap 2
20m : Both parts + whip + tap 3
40m : Both parts + whip + tap 1
80m : Both parts + whip + no tap (full coil)
The WARC bands 30, 17, and 12 m can be operated by just adding coil taps without changing the coils.

Feeding:

The antenna is fed by 50 Ohm coax (Type RG 58) of about 2 m length.
On the antenna side the center conductor of the coax is connected to the antenna wire and the coax braid is connected to the car chassis ground.

The antenna system requires a good ground !
I soldered a flexible wire at both sides inside the door frame leading to the coax braid.

Don't forget to connect the two windings on the fiberglass rod together, either through the metal sleeve between the rods, or simply by a connector. The whip on the top is connected to the end of the wire below.

The desired resonance frequency is adjusted by changing the length of the whip on top of the antenna. Extending the whip lowers the frequency.

The antenna requires an antenna tuner for operation, as the impedance differs from 50 Ohms on 40 and 80 m.
With the aid of the tuner, the antenna is adjusted to SWR 1.0 on all bands.

The MFJ-901B tuner is fine for this use. It has little weight and is very small (12.5 x 5 x 15 cm).
(Before its use it's recommended to open it to check the adjustment of the variable capacitors. They are frequently bad centered, which produces easily shorts ...)
If the transceiver and tuner are without SWR meter then a separate instrument is to be connected between TX and tuner. I am using a DAIWA CN410M which is a small cross needle instrument best suited for this use.

Mounting of the antenna:

**I installed the antenna on top of the car on a roof carrier.
Two aluminum angles, 30 cm length, 30mm thigh, were fixed
with screws to the carrier and the rod below the coil fixed to the angles
by means of two hose clamps.**

**Instead of the Aluminium tubes copper tubes may be used, whatever
is found to be better. The tubes are glued in 5 cm length over the
fiberglass rod. At the end of the 7 cm open part of the tube, a 2 cm
long slot is sawed and a small clamp is used to hold the inserted antenna
part .**

**The antenna is directed backwards at an angle of abt. 70 degrees.
In order to prevent swinging up, the antenna is fixed slightly down
at the end with a nylon rope. Use 2 nylon ropes, to both sides to prevent
swinging sidewise when driving. This is required when both antenna
elements are installed.**

**The top of the antenne nearly reaches 3.2 m height above ground when
both elements are in use and fixed by a nylon.**

Adjustment hints:

**Initially, the antenne has te be tuned to resonance on each band
without using the tuner.
This adjustment is done by changing the coil tabs and then varying
the spacing between turns.
In operating mode, only the tab setting is changed, the whip length set,
and tuned with the tuner.**

Before initial adjustment, both elements have to be checked: click here

**The initial adjustment is done by using an antenna analyzer (e.g.MFJ-259).
Resonance is found by obtaining minimum SWR on the instrument.**

Procedure of initial adjustment : (this is done without tuner)

Lower part + whip (10 to 20 m)
- Coil tap 3 (= all turns closed)
Adjust length of whip to obtain min. SWR at 21.2 MHz.
Note length of whip. This is the 15 m setting.

- Coil tap 2 (27 turns closed)

Keep length of whip from previous setting.
Adjust spacing of the upper 6 turns to obtain min. SWR at 14.2 MHz.
Fix coil, this is the 20 m setting.

- Coil tap 3
Make a bridge using a flexible wire of 150 cm length with clips between tap 3 to whip connection (wound 2 - 3 times around rod).
Adjust length of whip to reach min. SWR at 28.4 MHz.
Note length of whip. This is the 10 m setting.

Both parts + whip (20 to 80 m)

- Coil tap 3
Adjust length of whip to reach min. SWR at 14.2 MHz.
Note length of whip. This is the 20 m setting.

- Coil tap 1
Measure SWR on 7.05 MHz and adjust spacing of coil between taps 1 and 2 to reach minimum SWR. Change length of whip only, if minimum SWR remains outside indicated frequency.
Fix coil and note length of whip. This is the 40 m setting.

- Coil without tap (33 turns active).
Keep length of whip and measure SWR on 3.7 MHz.
Adjust spacing of coil of the first 21 windings to reach miminum SWR.
Change length of whip only, if min. SWR remains outside 3.7 MHz.
Fix coil and note length of whip. This is the 80 m setting.

After terminating this adjustment the coil winding is fixed permanently.
After this initial adjustment, the tuner is connected to mach the SWR exactly on operating frequency.

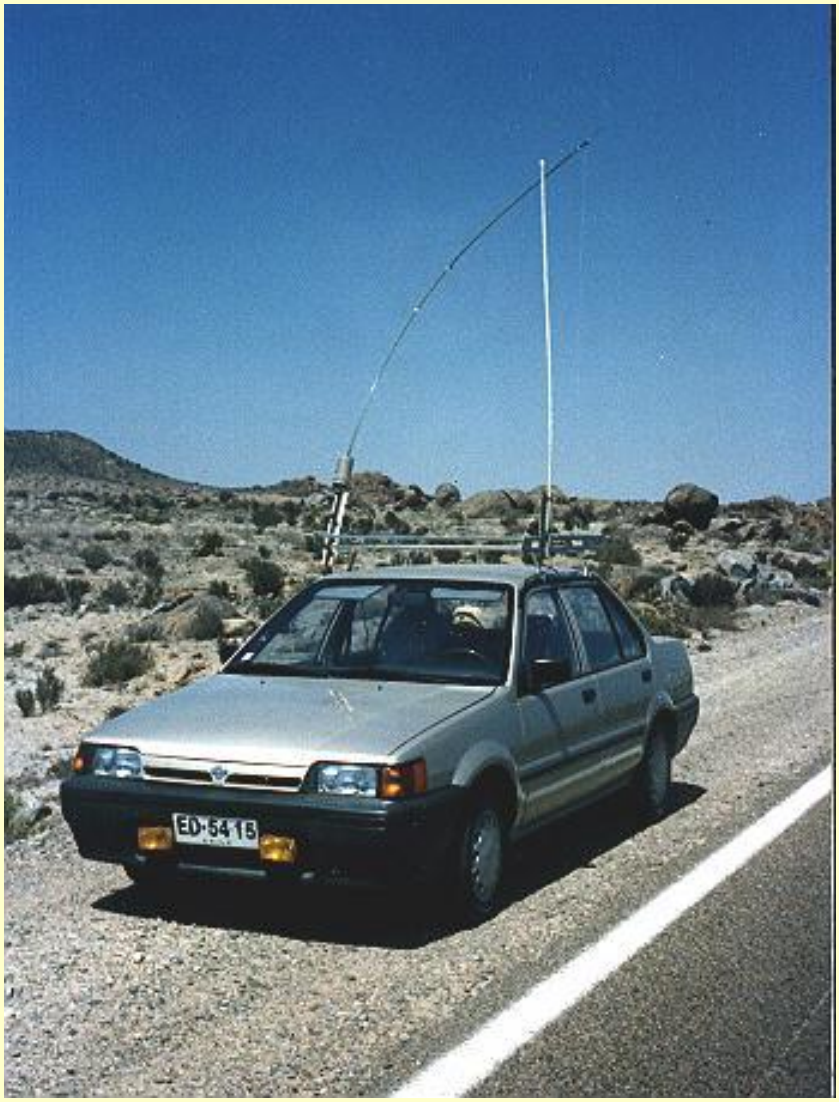
With my antenna the SWR without tuner on 10, 15, and 20 m is better than 1.2 therefore tuning is only required for 40 m and 80 m operation. This however depends from the actual installation, especially from the ground connection.

See further details from the following drawings:
Drawing 1 (lower part)
Drawing 2 (upper part)

The photograph below shows the installed antenna in Chile as CE3CWF/mobile.
(The white antenna is a 2m antenna)

Good luck in construction.

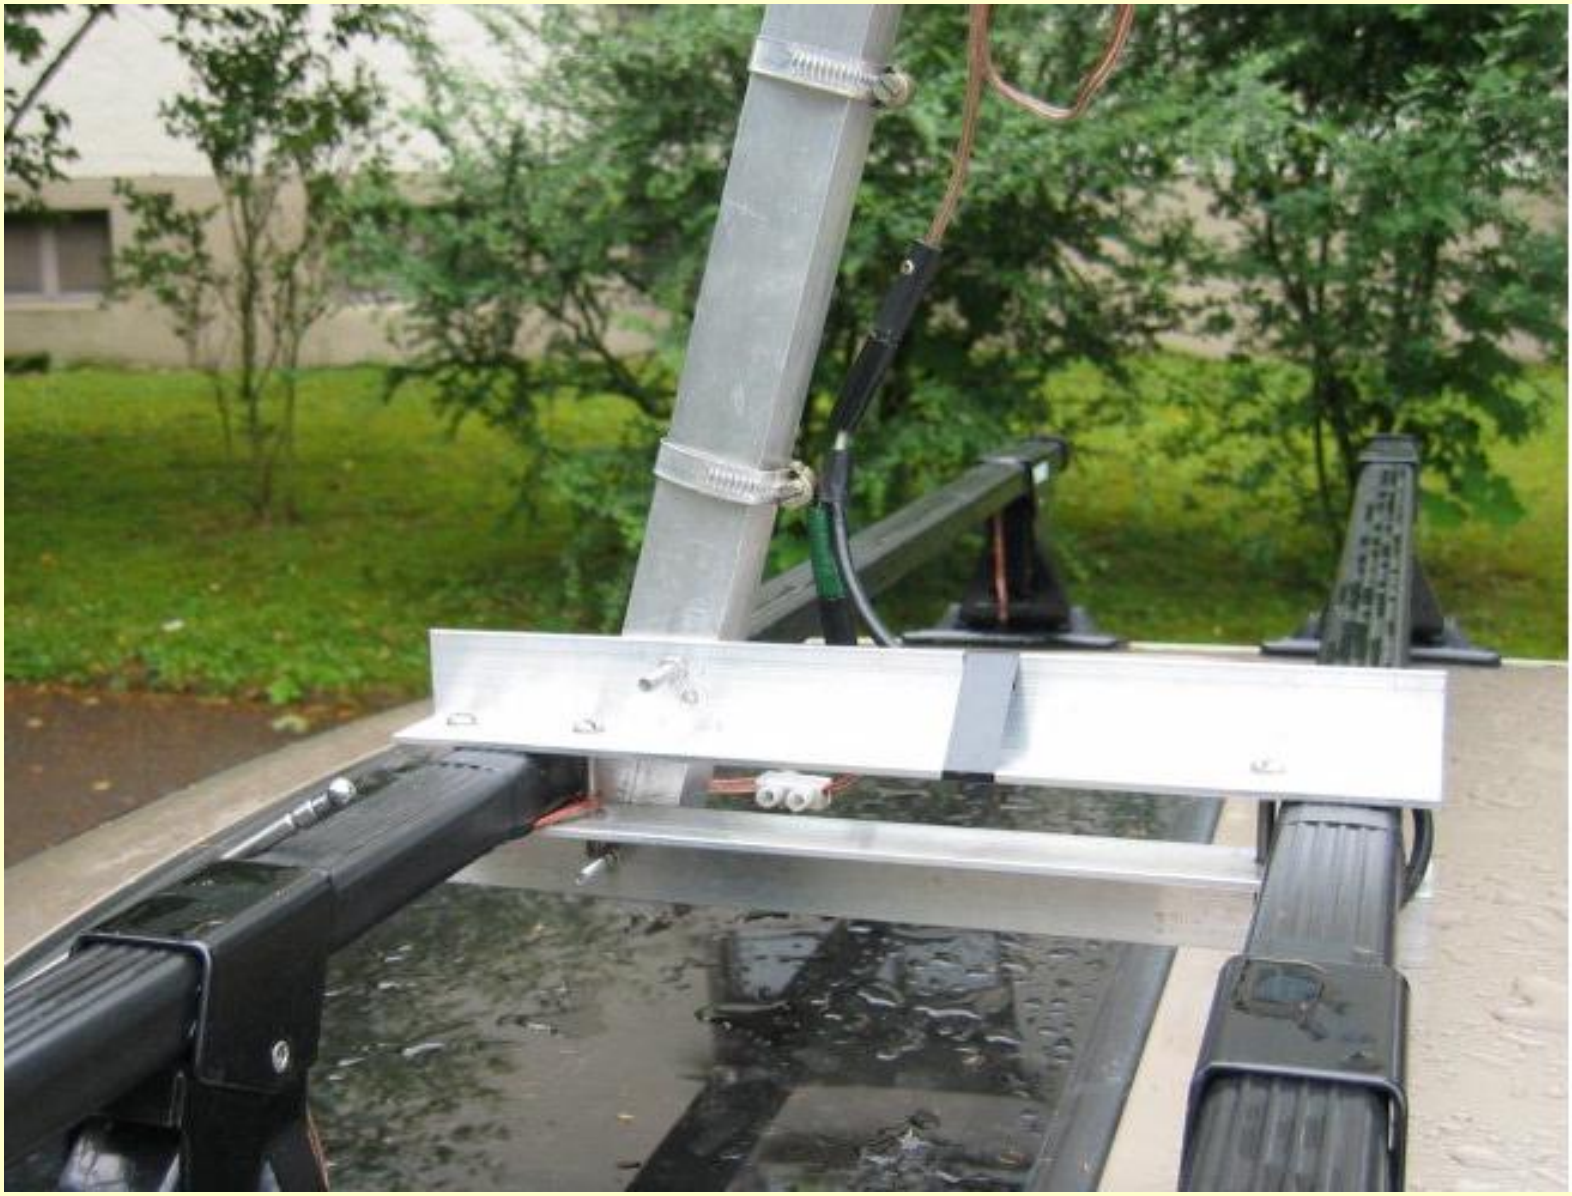
For additional questions: see here



my antenna as CE3CWF

Below the mobile antenna in Switzerland as HB9ABX:

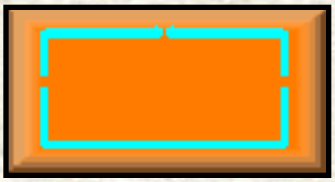
And finally the mounting of the antenna on the roof of the car:



WARNING

Working with fiberglass rods produces dangerous dust, which easily produces allergies on the hands. Inhalation of the dust is extremly dangerous !
Already holding the raw bars with the hand can produce problems, therefore use protecting gloves
whenever working and handling raw fiberglass rods and observe appropriate care when sawing.
Wash well the hands with soap after the work !
After terminating the work paint the complete rods with a suitable lacquer to protect the surface.

BACK



Moxon Rectangles

L. B. Cebik, W4RNL

The Moxon Rectangle is growing in popularity as a compact 2-element array that approaches a full-size 2-element in gain but with a far superior front-to-back ratio and a direct match for the standard 50-Ohm coaxial cable. The antenna can be built as a wire array--especialy for the lower HF regions--or as a rotateable alumunum beam. For convenience, I have pulled together the growing selection of Moxon Rectangle notes into this single subdirectory and organized them in the order of recommended reading--unless you already know what you are looking for.

- **VK2ABQ Squares and Moxon Rectangles** (7-25-99)
- **The Moxon Rectangle: A Review** (12-18-99)
- **An Aluminum Moxon Rectangle for 10-Meters** (4-6-98)
- **Wire Moxon Rectangles for 40-10 Meters** (1-1-97, 6-10-99)
- **Further Notes on 40-Meter Wire Moxon Rectangles** (5-4-99)
- **Notes on the Moxon Rectangle Pattern** (2-22-2000)
- **The Double-D Antenna** (3-18-97, 5-4-99)
- **Multi-Banding the Moxon Rectangle** (8-12-99)
- **The Moxon Rectangle on 2 Meters** (10-01-99)
- **Building a 2-Meter Moxon** (12-18-99)
- **Designing Moxon Rectangles by Equation and by Model** (10-01-2000)
- **40 + 30 = 50 (Not 70)** (10-23-2001)

- **A Truly Portable Moxon Rectangle for Nearly No-Tool Field Assembly** (02-01-2003)
- **Moxon Rectangles for 6 Meters** (02-03-2003)
- **The Elusive Moxon Nest** (06-01-2003)
- **Part 1: Vertically Stacking Horizontally Oriented Rectangles** (12-04-2003)
- **Part 2: Vertically Stacking Vertically Oriented Rectangles** (12-04-2003)
- **Understanding the N0KHQ Coax Square** (12-08-2003)

Additonal information on building wire and tubing versions of Moxon rectangles for a direct 50-Ohm feed is available in ***Simple and Fun Antennas for Hams***, ed. Hutchinson and Straw (ARRL, 2002), pp. 12-19 to 12-28. The **KD6WD Moxon Antenna Project** at Murray State University is another good source of information on various construction techniques, especially for the operator needing a light-weight or a semi-stealthy antenna.

MOXGEN: A stand-alone Windows program that calculates the dimensions of a Moxon rectangle for a near-50-Ohm feedpoint impedance, as described in "Designing Moxon Rectangles by Equation and by Model," has been developed by Dan Maguire, AC6LA. You may obtain a free copy from his website: http://www.qsl.net/ac6la/moxgen.html. The program will also create a model in .EZ format for use with EZNEC or in .NEC format for use with NEC-Win software or with generic NEC programs. The only required input entries are the design frequency and the diameter of the wire or tubing to be used. Dan's site also contains a number of other very useful programs for modelers and others interested in antenna design and analysis.

Below is a version of the Moxon dimension calculator that you may use right on this page, thanks to Joe Faber, KG4UHP, who created the JAVAScript and gave me permission to place it here. Remember that the dimensions apply to Moxon rectangles that use the same diameter material throughout. Decide on the design frequency and the diameter of the elements. You may use inches or millimeters for the diameter--or you may select an AWG wire gauge. Be certain to select the unit of measure for the output. Then, click on any of the output boxes if the calculations have not already appeared.

The aim of this website is to share the experiences of MOXON antenna builders everywhere. It's all about Hams Helping Hams which is the overlying theme of the MOXON Antenna Project.

The MOXON is a stealthy gain antenna that can be easily home brewed for a small investment. This antenna can be mounted on a simple push-up mast and rotated by hand or with an inexpensive light duty rotor. It should be especially attractive to hams who want to avoid purchasing more expensive towers, rotors and directional antennas.

We invite you to click on the various links at left to learn more about the project.

Petlowany Three-Band Burner Antenna

June 23, 2002

The *Petlowany Three-Band Burner* is a simple, low-cost, trapless short vertical antenna which amazingly works on three HF bands (20, 15 and 10 meters). This web page contains pictures, performance data, and enough construction details so you can "homebrew" your own.

Petlo... Who?

A ham named Bill Petlowany (K6NO) published an article in the March 1998 issue of Worldradio magazine, reporting some interesting results from placing spiral coils on the ends of antennas. A handful of others have experimented with these peculiar antennas. (Another article by W. Caldwell (WA8ABE) appeared in the June 1999 issue of Wires and Pliers.) I kept *Petlowany* in the name of my variant in honor of the original experimenter, and called it a *burner* because of its shape.

Basic Description

Fundamentally it's a quarter wave ground plane with 4 radials cut for 15 meters. The interesting twist is the spiral coil "hat" on top, which makes the antenna resonant on 20 and 10 meters as well. The higher wires you see in the picture are guy wires, broken into small enough pieces that the RF doesn't see them. They're not really part of the antenna, electrically speaking.

Performance-wise, it is pretty much indistinguishable from a quarter wave ground plane vertical on all three bands. As such, it does a reasonable job of delivering the low angle radiation required for DX operation.

SWR Measurements

Here are some SWR charts, to demonstrate the antenna's performance on various bands. These are actual measurements of the antenna pictured.

Here are the three bands that give the *Petlowany Three Band Burner* its name.

- SWR chart for 20 meters (1.4:1 at 14.0, 1.2:1 at 14.5)
- SWR chart for 15 meters (1:1 at 21.0, 1.1:1 at 21.5)
- SWR chart for 10 meters (1.2:1 at 28.0, 2:1 at 29.3)

Here are two more bands that will at least accept power. Performance isn't great on these bands, but it's usable in a pinch.

- SWR chart for 80 meters (2:1 at 3.5, 2.5:1 at 4.0) SWR is high but it won't cook your finals. For an antenna this short to do *anything* on 80 is pretty nifty.
- SWR chart for 2 meters (1.1:1 at 144, 1.5:1 at 146) Don't let the low SWR fool you. The vertical is so long for 2 meters that most of the energy goes up at a 60 degree angle.

Construction Details

Following are detailed instructions for building the antenna as I have built it. Naturally many other types of construction are possible, and different dimensions could yield antennas that work on other frequencies.

Parts List

Most everything can be found at a hardware store and a radio shack.

- 12 feet of 1/2 inch PVC pipe (thicker variety preferred)
- one 1/2 inch PVC cross
- one 3/4 inch PVC male plug
- 5 meters of 12 ga. wire (recommended: stranded, insulated)
- 20 cm of 3/4 inch copper pipe (as above, the thicker kind is apt to be stronger)
- two 3/4 inch copper male adapters

- two 3/4 inch copper pipe mounting brackets
- one 10 foot length of one inch copper pipe (In hardware stores, two grades are available. Get the thicker one, "blue" or "type L")
- one 1 inch copper male adapter
- one 3/4 inch thread to 1 inch copper male adapter
- 2 radio shack guy rings
- a few feet of solid wire (14 ga or 12 ga, not critical)
- one 5 foot galvanized pipe (one inch) with threaded ends
- two inches of one inch PVC pipe (thicker variety preferred)
- two 1 inch PVC female adapters
- 20 meters of 12 ga. wire (I used stranded, bare wire from radio shack, but the exact type is not crucial)
- 100 feet of steel guy wire (available at radio shack)
- 1 radio shack roof apex antenna mount kit
- lag screws suitable for attaching roof mount to roof
- roof tar to seal over roof mount
- 4 large hooks for guy wires (available at radio shack or hardware store)
- coax

Making the spiral top

Click the picture above for a more detailed view.

The spiral coil is wound on a form built of half inch PVC pipe. The first step is to make the coil form. Cut four pieces of half inch PVC 20 cm long. Insert one of them into the half inch PVC cross as far as it will go. Make a mark on the pipe where you would be able to drill a 3/16 inch hole as close as possible to the cross without touching it. This is the hole through which the first turn of the spiral coil will pass.

Remove the pipe from the cross and make additional marks every 2 cm all the way out to the end (the long way, away from where the cross fits). Use the first pipe as a template and mark the other three pipes the same way. Now drill 3/16 inch holes as marked, all the way through both sides of all four pipes.

Using PVC cement, glue the four pipes into the cross to make the coil form. Be sure to glue the right ends of the pipes, so the innermost hole is close to the cross without being obscured by it. Take care also to keep the holes in line with the plane of the cross, so a coil can be wound, as in the picture.

Use 5 meters of 12 ga. wire for the spiral coil. Any type of wire is suitable electrically. I used wire with a slick insulation for ease of threading through the coil form. Starting from the inside, leave 10 cm of slack for the inner coil connection, and thread the wire through all four innermost holes in the coil form, pulling it tight.

Continue to thread the wire progressively outwards in a spiral shape, pulling it tight as you go. Make sure you always have the 10 cm of slack inside for the connection to the pipe. When done, use a cable tie to keep the wire from slipping back out, as shown. To reduce wind resistance, you may wish to saw off any excess length on the coil form arms. (The ones in the picture have not been trimmed.)

The final step in making the spiral coil is attaching the 3/4 inch male PVC plug to the side of the cross, so the coil can be screwed down onto the copper pipe. To do this, rough up one side of the cross with sandpaper. If you will do most of your communication in the Northern Hemisphere, let the coil run clockwise... (just kidding!). Also rough up the flat end of the 3/4 inch PVC male plug. Slather on some PVC cement and hold the plug in place until the glue has a chance to set up. Here is a close-up picture of the joint between the plug and the cross. It may not look strong but PVC cement forms a strong chemical bond. Do not screw the plug into anything until the glue dries overnight.

Now that you have the coil, you must make the pipe portion of the antenna top. This is easy. Sweat a 3/4 inch female adapter onto each end of a 20cm length of 3/4 inch copper pipe. (If you wish to experiment with tuning, you might want to leave one end unsweated (as shown) and/or start with a longer length of pipe. If you wish only to duplicate my results, don't worry about getting the length perfect -- the tuning is very forgiving, in terms of the length of the vertical element.)

As you can see in this detailed photo, I sweated on mounting brackets near the top end to make available four holes at right angles. Once I'm sure I won't want to take down the antenna for a while, I might use those to attach ropes to steady the top of the antenna. For now, though, I prefer not to use the ropes. It is so much easier to take the antenna down without them. Even if you don't plan to use ropes, you must sweat on something that will allow you to solder the spiral coil wire without damaging the PVC plug on the coil form with excessive heat.

To complete the spiral top assembly, screw the coil form into the pipe, with the mounting brackets (or other soldering post) toward the top. Cut off any excess length and solder the inner end of the spiral coil to the bracket or post. Be careful not to damage the PVC plug with heat.

When completed, your spiral top should look a lot like the one in the photo.

Making the main vertical element

Click the picture above for a more detailed view.

The vertical element is chiefly a 10 foot length of one inch copper pipe. The only critical thing about this assembly is that it is necessary to slide a guy ring over one end of the pipe *before* sweating the top end

on.

Choose an end of the pipe to be the bottom and sweat on a one inch male adapter. Also sweat a piece of wire (I used 14 ga. solid but it is not critital) to the bottom end for attachment to the feed line. In this detailed photo, the wire can be seen as a ring just above the male adapter sweat joint, and also where it attaches to the coax.

About six feet from the bottom end, sweat on a ring consisting of a few turns of solid wire. This ring will stop the guy ring from sliding down. (The picture at the beginning of this section shows this ring stopper in detail.)

Slide a guy ring onto the top of the pipe, making sure it is the right way up (skirts point down). Be sure the ring you just soldered onto the pipe holds the guy ring in place. Also make sure the guy ring can turn freely while straining against the stop. This will make it much easier to install and take down the antenna.

Finally, sweat a 3/4 inch male adapter (for 1 inch pipe) to the top end of the pipe. This will attach to the spiral top when the antenna is assembled.

Preparing the base

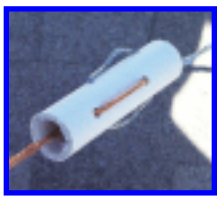
Click the picture above for a more detailed view.

The base of the antenna consists of a galvanized pipe which acts as a mast and a PVC "barrel" which secures the antenna to the mast mechanically without connecting it electrically.

To make the PVC barrel, simply cement two one inch PVC female adapters to a short length of one inch PVC. The pipe should be just long enough that the two adapters touch or nearly touch.

Before screwing the barrel onto the mast, it will be necessary to slide a guy ring on. If you use the recommended radio shack guy ring and one inch galvanized pipe, the guy ring won't *quite* fit over the end. Use a grinding or reaming tool (I used a dremel) to increase the size of the hole in the guy ring. It is not necessary to make it fit over the entire pipe. It only needs to be able to slide down over the threads enough that the barrel can screw on securely.

Slide the guy ring over the top of the mast, using the included bracket if necessary to keep it from sliding down. Screw the PVC barrel onto the top.



Making the radials and guys

Click the picture above for a more detailed view.

Both the radials and guys require insulators. If you have 24 good quality egg insulators, by all means use them. I had trouble finding any and decided to use PVC to make low-cost insulators. As you can see from the picture, I drilled four 3/16 inch holes through a 4-inch piece of half inch PVC, with interlaced pairs of holes at right angles. (No way that language would be clear without a picture!) The advantage to this approach is that the wires are actually linked, so when the PVC inevitably rots from the sun's UV rays, the structure is still mechanically secure. That's the theory, anyway. Note the way each wire is threaded into one end, out and over the side, then through to the other side, over and back in, then out the end again.

Once you have made or otherwise obtained 24 insulators, you are ready to prepare the radials and guys. We'll start with the radials.

To make the radials, cut four lengths of 12 ga. copper wire slightly longer than 3.5 meters, such that the radial will be 3.5 meters long once the ends are wrapped around the guy ring at the base and the insulator at the other end. Attach an insulator to one end of each radial. Solder the wire as shown for extra strength.

Attach the non-insulator end of each radial to the guy ring at the top of the mast (just below the PVC barrel). Do this by making a loop and soldering it as shown in this detailed photo. Solder a loose ring of copper wire to each loop, all the way around the guy ring, to ensure that the radials are electrically connected at all times. Coil up and tie the radials neatly. They are now part of the base, ready to install on the roof.

To make each guy, use steel guy wire to construct a string of five insulators spaced one meter apart, for a total length of 4 meters per guy string. (Longer, electrically continuous guy segments can mess up the antenna's performance.) Make 4 guys, using a total of 20 insulators.

Use the shortest length of steel guy wire possible to attach the insulator on one end of each guy string to the guy ring that slides freely on the main vertical element. This detailed photo shows how. Neatly coil up and tie the guy strings. These are now part of the vertical element, ready to install.

Installing the base

Click the picture above for a more detailed view.

Find a suitable location at the apex of your roof, surveying where the radials and guy wires will go. Avoid power lines for safety. Once you find a good spot, screw the roof mount down securely with lag screws. Use roof tar to weatherproof the mount as shown before the next rain or snow.

Install hooks for the guy wires and radials at four locations such that the radials will be spaced as evenly as possible (90 degrees apart), and such that the radials can be fully extended (3.5 meters from top of base) and not yet reach the hooks.

Place the mast near the mounting point. If an assistant is available, the mast can be held in mounting position. Run the radials out toward the hooks (they shouldn't reach yet) and secure them to the hooks with a length of steel guy wire extending from the insulator to the hook. This picture shows what the insulator looks like with one copper wire and one steel wire. Leave enough slack that the radials can be under tension, fully extended, once the mast is raised. Without an assistant, getting these lengths close enough to let go is cumbersome. Be patient and don't risk letting the mast get out of your control.

Once the mast is basically in place, adjust the tension at the hooks until the radials are fairly taut and the mast is vertical and feels secure. Tighten the mounting screws and lock nuts in the apex mount to complete the installation of the base.

Adjusting the guys

When the guys are adjusted to the perfect length, one person over five feet tall can easily raise and lower the antenna without help. It is necessary only to push the antenna up into the guys, then screw it down into the PVC barrel. Until the guys are perfectly adjusted, though, it can be dangerous to attempt to raise the antenna fully without assistance. Proceed cautiously and have patience, and make all guy length adjustments without the spiral top installed.

Attach fairly long pieces of steel guy wire to the end of each guy string, and secure them to the hooks. It

should be possible to raise the vertical element near to its mounting position without straining the guys. Now slowly and patiently, progressively shorten the guys at the hooks until they are just long enough to permit the vertical element to be raised into position and screwed into the base. (Having an assistant is extremely helpful.)

Completing the installation

Now that the guys are adjusted, raising the antenna is very easy. Screw the spiral top onto the vertical element, then hoist the antenna into place and screw it into the base. Connect coax as shown in this picture, without soldering yet, and run it to an analyzer, noise bridge, or transmitter with SWR meter.

The only critical adjustment is the length of the coil, which mainly affects performance on the 20 meter band. 5 meters is a bit too long for the spiral coil wire, so you should find that the antenna is initially resonant somewhat below 14.2 MHz. Carefully lower the antenna repeatedly, shortening the spiral coil to bring the antenna into resonance near 14.2 MHz. I ended up with a 4.75m coil length. If you were able to duplicate my design parameters, you should find the performance on the 15m and 10m band to be as shown in the SWR charts.

About N5IZU

I got my first ham ticket in 1978 at the age of 12, and I've been building the occasional antenna ever since. Most of them haven't worked, but every once in a while, something interesting happens. When I read about Petlowany's spirals I just had to know more about them. I had no idea what would actually be possible.

I still feel I know so little. I've put this project on the web in the hopes that someone will write me a breathless email one day, explaining, "No, -DT, you've got it all wrong! A little change here and there and you can have *five* bands!" Even more exciting would be to learn exactly how and why it works the way it does.

In the meantime, it is nice to just enjoy it for a while. Recently I've been content to just haunt the bands, chasing whatever DX gets snared in the *burner*.

Pfeiffer Quads

KQ6RH

(C) 1998, 1999, 2000

Ray Jurgens

(Up-Dated 3/07/2000)

Pfeiffer Quads:

The Pfeiffer Quad was described in QST and has the desirable feature that it is smaller than a standard cubic quad but does not compromise performance very much. The Pfeiffer design is rather difficult to construct because of the complicated linear loading networks required. However, these complicated structures are unnecessary and do not add much, if anything, to the performance. The Pfeiffer quad has linear loading stubs at each corner that are pulled into the center toward the hub forming a Maltese Cross. These could just as well be replaced with inductors or transmission line stubs. In fact, the losses on 450 Ohm ladder line are small to insignificant, so Pfeiffer's complicated stub assembly can be replaced with simple transmission line stubs with no loss of performance. The only complication is in the electromagnetic modeling; here the density of pulses must be very high to accurately handle the closely spaced wires. The stubs can be stretched along the spreaders and attached to the antenna wires at each of the tips. In this case, 8' spreaders are convenient, so all that is required is to find the proper length of the ¼ wave shorted stubs that act as inductors to bring the loop into resonance. These stubs can be made slightly longer for the reflector and shorter for the director if one is used. Placing the 450-Ohm ladder line along the spreader slightly lowers its impedance and lengthens its electrical length by the same proportion. The 8' spreaders can be used to cover 20, 17, and 15 meters. In the 15m case, the stubs are only a few inches long and for 20 meters they are about 3/4 of the length of the spreader. If terminal strips are mounted at the end of each tip, the stubs can be changed easily to accommodate various bands. Some experimentation may be required to get the length of the stubs set, but once set, assembly is very quick for this quad. Our **Products Page** lists the our design document which gives the a complete set of graphs and design data as well as full construction details for our modified Pfeiffer Quad.

The Pfeiffer Quad is normally operated in the X configuration. The impedance of this antenna will be lower than for a full size quad, and some matching network may be required. The

version presented in QST used a gamma match on one of the stubs to drive the loop. For example, at 20 m, the stubs must to be about 74" long, and the driving impedance of a single loop is about 47 Ohms. Thus, a single loop is a good match to 50-Ohm line. The addition of the parasitic elements further lowers the impedance, and depending on the spacing of the loops, the impedance could drop to 25 Ohms. For further details on the original Pfeiffer Quad, check the following reference:

Andy Pfeiffer, K1KLO, "The Pfeiffer Quad Antenna System," QST, March 1994, pp. 28-31.

Phased Arrays of Short Vertical Antennas

It is possible to devise an array of two or more vertical antennas to provide useful gain and directivity over a single vertical element, but proper design and adjustment may be a more complicated matter than one might think because gain depends on such factors as spacing between elements, phase difference, etc., and these will change from one band to the next. About the most one can hope to do is to work out a compromise design that will be truly effective on two adjacent bands.

Probably the simplest system would involve two vertical antennas spaced from 1/2 to 3/4 wavelengths apart at the highest frequency of operation and fed with equal in-phase currents. Such an array would be bi-directional and provide up to four decibels of "broadside" gain. At half the design frequency the broadside gain would be less than two decibels. Thus, an array of the two elements for 40 meters (spacing between elements approximately 35 ft.) would provide a fair amount of gain on that band and perhaps a few decibels less on 80 meters. The same array could no doubt be operated on the higher-frequency bands, but the directivity pattern (if any) would change considerably, for the great spacing (in terms of wavelength) would cause the production of "end-fire" as well as broadside radiation.

In the case of close-spaced elements (1/8 to 1/4 wave) it is possible to produce a unidirectional end fire pattern by feeding the two elements with a phase difference of 90 degrees by means of an electrical 1/4 wavelength "delay" line. This arrangement produces a rather broad single lobe (cardioid pattern) in the direction of the element with the lagging current, and very good front-to-back radiation are possible with such an array. However, both the radiation resistance and the feedpoint impedance will be much lower than for a single vertical element, making the system more critical with respect to operating bandwidth and impedance matching, especially if each element is physically shorter than 1/4 wavelength at the operating frequency and if the spacing between elements is less than 1/4 wavelength. Close-spaced out-of-phase short elements should have the best possible radial system under each element so that the earth loss resistance doesn't account for the major part of the overall feedpoint impedance. If this precaution isn't observed the earth loss may wipe out all or most of the theoretical gain of the array.

Still another problem with close-spaced arrays using physically short elements is that the power-handling capability may be less than for a single element because the mutual impedance between the elements will raise overall circuit Q while reducing the radiation resistance of the array.

As with the relatively wide-spaced in-phase arrays, the close-spaced out-of-phase types may be operated on other bands where the spacing and phase difference will not be optimum and where the directive pattern can be expected to change from band to band.

In general, the Butternut HF6V-X and HF2V will be under less of a disadvantage in phased arrays than conventional multi-trap designs that use a progressively smaller portion of the available radiator at 7 MHz and above, but the problems of devising an effective array on more than one band will remain the same. Wide-spaced in-phase arrays are generally better behaved than the close-spaced out-of-phase types and show higher values of radiation resistance. This makes the ground/radial situation somewhat less critical, but more real estate is required for effective broadside arrays, especially on 80 and 160 meters.

For further information on vertical arrays one should consult a recent edition of the ARRL Antenna Book.

Antenna Information

Rabbit Ears have been used to solve the limited space antenna problem of how to operate HF from a condo in Urban Honolulu. After much testing, this design has been working:

The Upright V Dipole for Limited Space

Near Vertical Incidence Antennas in Hawaii have been the source of much speculation. The NVI mode is ideal for HF communications statewide, critical to emergency communications where VHF simplex cannot span the distances required. Here is a modeling study of optimized NVI dipoles:

The 40 Meter NVI Dipole

A comparison of **Portable Antenna types** using EZnec modeling. Including dipoles, optimized 1/4 wave vertical systems, fan dipoles and inverted V's:

Common Portable Antennas Compared

The **"Stake Stick"** is a multi-band antenna for the higher bands designed for portable use such as backpacking. It uses full size, tunable elements on 20, 17,15 and 10 meters with six meter operation available as a 3/4 wave antenna:

The Stake Stick Vertical

Vertical antennas are great, as are end fed wires. Easy to put up and locate in restricted spaces. But they often put heavy demands on **ground systems and radials**. Here is some of the "bad news" about

grounds, ground enhancements, what does and does not work:

Radial Ground Systems

An entirely new area, Ham antennas for WiFi, extending operation of 802.11b wireless network access to allow high speed digital radio experiments cheaply, even up to and including adding amplifiers which for licensed Ham Radio operators is legal under part 97. When it exceeds part 15 specifications, it should be properly called HSMM or High Speed MultiMedia hamming:

Hinternet Antennas for WiFi and HSMM

For portable operations, many people are attracted to lofting field day type antennas with **gas filled balloons**. Here are details on what it takes to get such a project off the ground:

Balloon Lift With Lighter Than Air Gases

Almost as popular as balloons for portable antenna experiments are **kites**. Here are a few kite related notes:

Kites Suitable for Lifting

The SLOPO is the result of much research with EZnec looking for a reasonable portable antenna that had as little to carry as possible and yet had significant performance. It was hard to beat a simple dipole and come up with a single pole system that had merit, but the SLOPO, the combination of the sloper dipole with a reflecting support pole, making a sort of beam, shows promise:

The SLOPO portable antenna system

The EDZ extended double zepp antenna is a classic. It may have fallen from favor due to its ugly feed point impedance. It is highly reactive at about 120 ohms resistive. But a tuner like a Johnson Matchbox

and parallel line should make short work of that problem, and provide a multiband antenna of merit. It also makes a good gain producing antenna for portable use at the higher bands such as this example at 15 meters:

The 15 Meter Extended Double Zepp

Here are lots of numbers for **wire antennas** on various bands from 160 to 6 meters to help you decide how big a given antenna design will be, what might fit in your *"personal antenna farm"*, and what style of wire antenna might be appropriate for your QTH:

HF Wire Antenna Sizes

General Ham Radio Information

Information on the new **online Ham Radio Licensing** system, how to use it, the new forms and the FCC websites to download the new online forms. This is how all Ham licensing issues will be addressed in the future:

The FCC Universal Licensing System

Camping and Ham Radio, especially QRP or low power, go together well, but here are some things to consider to make life in da tent easier and more fun when the two activities are combined:

Radioactive Camping Tips

Batteries are a great emergency power source, but their ratings and chemistry, especially rechargeable ones, is often *Witchcraft*. Here is some information to help sort them out:

Using Batteries

Jumpstart Powerpacks have appeared that are compact units with a sealed lead acid battery and integral charger. This is a report on one such example and conversion to a highly portable QRP/HT power source:

MightyMite Conversion

If a repeater fails, a Net Control Station will have to establish a **net protocol** on a VHF simplex frequency. Here are some guidelines for both Net Control Stations and Net Participants:

Guidelines for Simplex VHF Net Operations

One of the hardest parts of traffic handling on a net is figuring out how to **count the message**. The message count is an important "checksum" to verify that the entire message was received. Getting it wrong can cause lots of confusion:

Guidelines for Word Counting Message Traffic

Rhombic Antenna, 30m-6m

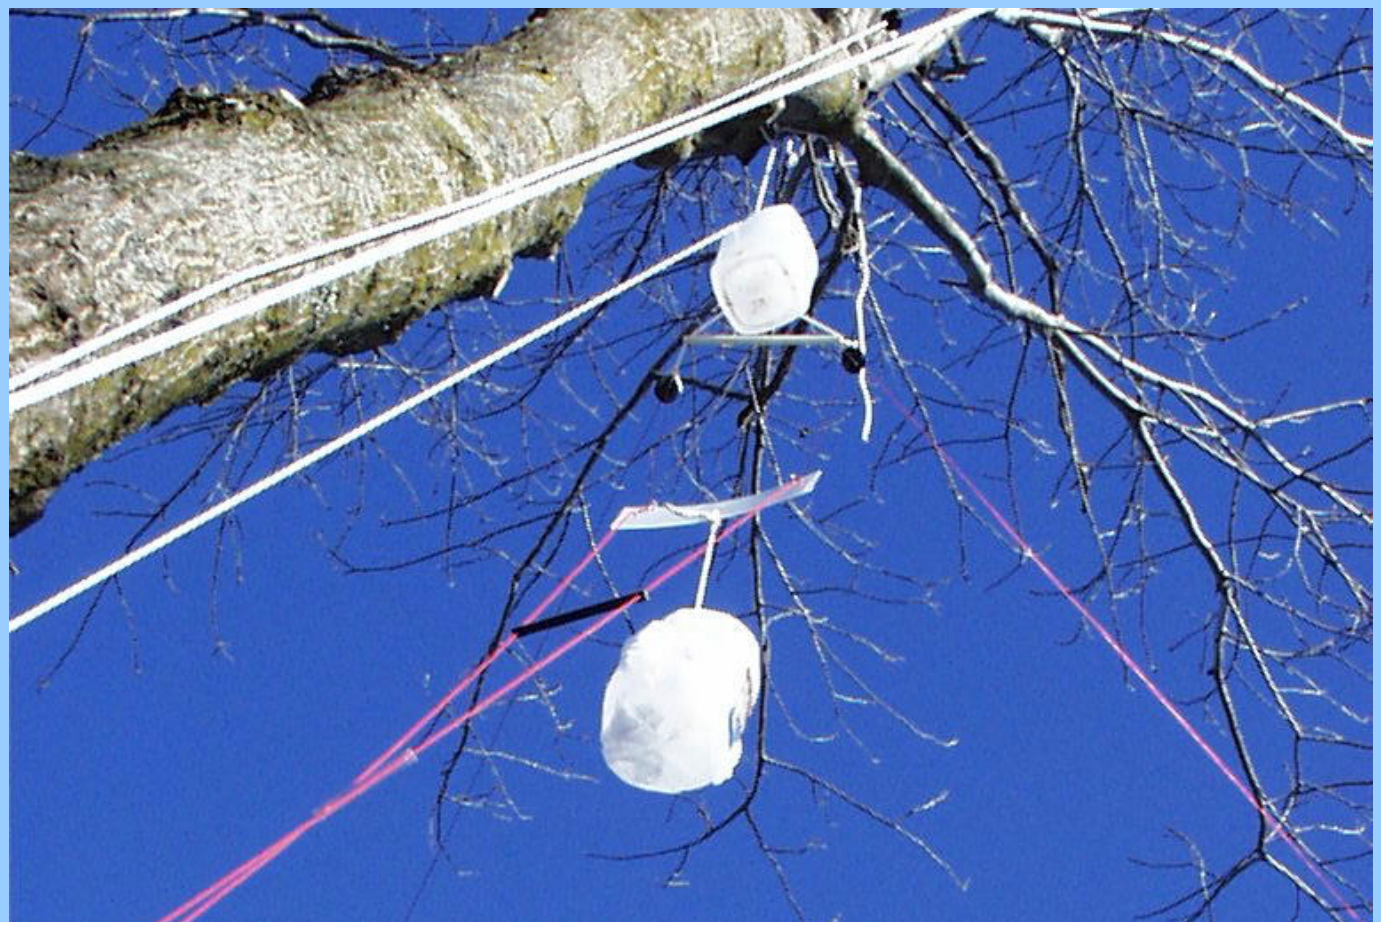
click here to go back to index-page

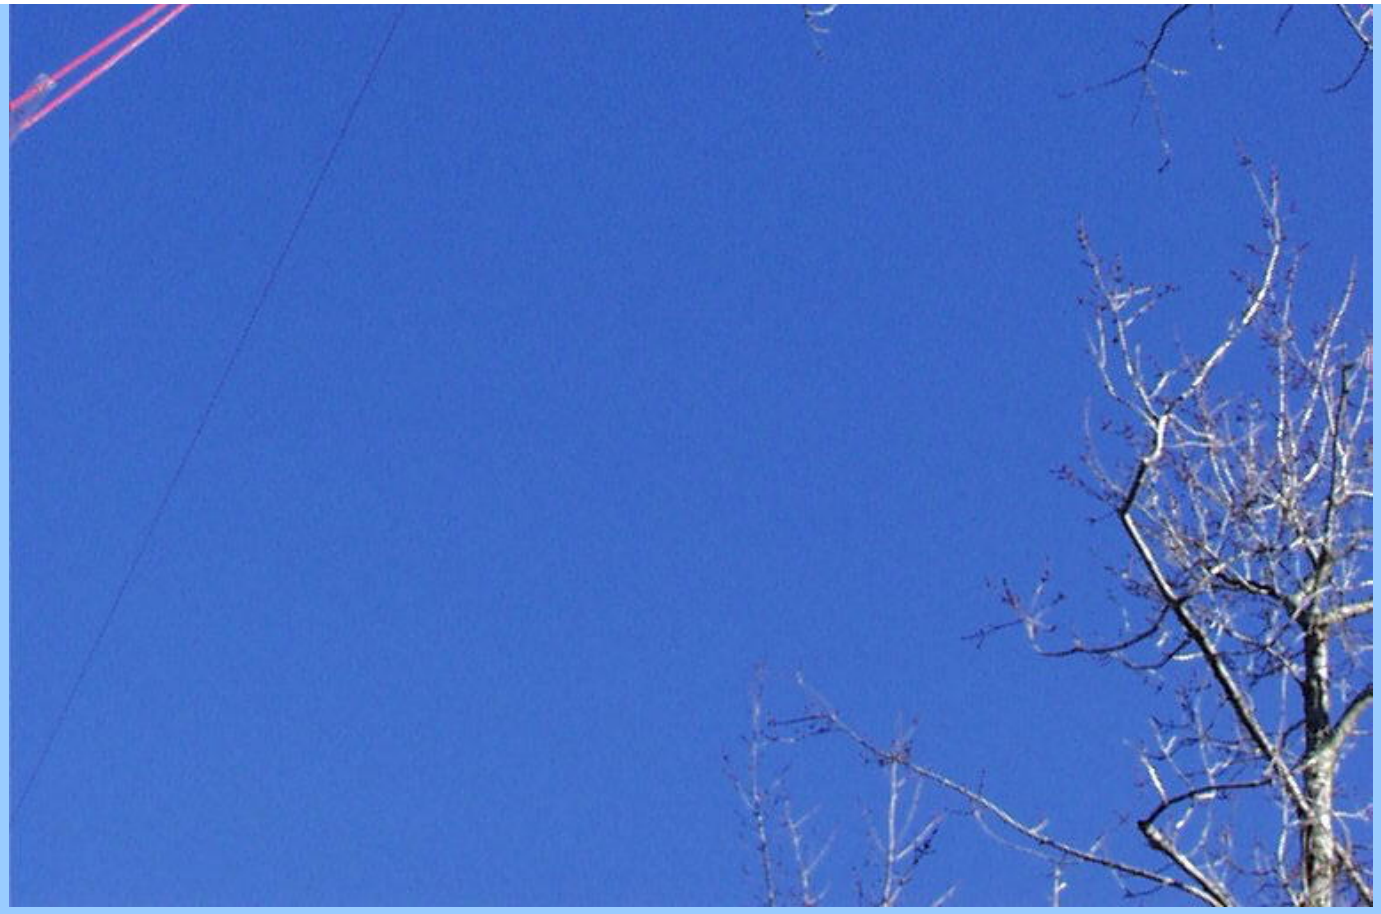
Rhombics are high gain directive wire antennas. A rhombic is shaped like a diamond, if you're looking down on it. I.e., there are 4 'legs', 2 end 'points', and 2 side 'corners'.

This one was designed for 10 meters and 6 meters, but it's proven useful all the way down to 30 meters. Gain figures are:

6m	11db	about equal to a 7el yagi
10m	10db	about equal to a 5el yagi
15m	8db	about equal to a 4el yagi
20m	6db	about equal to a 3el yagi
30m	4db	about equal to a 2el yagi

(gain figures are referenced to a horizontal dipole at the same height)





This particular rhombic is 120' long, 70' on a leg, 25' high, and it's a "terminated" rhombic, which means:

- it is *not* a resonant antenna
- it is *inherently* broadband, 2 octaves or even more
- it does *not* require a tuner...*if* you can match it to the xmitter properly!

Rhombics have a high input impedance of about 600-800 ohms, so it's a non-trivial matter to achieve a match to 50 ohm coax *while still retaining the very broadband nature inherent to the terminated rhombic.*

Matching the Terminated Rhombic:

After much wailing and gnashing of teeth (i.e. experimentation with many different balun transformer designs), I came to the conclusion that the books are right; you just can't get a ferrite balun xformer to work well at both high frequencies *and* high impedance. About 200-300 ohms is the limit for "broadband" work.

This led me to do some research on "tapered lines", the result of which is shown in the pictures here. After several prototypes, I settled on the tapered 2-wire transmission line shown here. I used a modified exponential taper, from 10.00" to .300", over a length of 33', creating a broadband linear transformer from 750 ohms to 200 ohms. The 200 ohm end feeds into a 'normal' 4:1 ferrite balun, which completes the 16:1 ratio required to match to 50 ohm coax.

Results with Tapered Line:

With this setup, I've finally achieved a good SWR over the entire bandwidth of the antenna; less than 1.3:1 from 10-60 Mc. At the important (to me) 15, 10, and 6m bands, the SWR is under 1.2:1. I was never able to get less than 2.5:1 when using two 4:1 baluns in series, so to me this represents a big success.

Power Handling:

Tapered line also has the interesting property, unlike ferrite xformers, of being able to handle lots and lots of power....<g> Now I need to work on a higher power terminator; and then I'll be able to run an amp on the rhombic if I choose. The current terminator is rated 50w continuous; enough for a 100w transceiver, but not for a linear.

Mechanical Design:

The picture above is a shot looking up the feed-end tree; showing the tapered line and the wire-supports. The entire antenna "floats" in its supports. I.e., it is only firmly attached down at the terminator end. At every other corner, the wires slide freely through their "pulleys", which are poly egg-insulators. This design automatically equalizes tension on all legs, and has proven to work very well. The antenna is always flat, and it handles high winds and tree-branch hits with ease.

The rhombic itself is made from #18 enameled copper wire, and the tapered-line is made from #18 stranded tinned-copper PVC insulated wire.

The 1-gallon jugs are the counterweights used to tension the antenna. The amount of water was adjusted to produce the correct tension in the wire.

It came as an unpleasant surprise to me that it's very difficult to take good pictures of thin wires against the sky and trees! <grin> In any case, below is another shot of the tapered line (red vertical wires). You can see some of the "spreaders", which were cut from IC-tubes.

The extra ropes in the picture are the halyards for the ends of the 80m and 40m dipoles, which also use this tree for support.

I'm going to try re-shooting these pictures when the sky is a 'white' overcast, in hopes that the wires will be more visible. I also hope to get a better focus. Usually this Oly D500-L shoots outstandingly sharp pics. Maybe I was vibrating...<g> Stay tuned...

It took a *lot* of clearing to put up this antenna! Three hundred and fifty feet of this....but hey, we needed the firewood anyway <g>.

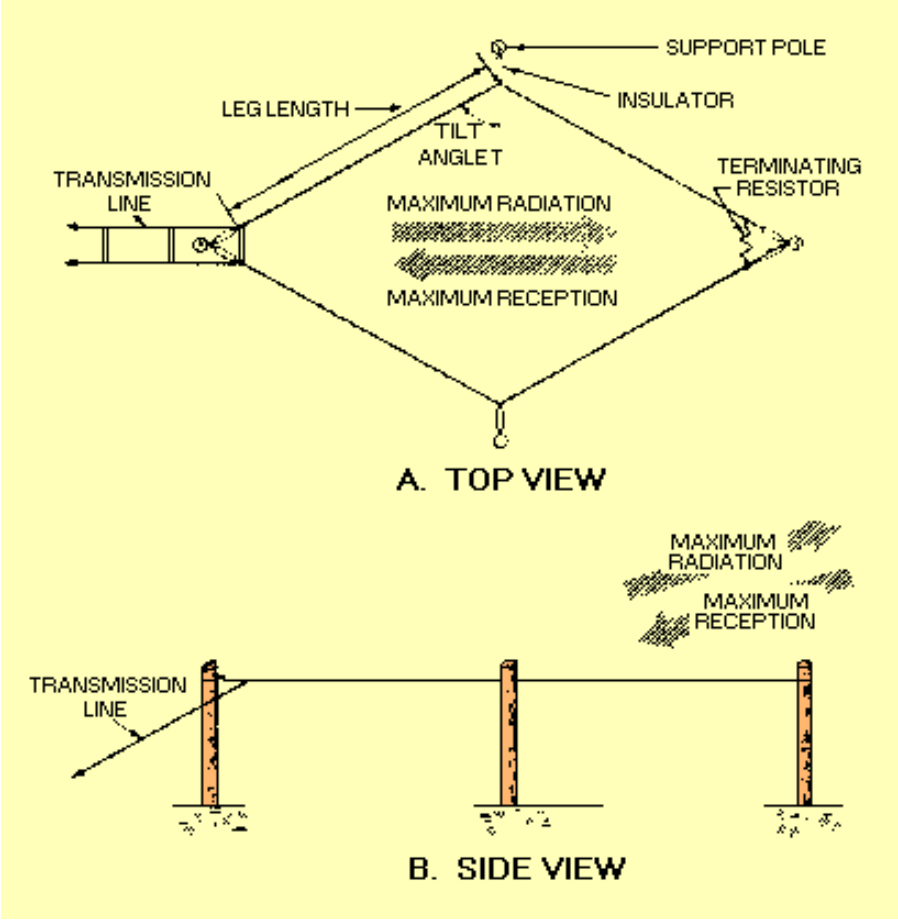
RHOMBIC ANTENNA

The highest development of the long-wire antenna is the RHOMBIC ANTENNA (see figure 4-37). It consists of four conductors joined to form a rhombus, or diamond shape. The antenna is placed end to end and terminated by a noninductive resistor to produce a uni-directional pattern. A rhombic antenna can be made of two obtuse-angle V antennas that are placed side by side, erected in a horizontal plane, and terminated so the antenna is nonresonant and unidirectional.

Figure 4-37. - Basic rhombic antenna.



The rhombic antenna is WIDELY used for long-distance, high-frequency transmission and reception. It is one of the most popular fixed-station antennas because it is very useful in point-to-point communications.

Advantages

The rhombic antenna is useful over a wide frequency range. Although some changes in gain, directivity, and characteristic impedance do occur with a change in operating frequency, these changes are small enough to be neglected.

The rhombic antenna is much easier to construct and maintain than other antennas of comparable gain and directivity. Only four supporting poles of common heights from 15 to 20 meters are needed for the antenna.

The rhombic antenna also has the advantage of being noncritical as far as operation and adjustment are concerned. This is because of the broad frequency characteristics of the antenna.

Still another advantage is that the voltages present on the antenna are much lower than those produced by the same input power on a resonant antenna. This is particularly important when high transmitter powers are used or when high-altitude operation is required.

Disadvantages

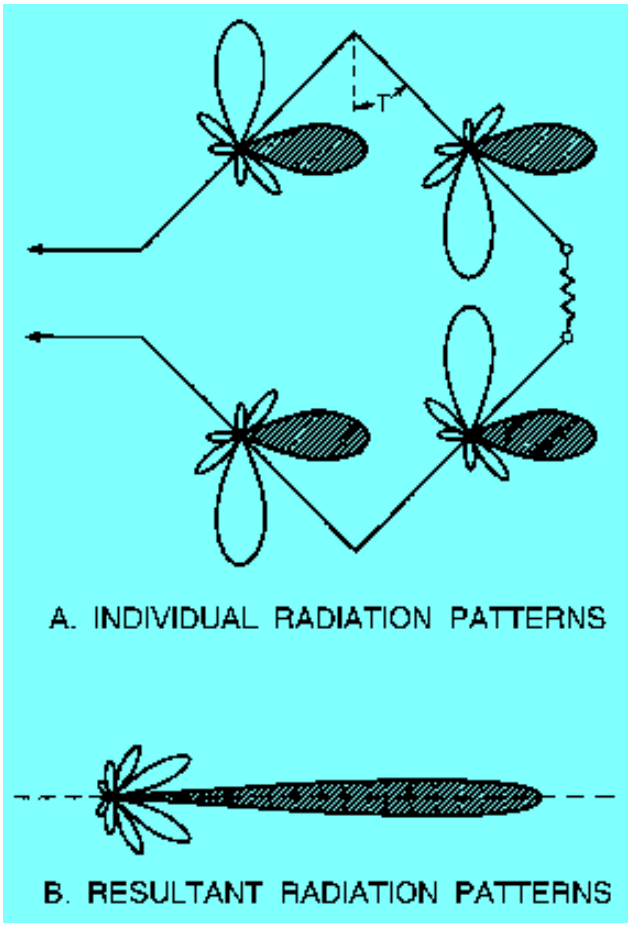
The rhombic antenna is not without its disadvantages. The principal one is that a fairly large antenna site is required for its erection. Each leg is made at least 1 or 2 wavelengths long at the lowest operating frequency. When increased gain and directivity are required, legs of from 8 to 12 wavelengths are used. These requirements mean that high-frequency rhombic antennas have wires of several hundred feet in length. Therefore, they are used only when a large plot of land is available.

Another disadvantage is that the horizontal and vertical patterns depend on each other. If a rhombic antenna is made to have a narrow horizontal beam, the beam is also lower in the vertical direction. Therefore, obtaining high vertical-angle radiation is impossible except with a very broad horizontal pattern and low gain. Rhombic antennas are used, however, for long-distance skywave coverage at the high frequencies. Under these conditions low vertical angles of radiation (less than 20 degrees) are desirable. With the rhombic antenna, a considerable amount of the input power is dissipated uselessly in the terminating resistor. However, this resistor is necessary to make the antenna unidirectional. The great gain of the antenna more than makes up for this loss.

Radiation Patterns

Figure 4-38 shows the individual radiation patterns produced by the four legs of the rhombic antenna and the resultant radiation pattern. The principle of operation is the same as for the V and the half-rhombic antennas.

Figure 4-38. - Formation of a rhombic antenna beam.



Terminating Resistor

The terminating resistor plays an important part in the operation of the rhombic antenna. Upon it depend the unidirectivity of the antenna and the lack of resonance effects. An antenna should be properly terminated so it will have a constant impedance at its input. Terminating the antenna properly will also allow it to be operated over a wide frequency range without the necessity for changing the coupling adjustments at the transmitter. Discrimination against signals coming from the rear is of great importance for reception. The reduction of back radiation is perhaps of lesser importance for transmission. When an antenna is terminated with resistance, the energy that would be radiated backward is absorbed in the resistor.

Q.47 What is the main disadvantage of the rhombic antenna? **Answer**

TURNSTILE ANTENNA

The TURNSTILE ANTENNA is one of the many types that has been developed primarily for omnidirectional vhf communications. The basic turnstile consists of two horizontal half-wave antennas mounted at right angles to each other in the same horizontal plane. When these two antennas are excited with equal currents 90 degrees out of phase, the typical figure-eight patterns of the two antennas merge to produce the nearly circular pattern shown in figure 4-39, view A. Pairs of such antennas are frequently stacked, as shown in figure 4-40. Each pair is called a BAY. In figure 4-40 two bays are used and are spaced 1/2 wavelength apart, and the corresponding elements are excited in phase. These conditions cause a part of the vertical radiation from each bay to cancel that of the other bay. This results in a decrease in energy radiated at high vertical angles and increases the energy radiated in the horizontal plane. Stacking a number of bays can alter the vertical radiation pattern,

causing a substantial gain in a horizontal direction without altering the overall horizontal directivity pattern. Figure 4-39, view B, compares the circular vertical radiation pattern of a single-bay turnstile with the sharp pattern of a four-bay turnstile array. A three-dimensional radiation pattern of a four-bay turnstile antenna is shown in figure 4-39, view C.

Figure 4-39. - Turnstile antenna radiation pattern.

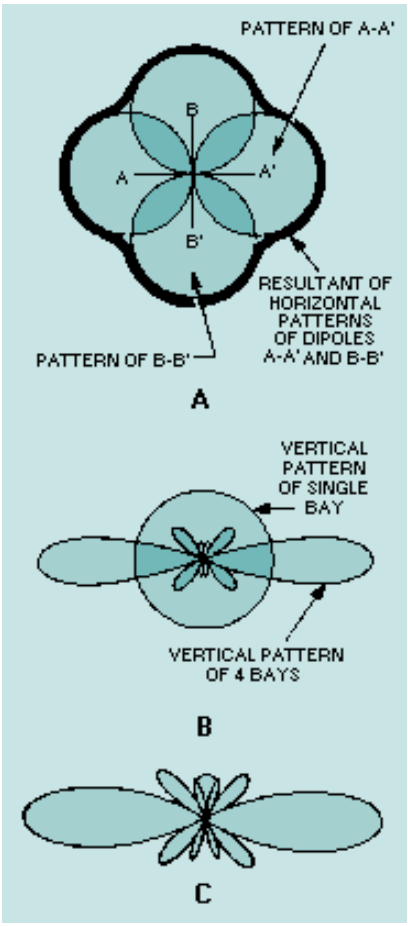


Figure 4-40. - Stacked turnstile antennas.

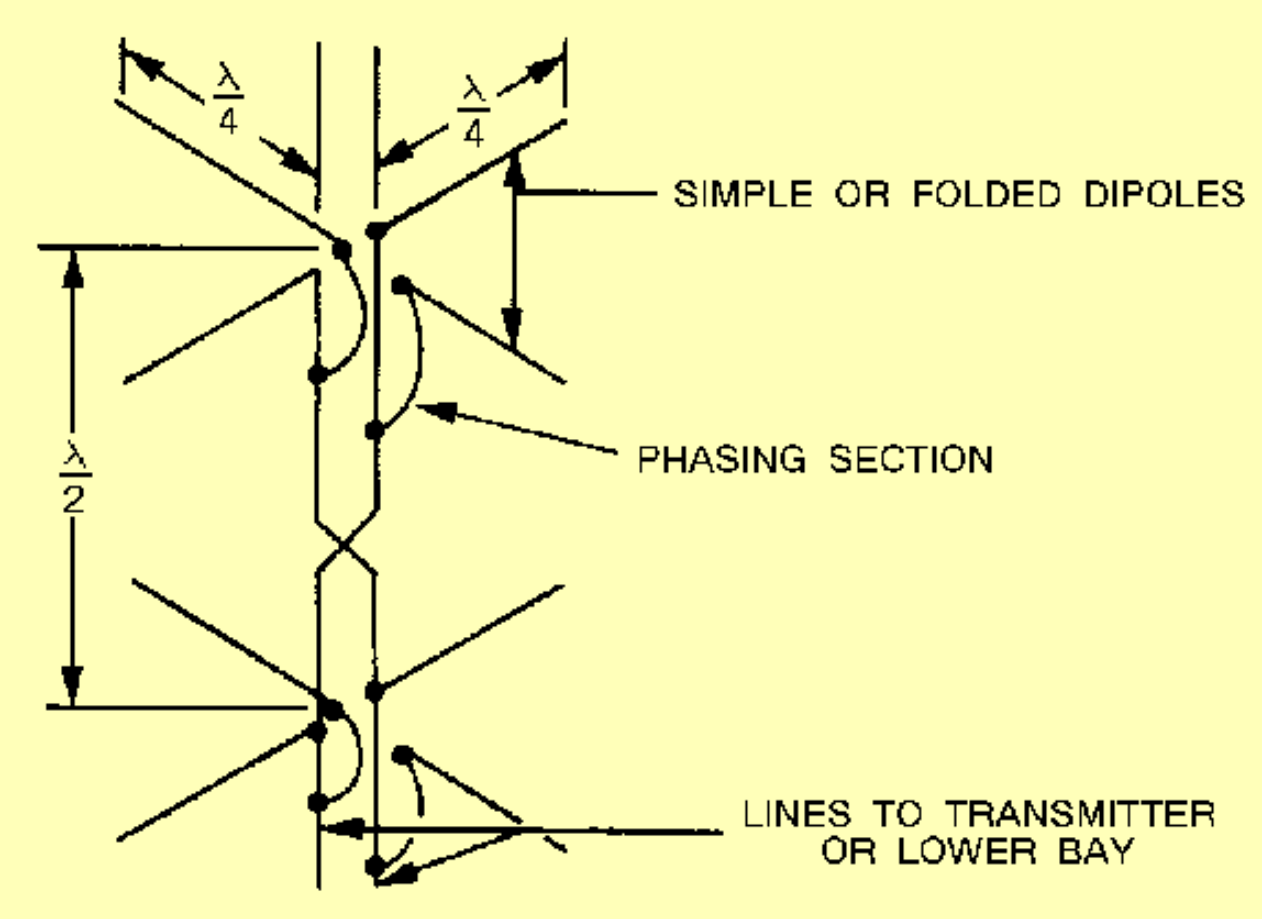
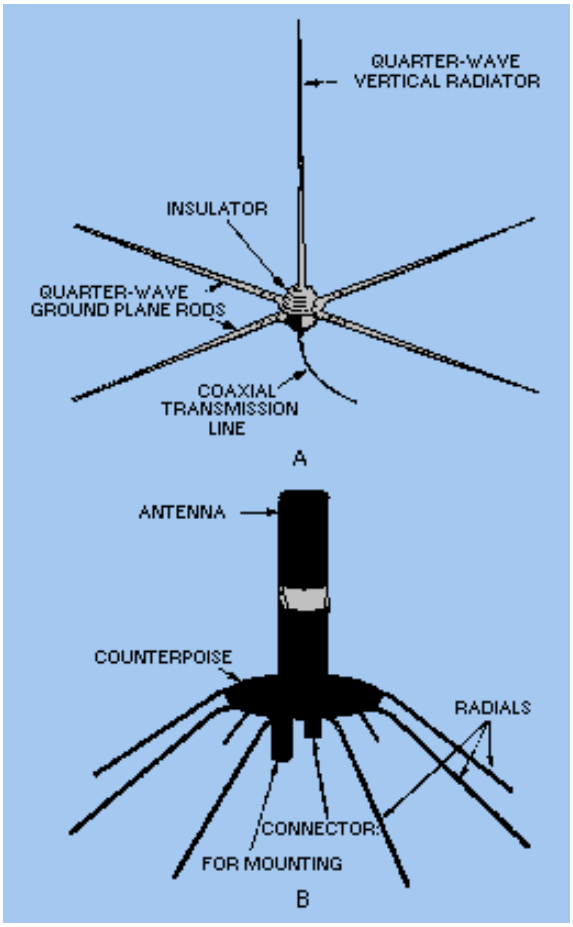


GROUND-PLANE ANTENNA

A vertical quarter-wave antenna several wavelengths above ground produces a high angle of radiation that is very undesirable at vhf and uhf frequencies. The most common means of producing a low angle of radiation from such an antenna is to work the radiator against a simulated ground called a GROUND PLANE. A simulated ground may be made from a large metal sheet or several wires or rods radiating from the base of the radiator. An antenna so constructed is known as a GROUND-PLANE ANTENNA. Two ground-plane antennas are shown in figure 4-41, views A and B.

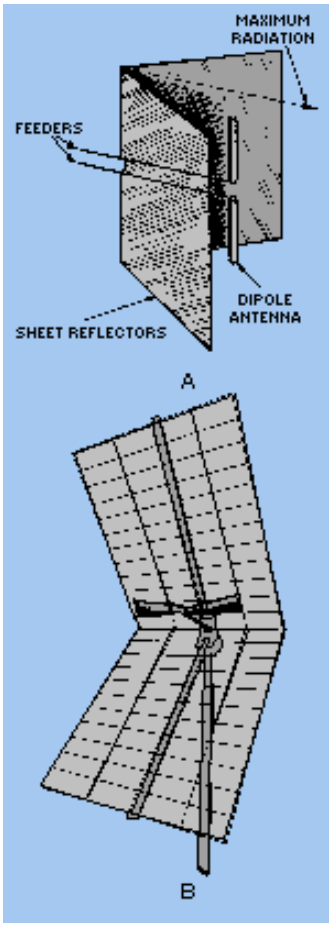
Figure 4-41. - Ground-plane antennas.



CORNER REFLECTOR

When a unidirectional radiation pattern is desired, it can be obtained by the use of a corner reflector with a half-wave dipole. A CORNER-REFLECTOR ANTENNA is a half-wave radiator with a reflector. The reflector consists of two flat metal surfaces meeting at an angle immediately behind the radiator. In other words, the radiator is set in the plane of a line bisecting the corner angle formed by the reflector sheets. The construction of a corner reflector is shown in figure 4-42. Corner-reflector antennas are mounted with the radiator and the reflector in the horizontal position when horizontal polarization is desired. In such cases the radiation pattern is very narrow in the vertical plane, with maximum signal being radiated in line with the bisector of the corner angle. The directivity in the horizontal plane is approximately the same as for any half-wave radiator having a single-rod type reflector behind it. If the antenna is mounted with the radiator and the corner reflector in the vertical position, as shown in view A, maximum radiation is produced in a very narrow horizontal beam. Radiation in a vertical plane will be the same as for a similar radiator with a single-rod type reflector behind it.

Figure 4-42. - Corner-reflector antennas.



Q48. What is the primary reason for the development of the turnstile antenna? **Answer**

Rhombic Antenna Home Page

While amateur radio operators today largely employ rotating array antennas such as the Yagi dipole array and the cubical quad antenna, some still use wire antennas, some of which can afford higher gain and lower receive noise characteristics. In fact, the rhombic antenna is usually described as the "King of antennas" because of it's very desireable characteristics. The rhombic antenna is basically a diamond-shaped wire curtain that is made of 4 wires, each several wavelengths long connected to form a "diamond" or rhombus shape . The diamond is constructed with the narrowest ends left open for the feed point on one end and a non-inductive resistive termination on the other. This creates the terminated (also called non-resonant) rhombic which is a unidirectional antenna with broad bandwidth. Non-terminated (also called resonant) rhombics do work but have narrower useful bandwidth and are bidirectional (non-resonant rhombics are fed on one end and the opposite end is left open. In my experience both non-resonant and resonant rhombics work quite well. All wire antennas tend to be less "noisy" on receive and longer antennas like the rhombic are very low noise antennas with the solitary exception of precipitation static (snow and rain add small charges to the curtain and you get very high noise under such conditions). Precipitation static can be minimized by using termination resistors with a grounded center tap (leaks static to ground continuously).

The sides of the rhombic (with the broadest included angle) are constructed of differing dimensions to determine what radiation angle will be obtained. Half of the angle included by the rhombic side is called the "tilt angle" or theta ø and as the tilt angle is varied, the radiation angle will also vary. There exist various ways to calculate the ideal tilt angle to choose relative to the radiation angle and gain desired for a given rhombic application. Generally the tilt angle is between 65 and 75 degrees. The apex angle is the angle included by the feed point end of the rhombic and is between 30 and 50 degrees and varies with the tilt angle (the sum of half the apex angle and the tilt angle will be 90).

Height is very important for rhombics, as it is for all antennas. Basically, the radiation angle of the main beam of any antenna is related to the height above the ground and the ground characteristics. Generally, for any antenna the following height (in wavelengths)/wave angle (degrees) relationships hold: 0.5/30; 1.0/15; 1.5/8; 2.0/6; 3.0/5. As you can see, to take advantage of the rhombic's extraordinary gain for distant (low angle) communications, you will need to have the antenna at least 1.5 wavelengths high: on 14.0 Mhz, this is around 90 feet, the "usual" height used for rhombic antennas (most rhombics used are in amateur radio usually optimized for 14 Mhz or 20 meter band).

Rhombic antennas are generally fed with open feedlines of around 400 to 600 ohm impedance. This is not critical and any issues related to feeder loss and/or standing wave ratios pales in significance in relationship to this antenna's gain. In the real world things work fine without worry related to feedlines so long as you use a good antenna tuner. Use of baluns is probably unwise as this is likely to limit the useful frequency range of this intrinsically broadbanded antenna. Many commercial applications of the rhombic use what are called "exponential feeders" with the nominal impedance being 300 ohms at the feeder end and with the paired feedlines gradually spreading to a spacing of around 12 inches at the rhombic feedpoint (a distance calculated to provide the rhombic feedpoint impedance of 600-800 ohms). This exponential feeder provides a smooth transition of impedance and acts as a sort of impedance transformer.

In current antenna publications it seems very hard to find anything other than a very abbreviated discussion of rhombics and perhaps some basic design charts and dimensions for a simple rhombic. Little discussion is generally available of the more complex details important to anyone seriously interested in constructing a rhombic antenna. With this in mind, this page has some images of real-world installations and discussion of most of the important practical details you would need to be aware of to construct and maintain a proper rhombic. I am always interested in hearing from anyone with experience with building, maintaining or using rhombics. Images, plan sets and even parts from dismantled rhombics are of interest to me. I will add anything to this page that fits, and then some.

Click here for an abbreviated discussion of practical rhombic antenna design

Click here for a detailed text outlining apects of practical rhombic antenna design (under construction)

Click here to view construction images for the North American Center for Emergency Communications (NACEC) rhombic station in Minnesota

Click here to read about the World War II rhombic station in Scituate Rhode Island (Chopmist Hill)

The three images included here are from the WJCR short wave station in Millersville Kentucky and the images were kindly provided courtesy of WJCR. Note the feeders are attached directly to the antenna with little concern for matching. This is not unreasonable as the loss involved is trivial compared to the gain of the antenna (I feed mine directly as well). Also note the use of three wire curtains (slight increase in gain and smoother impedance characteristics across the broad frequency coverage of the rhombic.

The issue of frequency coverage itself is also worth further discussion. While the rhombic is very broad banded, especially the non-resonant terminated antenna, in my hands when optimized for 14Mhz, the antenna is still useful from 10 through 18 Mhz. On the higher bands (18-30 Mhz), the main beam becomes unaccepably "split" with less effective gain in the resulting lobes in the azimuth plane. The antenna is still useful but limited. Perhaps the answer is to build the larger rhombics with smaller antennas that are optimized for the higher frequencies supported at a lower height from the 4 support poles. The rhombics work well when "nested" in this manner and you can conserve space in this way. Additionally, if you get really carried away, you can use the side poles as ends for other rhombics and vica versa. You can even "stack" rhombics running in different directions with clearances of anything greater than 5 feet on HF. Yes, there is a slight degradation but big rhombics are such good antennas that in the real world you shouldn't care. Designs have been built where rhombics are phased together so that in a given direction, one or more rhombics are fed in phase.

Monsterous rhombic arrays have been built in this manner and one can only guess what kind of signals resulted (it's actually rather frightening)!

Harper, of Bell Laboratories, did much of the pioneering work on the rhombic antenna and determined a famous curve that is largely used to design rhombics. Usually some optimization is needed to make sure that the main lobe and the radiation angle coincide. This usually results in a slight loss of gain because of the slightly shorter legs used for a given angle on the sides. Some additional advantage is obtained by having several wires per leg (several curtains), with up to 2 db more gain resulting.

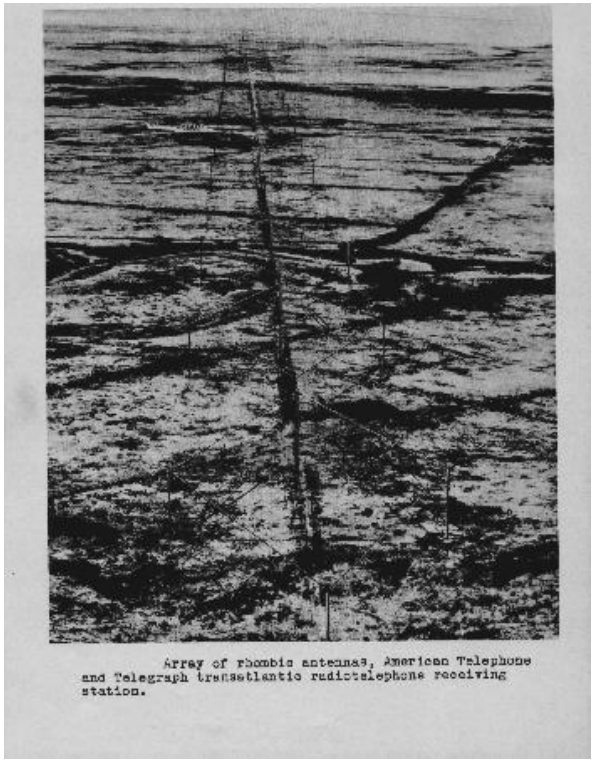
The ability of the rhombic to provide high gain (typically over 9 db for most antennas made and often up into the 20 to 30 db area in arrays of rhombics) , narrow predictable patterns in the azimuth plane, optimized patterns for a given wave angle and physically sturdy construction make the rhombic still the choice antenna for point to point communications operations. Many large rhombic stations existed until recent times and several still are in operation.

Some famous stations included WCC in Chatham Massachusetts, the Rocky Point RCA station and the Palos Verdes Press Wireless Station of the late Don Wallace W6AM's (below). These stations began as commercial stations and had many rhombics, usually with each rhombic covering a given city (again, because you can optimize the wave angle and the azimuth direction is known, you would choose a rhombic with a higher wave angle for cities that are closer and a lower angle for farther destinations). These antennas almost guaranteed an open circuit to the desired locations despite the conditions. Such arrays would usually be fed via open feeders (oftern 4 wire feed lines to limit loss over the thousands of feet of feeders) and if both directions were desired a switching array would be used to select the direction. Stations would usually have a matrix of open frame RF relays in the shack or in a switch house with a DC switch at the operator's station to select the direction desired. The feeders would arrive in the switch area in layers.

The military has used rhombic antennas for years. In fact, in World War II, the War Department had a rhombic antenna kit (TM11-2611) . This manual was designed to allow the construction of rhombics in the field with indiginous timber for supports and using tables to determine the optimum leg length and tilt angle for communications back to the United States. This design is near optimum for the largest rhombic feasible for practical HF communications.

During World War II not far from my station's location was a classified HF listening station where it is said that rhombics there were used to eavesdrop upon German submarines during the war. This station was said to be involved in the breaking of the German Enigma codes during World War II. This station was located on the top of Chopmist Hill, not far from the highest spot in Rhode Island. This location in the town of North Scituate was designed by Thomas Cave of the Federal Communication Commission's Radio Intelligence Division (RID). The RID had leased the 183 acre Stoddard Farm, chosen for it's location and open acreage that was amenable to a large wire array receiving station far from industrial and power line noise sources. Nationwide there were 150 such RID stations used to intercept wartime radio traffic. The Chopmist

Hill station had 85,000 feet of wire antenna curtains aloft. The poles were typically 80 feet high and were still aloft in 1968. Not being rotary antennas caused some problems with the strategic listening needs. During the critical Second World War battle of El Alamein in 1942, Cave was calling the Narragansett Electric Company several times daily to reposition antenna poles to optimize reception (truely the "armstrong rotor" method)! On another occasion the rhombics on Chopmist saved the Queen Mary carrying 10,000 American troops overseas by interceptin orders to sink her sent to the U-boat fleet in the Atlantic. The station was also credited to accurately pinpointing the location of every Axis spy within the US by triangulation with other RID stations. Curiously, Frank W3LPL (who had seen the site in the 60's) has told me that the site had a Swastika-shaped fireplace, I suspect as a reminder of their mission, although I am not certain of this. This site was later proposed as the potential site for the United Nations but was later passed up for New York.

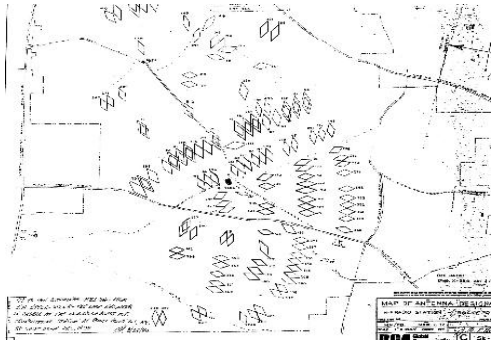


Array of rhombic antennas, American Telephone and Telegraph transatlantic radiotelephone receiving station.

Various commercial rhombic stations exist even today. One is on Cape Cod (Chatham) and is the receiving end of an HF relay link. One of the largest rhombic stations ever was on Long Island at Rocky Point and was an RCA station.

This station was off Route 25A. This station was operational until 1978 and at it's peak had 137 rhombic antennas, many phased together. I have many insulators from this station, including some very distinctive custom-built 4-wire feedline insulators with brass/ceramic turning and termination insulators that were obviously built specifically for the rhombic station. Rhombic termination was accomplished with stainless steel wires strung up the middle of the rhombic. Other commercial stations have used "reentrant" termination, a term I have not yet found a definition for. Evidently reentrant termination permits the station to run unlimited power output without "frying" the termination medium (i.e. melting your stainless steel wire or your resistors)

Click here to see the Rocky Point rhombic map with better resolution.



Amateur radio operators still occasionally employ rhombic antennas. In fact, I began my involvement after one day encountering the Don Wallace, W6AM, rhombic station. I at the time was a teenager in Palos Verdes, California. I was riding my bike down a country road and came across a huge installation of rhombics each perched upon telephone poles, some over 150 feet tall! (he used two 75 foot poles spliced butt to butt with redwood and angle iron splices to hold these monster poles together, he also did not like to waste pole length by burying pole in the ground and instead used a metal spike inserted into the bottom of the pole to secure the pole to the ground). The station in 1945 had 120 acres of land (when Don purchased it) with 16 rhombics, the longest being 1500 feet (end to end) and beaming Asia (his favorite antenna). This 1500 foot rhombic is widely believed to have been the largest beam antenna ever in amateur service. He had 61 telephone poles, each at 80 feet and another 90 feed line poles (25 feet high each). These antennas were fed by 52 MILES of feed lines (#8 copperweld). Several of these antennas had 2 or 3 curtains (to smooth impedance and increase gain). In 1962, Don sold 95 acres and consolidated his antennas. He installed ten 140 foot poles on the perimeter of his remaining 25 acres with rhombics layered every 6 feet in various directions with rhombics beginning at the 90 foot level and going in layers of 6 feet up to 140 feet high.

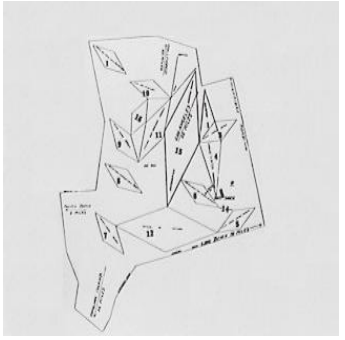
Click here to read Don's handout he sent anyone inquiring of his rhombic farm

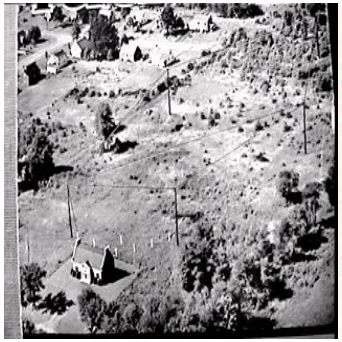


Now his longest (and still favorite) rhombic was 1100 feet end to end. Overall these antennas now covered 16 directions using the 8 rhombics he installed. This was the station I bicycled by. Don showed me his station with the miles of curtains and feedlines stretching for as far as the eye could see and with an operator's desk with a separate Collins station per band. He had his linear amplifier in a cage behind the operator's station and you would tune the amp with a fiberglass rod. The antenna feedlines crossed the ceiling of the station and when you changed directions, you would turn a heavy bakelite know on a rotary switch and the open frame relay matrix would chatter accordingly to your right. In the receiver you would hear various distant stations peak and fall as you electronically swept the horizon faster than any other operators could with their rotary arrays. Additionally, you would hear stations earlier during band openings and often you would communicate easily with far away stations others could not even hear. Nothing short of amazing. Don had an annual "open house" that was well attended. He always would fire up his spark gap transmitter especially for the occasion and demonstrate how a spark station sounded. I also recall Don's KW mobile station in his convertible Cadillac working Russian stations on the 495 Freeway at 60 MPH using an old bug strapped to the seat (on the way to Clifton's in downtown LA for the Southern California DX Association meeting). The code would sound slightly different as we would round steep turns

Eventually, after Don's passing, the station was dismantled for condomiums (Wallace Estates) and there is now a museum station there. At it's closure, the W6AM station had made over 500,000 contacts. I have a few of the W6AM insulators with which to remember this now silent station.

The American Radio Relay League (ARRL) in Newington Conecticut (not far from my home) had a rhombic until 1989, when dry rot in it's cedar support poles forced it to be dismantled (seems to be the fate of

most rhombics at some point, they outlive their supports!).



OUR COVER

We present an aerial eyeful of that ethereal eyeful, W1AW, ARRL headquarters station, shot by Staff Photographer Frank Benedin while flying at 600 feet. To the rear of the W1AW building are the five 65-foot antenna poles and the feed-line supports. The station occupies a 7-acre site at Newington, Conn., 4 miles from Hq.

Diagram of W1AW antennas: AB, 14 Mc. DE, 7 Mc.; AF, 28 Mc.; ABCDA, rhombic used mainly on 14 Mc. A 50-Mc. horizontal "Q" is mounted atop Pole E.

QST for

The four 65-foot red cedar poles that supported the famous W1AW Rhombic were taken down in August. The poles came from the West Coast and were transported through the Panama Canal. Installation took place in 1937 by a volunteer crew from the Hartford Electric Light Co. The poles had been the victims of noticeable dry rot. Here, a tree service employee cuts one of the antenna supports into sections before it's transported off the HQ site.

This antenna was supported at 65 feet and had leg lengths of 350 feet (theoretical gain of 17dbd on 14 Mhz) with a tilt angle of 70 degrees. It was oriented East-West and is said to have had a stomping signal (loudest in the US as the one wavelength height limited the radiation angle to 15 degrees, about right to be optimum for the 1500 mile hop to the West Coast).

More recently, during the Desert Storm engagement, a group in the Midwest set up a rhombic beaming the Saudi Peninsula to provide point to point communications for the Military Amateur Radio Service (MARS). Again, the rhombic was chosen because of it's excellent point to point communications ability. This rhombic was up around 100 feet high with leg lengths of 294 feet (theoretic gain 15 dbd) and a tilt angle of 70 degrees. This antenna was said to permit eavesdropping on "manpack" tranceivers on the ground with rudimentary whip antennas (I don't doubt this).

Lastly, my modest rhombics. I have a "baby" rhombic that is 377 feet long (end to end) with leg lengths of 210 feet beaming East-West. The tilt angle is 64 degrees and because it is only 40 feet high ("on the ground" in rhombic terms), the radiation angle is around 25 to 30 degrees (very loud to the West coasts of the United States and Africa to say the least!). I also have a rhombic on an unoccupied property that is a bit bigger: 288 feet leg length, 520 feet end to end with a tilt angle of 65 degrees. It is also a bit low at 45 feet (tree supports). Someday I aspire to install a few 90 foot telephone poles but am still trying to figure out an economical way of getting/installing same (any help from out there in internet land?).

As time permits I will be scanning some rhombic-related images in to place here on my page. Some links:

Rhombic Antenna Design Software. This software is included here courtesy of Orrin Winton WN1Z. This program is a windows app and allows you to optimize rhombics for desired wave angles and gain. You will need VBRUN300.dll to install this program.

Visit Joby Wieser's Rhombic Ranch. Joby has a number of rhombic antennas running

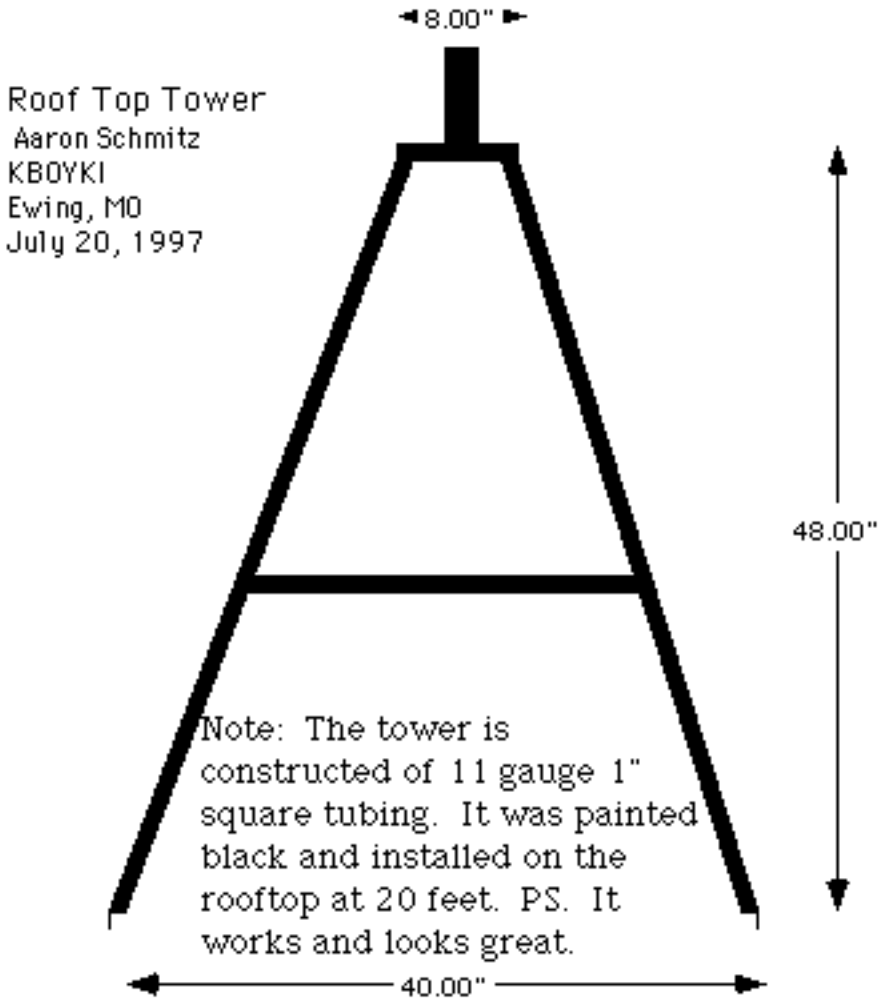
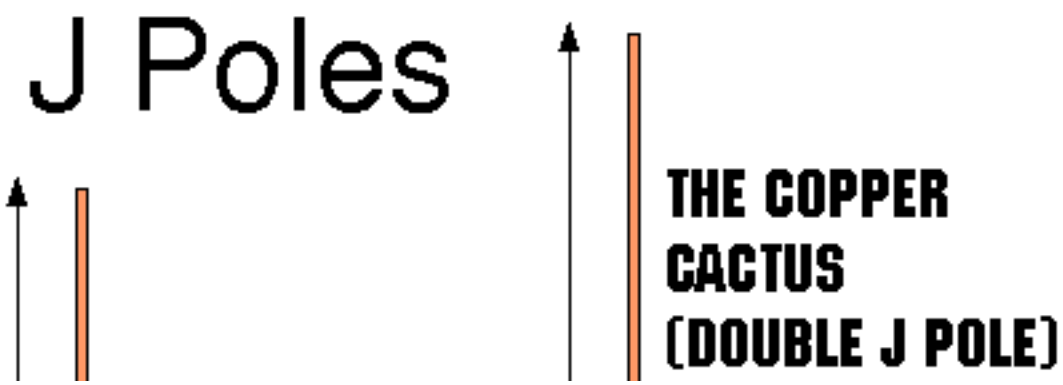
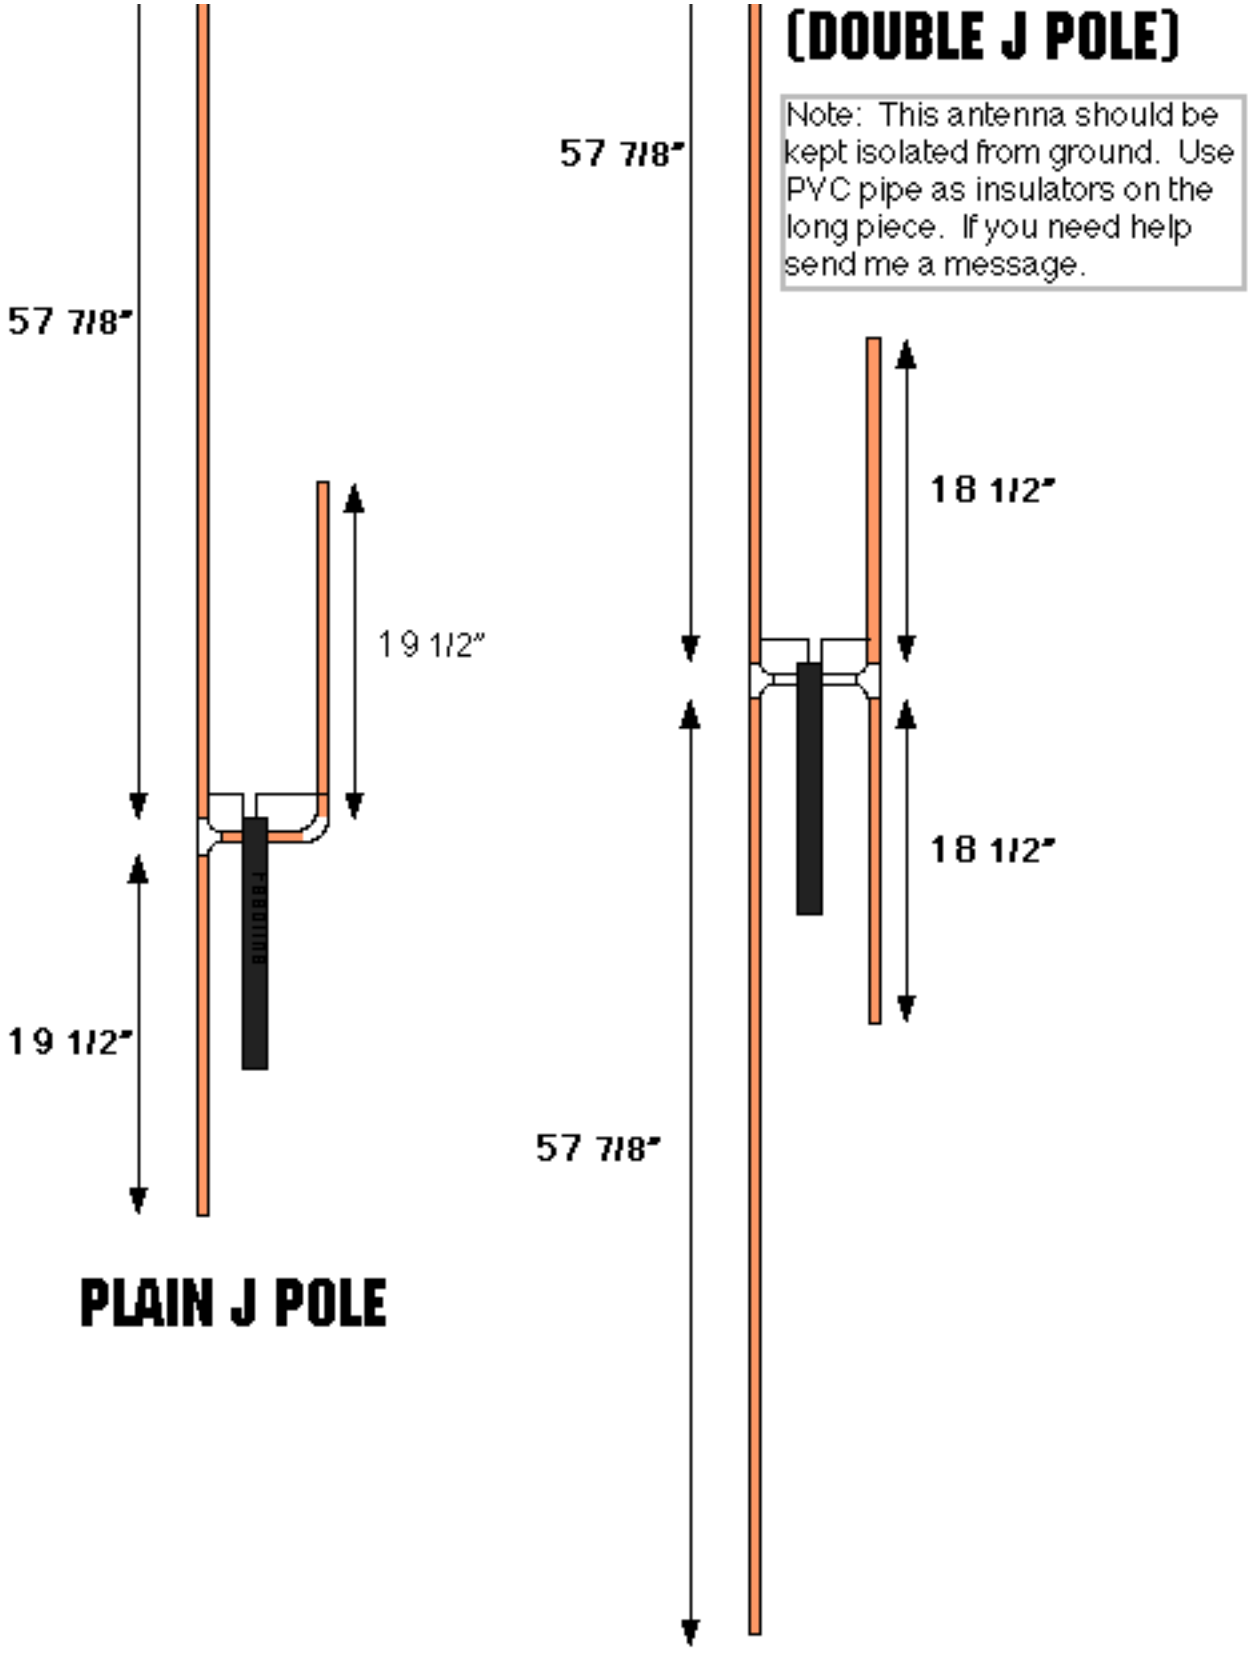
The Rooftop Tower



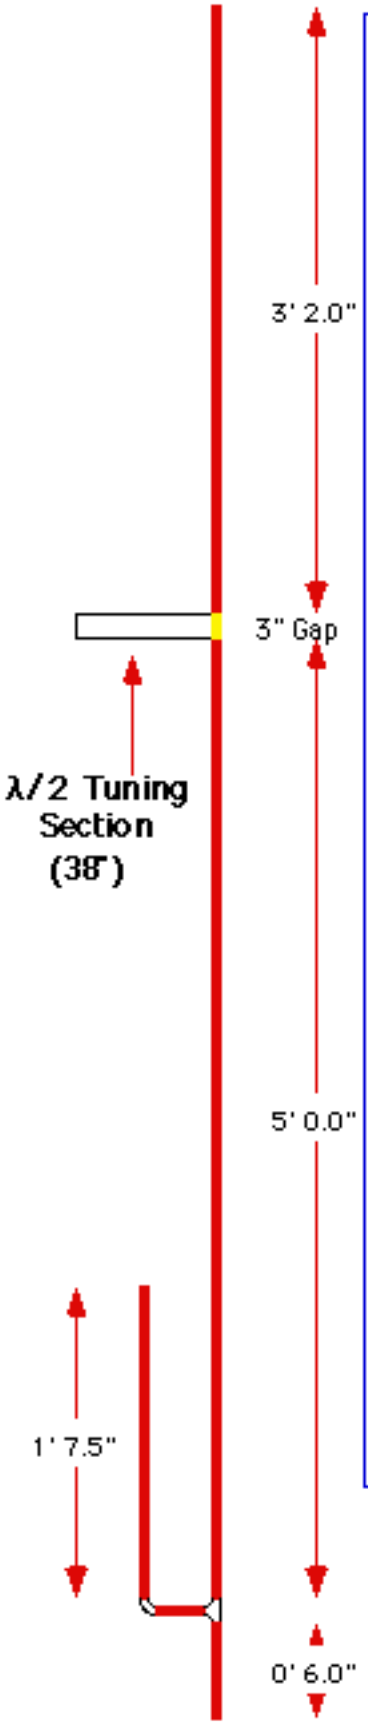
Common Amateur Radio Antennas

The J Pole





The Super J Pole



Super 2 Meter J Pole Antenna (a.k.a. Collinear Antenna) with helpful modifications by Aaron Schmitz, KB0YKI

Construction Details:

1. Cut copper to proper lengths.
2. Flux and solder bottom J Pole section.
3. Cut a 38" piece of 12 gauge wire.
4. Solder a 1/2" coupler on the top J pole section and bottom of the top λ/2 length of pipe.
5. Drill a 1/8" hole into each coupler through the pipe.
6. Strip back 3/8" of insulation on wire.
7. Insert wire ends into holes and solder.
8. Bend wire into a 3/4 circle around pipe with a 6" radius.
9. Insert 1/2" X 4" dowel rod into coupler.
10. Completely seal all areas from moisture. Paint it if you would like.
11. Attach coax and have fun!!
